Published monthly by the Physical Society of Japan and devoted to original papers in physics and related fields which materially contribute to the progress of physics

BOARD OF EDITORS (1960–1961)

M. Toda (Chief Editor), S. Asaka, M. Hatoyama, H. Horie, I. Imai, T. Inui, E. Ishiguro, K. Ishiguro, T. Kato, K. Kinosita, K. Kohra, H. Kumagai, G. Kuwabara, S. Miyahara, T. Nagamiya, Y. Nogami, S. Ogawa, T. Okada, S. Ono, K. Senda, T. Suzuki, H. Takeyama, H. Takahasi, Y. Tomono, S. Tomotika, R. Uyeda.

SUGGESTIONS TO OVERSEAS CONTRIBUTORS

Manuscript should be addressed to the Office of the Physical Society of Japan, Room No. 342, Physics Building, Faculty of Science, University of Tokyo, Bunkyo-ku, Tokyo.

Each manuscript should be prepared as concisely as possible. Its organization should conform to the following: title author's name, name and address of the author's institution, synopsis of about 100 words, body of the paper, list of references, tables and figures. The textual material should be typewritten, double-spaced on white bond paper of letter size. The original copy is required. Literature reference should be numbered consecutively. Figures and photographs will be printed in any of the following sizes (at the choice of the author): 3 cm, 6 cm, 12 cm in breadth, less than 18 cm in height. The original should be 2.5 to 3 times as large as the size in print. The drawing should be a very neatly prepared original with lettering, in Indian ink. Self-explanatory titles to figures and photographs are essential.

Short Note Section is provided for brief reports which need prompt publication. The manuscript of a Short Note should follow the same style and form as that required for a full paper with the exception that it needs no synopsis. The available space for a Short Note is one page of the Journal (about 800 words).

Galley proof only will be sent to the author. Proof should be carefully corrected and returned as soon as possible to the Office of the Society. For prompt publication, proof of the Short Note will sometimes be read by the Editor in place of the author.

Reprints may be ordered in lots of 50. The author or the author's institution is requested to pay charges according to the following formulae:

\$ $(2.00+0.10p^2+(3.00+0.01x')p+3A)$ for full paper, \$ $(4.50+0.01x')$ for Short Note. Here p stands for the number of printed pages of the paper, $x'=x-50$ where x is the number of copies required ($x \geqq 50$), and A stands for the number of sheets of art paper if any.

SUBSCRIPTION

Subscription orders as well as related inquiries should be addressed to the Office of the Society or to one of the following agents:

Plane Polarization of 8.5 MeV Bremsstrahlung

By Katsufusa SHODA

Department of Physics, Tohoku University,
Sendai, Japan

(Received February 28, 1961)

The polarization of bremsstrahlung produced by 8.5 MeV electrons incident on thin Al, Ag, Au and U targets in a betatron was studied with D_2O-loaded nuclear emulsions. The Polarization was measured at the characteristic emission angle $\Theta = mc^2/E_0$ by observing the azimuthal angular distribution of photoprotons from deuterons.

The results show different energy dependence of polarization for different elements. For low Z targets the polarization is positive and large in the lower energy part of bremsstrahlung spectrum, in qualitative agreement with the theoretical calculations. For high Z targets the polarization is negative in the higher energy range and positive in the lower energy range. This reversal of the sign of polarization occurs at much lower energies than those expected from the theory.

§1. Introduction

Photons emitted in the bremsstrahlung process have been known to exhibit polarization.

The linear polarization of bremsstrahlung, P, is defined by

$$P = \frac{d\sigma_\perp - d\sigma_{/\!/}}{d\sigma_\perp + d\sigma_{/\!/}}$$

where $d\sigma_\perp$ and $d\sigma_{/\!/}$ are the differential cross sections for the production of bremsstrahlung photons polarized along the directions perpendicular and parallel respectively, to the emission plane given by the directions of the photon and the incident electron. These differential cross sections are functions of the electron energy E_0, the photon energy k, the angle θ between the photon and the incident electron and the atomic number Z of the target.

The polarization in non-relativistic bremsstrahlung was first studied theoretically by Sommerfeld$^{1)}$ and was later estimated numerically by Kirkpatrick and Wiedmann$^{2)}$. It has also been observed in a few experiments$^{3)}$. The observed results, however, are not always consistent with each other, although the most recent one of Kulenkampff et al.$^{3)}$ is in agreement with Sommerfeld's theory$^{1)}$.

The study of the relativistic case has been developed recently. A theoretical treatment for the relativistic case was first given by May and Wick$^{4)}$, using the method of virtual quanta$^{5)}$. Subsequently May$^{6)}$ investigated the polarization of bremsstrahlung due to electrons of $E_0 \gg 137Z^{-1/3}mc^2$ more carefully using the Born approximation for the electron wave functions and he summed over the directions of emergent electrons. According to his calculation the maximum polarization occurs at the characteristic angle, $\Theta = mc^2/E_0$, where m is the electron rest mass. His results are valid for complete screening and are applicable to $E_0 \gtrsim 16$ MeV for a target of very large Z. Olsen and Maximon$^{7)}$ treated the extreme relativistic case including both the Coulomb and screening corrections exactly. The final results, however, do not differ very much from May's ones. Gluckstern, Hull and Breit$^{8)}$ also calculated the differential cross sections by the Born approximation procedure. Gluckstern and Hull$^{9)}$ summed over the direction of the emergent electrons. The limit of validity of their Born approximation is the usual ones in the treatment of the bremsstrahlung process$^{10)}$. The low energy limits of validity are given by

$$(Ze^2/k) \ll 1\,, \quad \text{and} \quad (E_0 - mc^2)/mc^2 \gg (Z/137)^2\,.$$

Their calculations were carried out without screening corrections. They however estimated the effect of screening, and concluded that the results obtained without screening were approximately correct as long as $E_0 \ll 137Z^{-1/3}mc^2$ and $k \gtrsim mc^2$.

The effect of screening was treated more accurately by Fronsdal and Überall$^{11)}$ who used the Born approximation and an exponential atomic form factor to account for screening. Their results do not differ appreciably from Gluckstern and Hull's ones in the inter-

5/11 63/2 owen

mediate electron energy region.

The first experiment in relativistic energy range was performed by Phillips[12]. He used a betatron to produce 20 MeV bremsstrahlung from a 5 mil W target and detected the polarization by observing directions of photoprotons from deuterons. The results for photons from 6 to 15 MeV were in qualitative agreement with the theory. Tzara[13] also performed the experiment using 22 MeV bremsstrahlung from a 0.8 mil target and reported a very high polarization, i.e. $d\sigma_{\perp}/d\sigma_{\parallel}=3.5\pm0.5$. Muirhead and Mather[14] examined 11.5 MeV bremsstrahlung from a 5 mil Pt target. Their results did not show so large polarizations as the theory predicted. Dudley, Inman and Kenney[15] examined the polarization of 24 MeV bremsstrahlung from a 1 mil Al target using a linear accelerator. They obtained the following values of polarization for photons from 4 to 8 MeV; 24.2±18.1%, 33±15% and 12.3±10.2% at $\theta=\Theta$, 1.6Θ and 2.5Θ respectively.

Jamnik and Axel[16] examined the polarization of 15.1 MeV gamma rays from 25 MeV bremsstrahlung produced with the aid of a special betatron doughnut. They observed at $\theta=\Theta$ asymmetric azimuthal angular distributions of elastically scattered gamma rays from the 15.1 MeV level of C^{12} which had been interpreted as $M1$ transition. For an Al target the observed polarization was $d\sigma_{\perp}/d\sigma_{\parallel}=1.53\pm0.05$ and was in good agreement with the theoretical prediction. For a Pt target, $d\sigma_{\perp}/d\sigma_{\parallel}=1.28\pm0.04$, which was about 10% lower than the theoretical calculation neglecting screening. But according to them the screening and Coulomb corrections are expected to bring the theory into agreement with the experiment.

For 1.0 MeV bremsstrahlung from very thin targets (0.43 mg/cm² Au foil and 1.0 mg/cm² Al foil), Motz[17] observed photon energy dependence of polarization using Compton effect as a polarimeter and found such reversal of the sign of polarization as was predicted theoretically by Gluckstern-Hull[9]. The observed polarization, however, was slightly smaller than that of the theory. For Al the discrepancy is small, but for Au it is large and the energy dependence of polarization is similar to that for lower energy electrons. Motz and Placious[18] also examined the angular dependence of the polarization for 0.5 MeV bremsstrahlung near the high frequency limit and confirmed Gluckstern-Hull's equation[9]. They extended these experiments for several electron energies from 0.05 to 1.0 MeV[19], using thin Be, Al, and Au targets. The agreement with Gluckstern-Hull's estimation is fairly good.

The present author[20] examined the polarization of 8.5 MeV bremsstrahlung from a 80 μ Pt target in a synchrotron. The polarization was found to be negative and larger for higher energy gamma rays. The energy at which the polarization was estimated to be zero was 4.7±2 MeV.

It has been well established from these studies that bremsstrahlung produced by about 20 MeV electrons and also electrons of lower energy than 1 MeV is linearly polarized, and that the observed polarization is qualitatively in good agreement with the theory. But some difference in the energy dependences of polarization observed with Al and Au targets at 1 MeV suggests that the atomic number dependence of polarization may be somewhat different from the existing theory for low energy bremsstrahlung.

In the present work, the photon energy dependences of polarization for 8.5 MeV bremsstrahlung produced in thin Al, Ag, Au and U targets have been studied at the characteristic angle using D_2O-loaded plates. Since the effects of multiple scattering of electrons in targets might be serious, the experiments were performed with care at this point. Multiple scattering and other effects which affect the polarization seriously were monitored by observing the bremsstrahlung angular distribution which was sensitive to such effects. Finally the energy at which the reversal of the sign of polarization occurs, one of the important parameters in the polarization of bremsstrahlung, has been discussed.

§ 2. Experimental Procedure

a) *Preliminary experiments*

The polarization is known to be strongly dependent on the photon emission angle. Therefore it is important to keep both the oscillation amplitude and the cross section of incident electron beam small and also to reduce recirculation of the beam and multiple scattering in the target.

The experimental arrangement is shown in Fig. 1. To intercept electrons scattered in the target a beam stopper (Pt 1.5 mm thick) was placed near the gun which was 15 mm apart from the stable orbit. The target position was so decided as to give a high intensity yield of bremsstrahlung. Jamnik and Axel[16] investigated the relation between the multiple scattering in the target and the position of the beam stopper. No such investigation was performed in the present experiment. Thus the position in our case may not be the best to prevent multiple scattering, but this position was necessary to have a resonable intensity. Examples of the dependence of beam intensities on the target position and the expander current are demonstrated in Fig. 2 and Fig. 3 for 25 MeV excitation, because at this energy the intensity is the strongest. The bremsstrahlung intensity from the beam stopper increases suddenly at a certain value of the expander current, suggesting that circulating electrons become strongly divergent in the orbit expansion. The expander current was chosen as small as allowable in the present experiment.

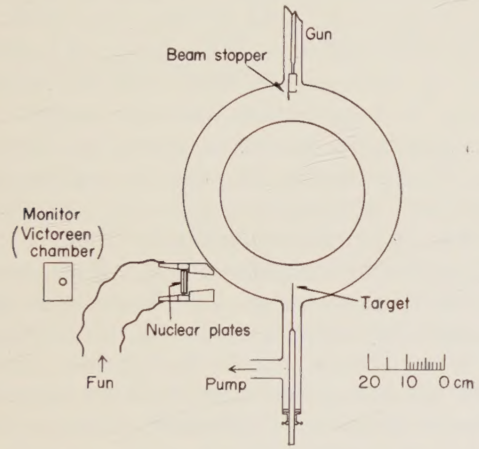

Fig. 1. Experimental arrangement.

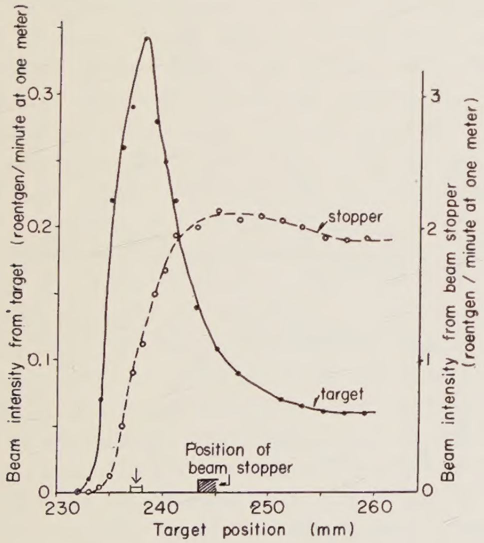

Fig. 2. Dependence of the beam intensity on target position.
Electron energy: 25 MeV. Radius of the betatron orbit: 232 mm. Position of the beam stopper: $r=243$ mm. Target: 1 mm×2 mm Al 10 μ thick. Full line: bremsstrahlung intensity from the target. Broaken line: bremsstrahlung intensity from the beam stopper. The arrow shows the final target position.

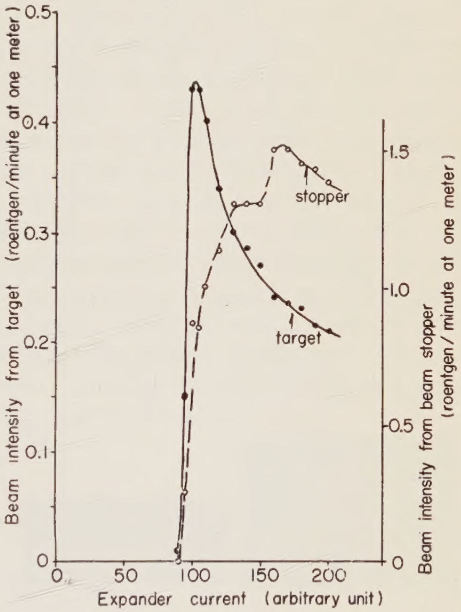

Fig. 3. Dependence of the beam intensity on expander current.
Electron energy: 25 MeV. Radius of the betatron orbit: 232 mm. Position of the target: $r=238$ mm. Position of the beam stopper: $r=245$ mm. Target: 1 mm×2 mm Al 10 μ thick. Full line: bremsstrahlung intensity from the target. Broaken line: bremsstrahlung intensity from the beam stopper.

The cross section and the oscillation amplitude of the electron beam were measured by autoradiography of induced activity on a 20 μ copper target at 25 MeV. The horizontal component of the amplitude of electron oscillation and the dimension of the beam cross section were estimated from the width and the length of strongly active area along the target edge in Fig. 4 (a) and the amplitude of oscillation was found to be smaller than 0.3 mm and the dimension of beam cross section was about 4 mm in diameter at 25 MeV. The result of another experiment using the target of different shape has shown that the horizontal and vertical components of the amplitude of electron oscillation are nearly equal. No such experiment was performed at 8.5 MeV. However the amplitude of electron oscillation at 8.5 MeV would not be expected to be very different from those at 25 MeV, because the amplitude of electron oscillation is in inverse proportion to the square root of electron momentum which is about twice as large in 8.5 MeV as in 25 MeV of electron energy. The amplitude of electron oscillation causing ambiguity of the order of $\Theta/10$ in the beam direction is estimated to be about 1.5 mm at 8.5 MeV. The beam oscillation therefore would not affect the present experimental results very much. However, to keep the ambiguity in the beam direction below the order of $\Theta/10$ the cross section of the beam must be smaller than 3 mm in diameter. Hence we have used a target of about 1.5 mm × 1 mm. Figs. 4 (b) and (c) are the autoradiograph and its photometry curve taken with the induced activity in a thin target which has the same thickness (3 μ) and dimension and was held in the same conditions as in the polarization experiments. The region of activity is somewhat broader than that of Cu target, which shows some undesirable effect such as multi-revolution of scattered electrons (one type of multiple scattering).

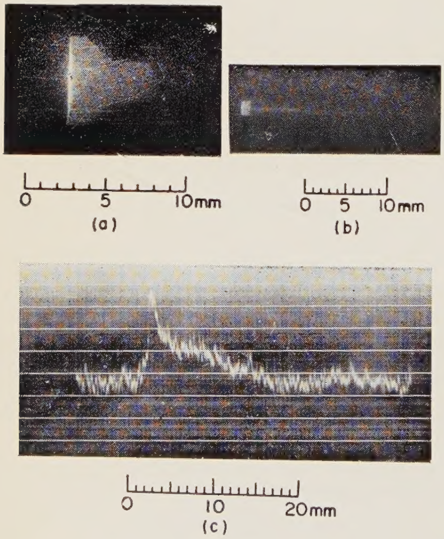

Fig. 4. Autoradiographs of induced activity on a 20 μ Cu target placed at $r=235$ mm (a), and on a 3 μ Ag target kept in the same conditions as in the polarization experiments (b), and its photometry curve (c).

To reduce multiple scattering of electrons in the targets supposed to have the largest effect on the observation of polarization, very thin targets were used as shown in Table I. They were supported by supporters of 0.3 mm wide cut out from the same foils as targets except U target which was supported by an Al supporter of 10 μ thick and 0.3 mm wide. The doughnut was supported in such a way that the vibration of target did not occur even at the maximum excitation.

The effect of multiple scattering was estimated by examining the bremsstrahlung angular distributions with Fuji Type 80 X-ray films calibrated for the dose-density curve. Since the subtraction of background radiation from the doughnut is not easily done exactly, certain systematic errors may be included in

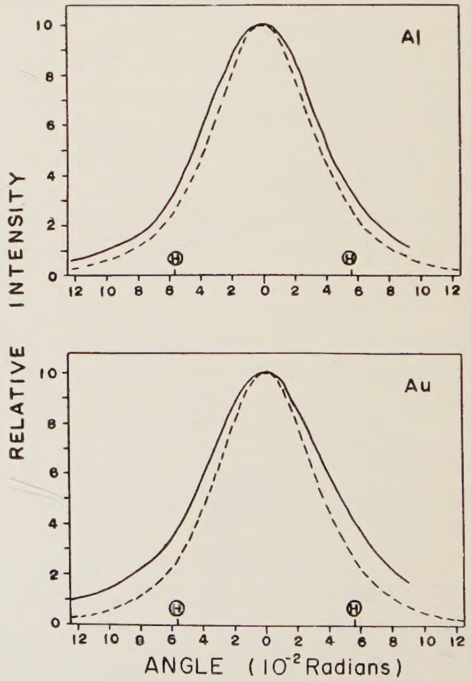

Fig. 5. Examples of bremsstrahlung angular distributions in the same arrangement as in the observation of polarization.
Full lines: experimental results.
Broaken lines: theoretical curves.

the results of angular distributions. Fig. 5 shows the examples of experimental results on the angular distribution of 8.5 MeV bremsstrahlung in the polarization experiment. Theoretical curves in the figure were calculated by the simple formula

$$F(\theta)=1/[1+(E_0\theta/mc^2)^2]^2 ,$$

which has been known to be in good agreement with the experiments on very thin targets[21]. It may be concluded that the deviations of experimental curves from theoretical ones are not so large, if the experimental error is taken into account.

b) *Measurement of polarization*

The polarization of bremsstrahlung was examined with Ilford C2, 200 μ nuclear plates soaked to be saturated with D_2O. The plates were mounted on a thin watertight bakelite holder containing excess D_2O and exposed to the beam at 28 cm from the target in a lead chamber which shielded them from gamma rays coming from the doughnut and other parts of the betatron. In front of the chamber a lead-stacked collimator having a conical aperture was placed to limit the exposed area to 5 cm in diameter. A lead plate of 1 mm thick was interposed to reduce the fogging of nuclear plates due to attenuating soft gamma rays. The plate holder was cooled by air blowing. With this precaution the fading of the tracks was not serious. The plates were developed by an amidol developer, pH. of which was adjusted to be 5.2 with HCl in order to minimize fogging.

Scanning was performed along a circular ring of 1.6 cm in mean radius and 2 mm in width, which corresponded $\theta=\Theta(1\pm1/16)$. The center of the bremsstrahlung beam was determined by photometry of the plates and also by the X-ray film examination of 25 MeV bremsstrahlung which produced a smaller spot than 8.5 MeV beam. The error in the determination of center was estimated to be nearly equal to or smaller than 2 mm. Tiyoda binoculare microscopes were used for the scanning at a multiplication of 60×1.5×10.

The length of proton tracks was determined by measuring the projected length of the tracks on the plane of the emulsion and the depth of the tracks corrected for the schrinkage factors which were determined by measuring the thickness of emulsion after soaking with a micrometer. For the range-energy relations of D_2O soaked emulsion, the table calculated by Krohn and Schrader[22] was used. The emission angle ϕ of proton tracks was determined by calculating the angle between the projected direction of the tracks in the

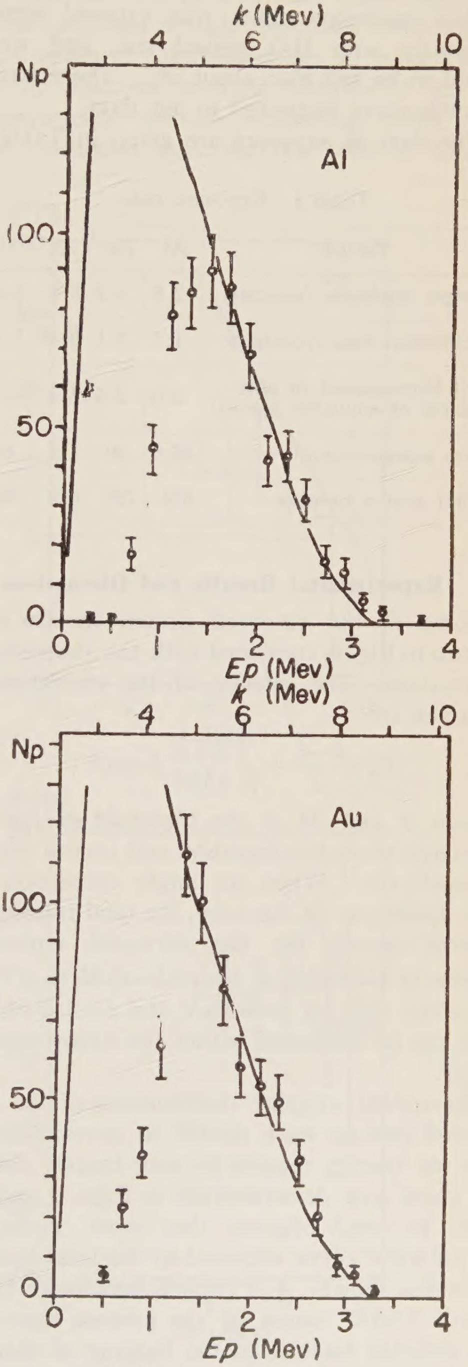

Fig. 6. Examples of photoproton spectra obtained with polarized bremsstrahlung.

plane of emulsion and the radial direction of scanning point. Only the tracks running within the glancing angle of ±45° from emulsion plane were observed. The yields of photoprotons from the elements in the emulsion except deuteron and neutron recoil protons were determined by examining H_2O soaked emulsions which was exposed simultaneously with D_2O soaked one, and were found to be less than about 5%. These backgrounds were neglected in our data.

The data of exposure are given in Table I.

Table I. Exposure data.

Target	Al	Ag	Au	U
Target thickness (mg/cm²)	2.5	3.2	5.6	8.5
Irradiation dose (roentgen)	1.7	1.1	0.46	1.74
D_2O impregnated in unit volume of emulsion (g/cm³)	2.0	2.6	2.3	2.0
Area scanned (mm²)	85.6	90	113	69
Total proton number	624	726	644	962

§ 3. Experimental Results and Discussions

Some of the observed proton spectra are shown in Fig. 6, combined with the theoretical estimation. The energy of the photoproton is given by

$$E_p=\frac{k-\mathcal{E}}{2}+\sqrt{\frac{k-\mathcal{E}}{4Mc^2}}\,k\cos\theta$$

where $\mathcal{E}$ and M is the threshold energy of deuteron photodisintegration and proton mass, respectively. When an angle correction is not applied as in our case, the total fractional energy spread for the surveyed emission angles of 45°～135° is $\frac{1}{2}(k/\sqrt{(k-\mathcal{E})Mc^2})$. This is about 7% for $k=5$ MeV and $\mathcal{E}=2.23$ MeV, and can be neglected within the experimental error.

Azimuthal angular distributions of the observed protons were plotted in several gamma ray energy regions for each target. Some of them are demonstrated in Figs. 7 and 8, and in each figure the most probable $A+B\sin^2\theta$ curve obtained by the least square fit is also shown. For gamma rays lower than about 5 MeV, some of the protons may not be detected because of the fogging of plates, but this does not seriously affect the results of angular distributions.

Photodisintegration of deuteron is known to be induced by strong $E1$ and weak $M1$ transitions except near the threshold. The ratio

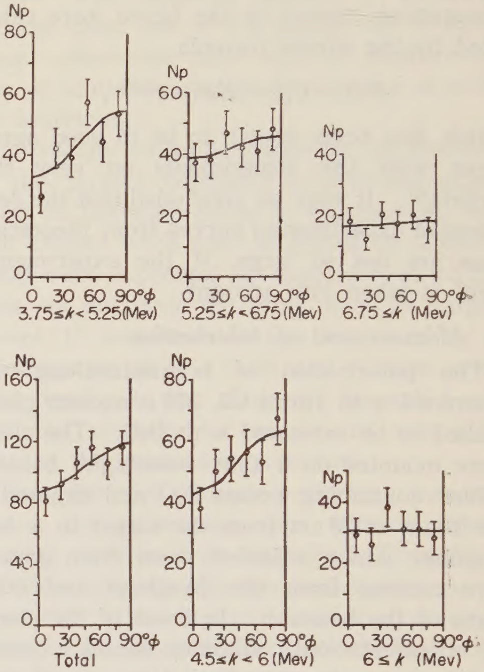

Fig. 7. Azimuthal angular distributions of photoprotons obtained with polarized bremsstrahlung from an Al target.

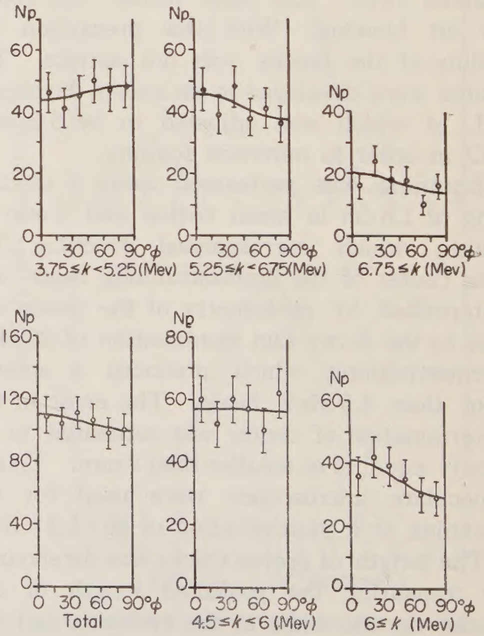

Fig. 8. Azimuthal angular distributions of photoprotons obtained with polarized bremsstrahlung from an Au target.

of $M1$ transition to $E1$ is about 5% for 6 MeV gamma rays and can be neglected in the higher energies. In $E1$ transition, protons are mainly emitted in the direction of the electric vector of gamma rays, and in $M1$ transition in the direction of the magnetic vector. The polarization degrees of bremsstrahlung therefore are immediately determined from the curves given in azimuthal angular distributions.

Fig. 9 shows the energy dependence of polarization thus evaluated. The $M1$ transition was neglected in the calculation. This neglect will not change the results beyond the present experimental error. Errors given in the figure are only statistical ones. Theoretical curves obtained by Gluckstern-Hull's equations[9] with approximate screening corrections are also given in the same figure.

As has been already described above, absolute values of polarization are strongly affected by electron multiple scattering. In our experiments multiple scattering effect was not examined quantitatively and no correc-

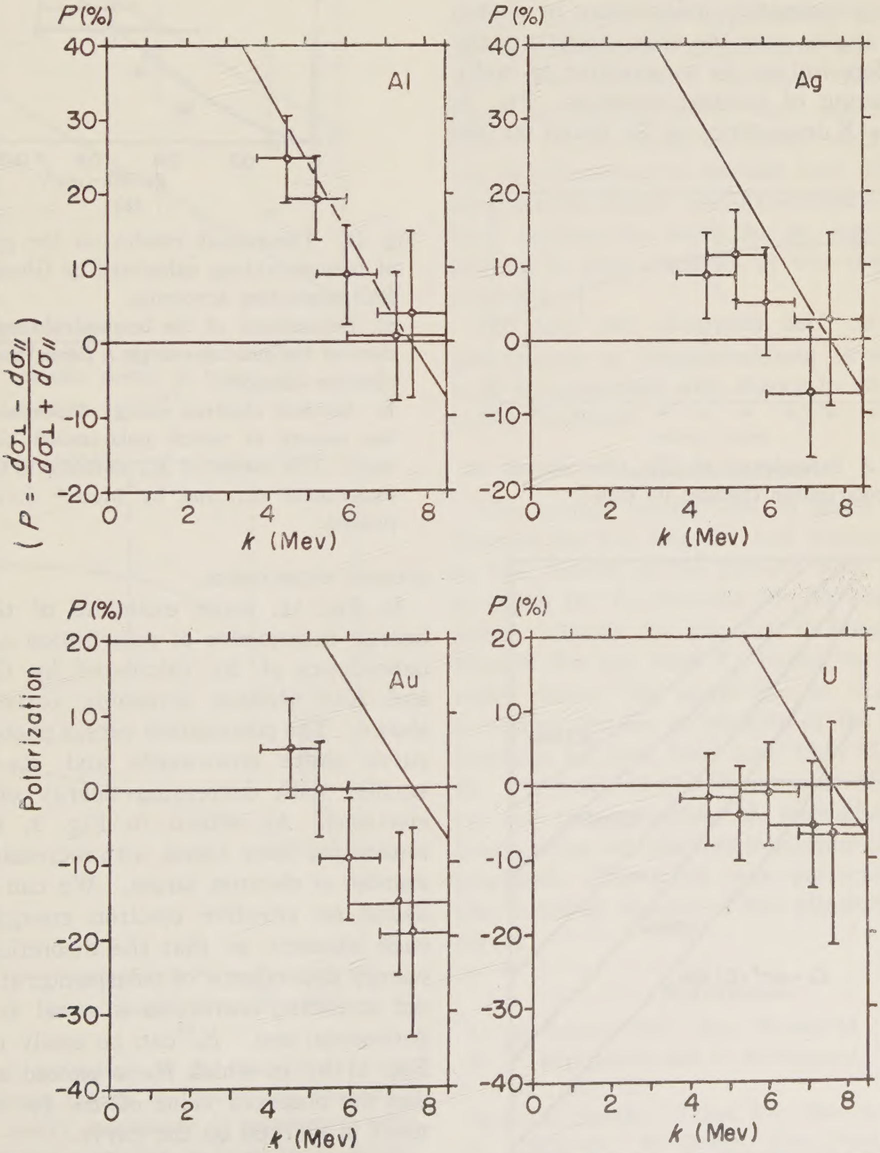

Fig. 9. Dependence of the bremsstrahlung polarization on photon energy for an electron kinetic energy of 8.5 MeV and for a characteristic photon emission angle. The solid lines are theoretical curves calcnlated by Gluckstern and Hull with approximate corrections for screening.

tions were applied for it. The experimental data therefore will deviate in the absolute values of polarization, but the qualitative aspects of energy dependence of polarization will not be changed seriously by the effect of multiple scattering. The energy dependence of polarization deviates fairly strongly from theoretical curves. The deviation is larger for higher Z targets and the data on Au is in agreement with that of earlier data on Pt[20].

According to Gluckstern and Hull[9], the energies E_R at which polarization changes its sign are approximately independent of photon emission angles near the characteristic angle. E_R therefore will not be so sensitive to multiple scattering of incident electrons. Fig. 10 shows the Z dependence of E_R found in the present experiment.

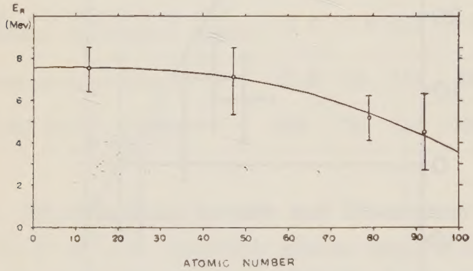

Fig. 10. Z dependence of E_R, the energy at which polarization changes its sign.

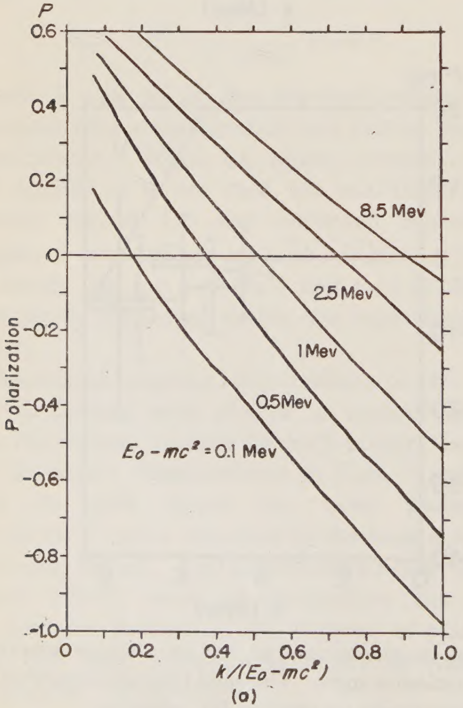
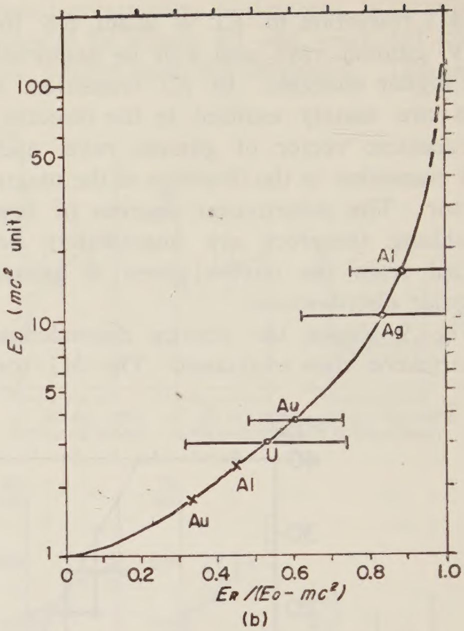


(a)



(b)

Fig. 11. Theoretical results on the polarization of bremsstrahlung calculated by Gluckstern and Hull neglecting screening.

a) Dependence of the bremsstrahlung polarization on the photon energy k for several incident electron energies.

b) Incident electron energy dependence of E_R, the energy at which polarization changes its sign. The values of E_R obtained in the present experiment (○) and by Motz[17] (×) are also plotted.

In Fig. 11, some examples of the photon energy dependence of polarization and the E_0 dependence of E_R calculated by Gluckstern and Hull without screening correction are shown. The polarization versus photon energy curve shifts downwards and E_R becomes smaller with decreasing energy of primary electrons. As shown in Fig. 9, the same tendencies were found with increasing atomic number of electron target. We can therefore define an effective electron energy E_0' for each element so that the theoretical photon energy dependence of polarization at E_0' without screening correction is equal to the experimental one. E_0' can be easily read from Fig. 11 (b), in which E_R is plotted against E_0 and the observed value of E_R for each element is marked on the curve.

In Fig. 12 the Z dependence of E_0' thus determined is shown in two types of plotting. The lines were drawn in the figure so as to fit the experimental values assuming that E_0' approached 8.5 MeV with decreasing Z. Motz's data[17)] for 1 MeV electrons are also plotted by the same method. In Fig. 12 (a) both Motz's and the present data can be expressed by a common empirical formula $E_0'-mc^2 \propto \exp(-0.023Z)$. According to Fig. 12 (b) Motz's data seem to correspond to the lower Z region than 47 in the present data. For larger Z than 47, our curve can be crudely expressed by a formula $E_0'-mc^2 \propto Z^{-2}$, although there may be no definite theoretical meanings in these empirical relations.

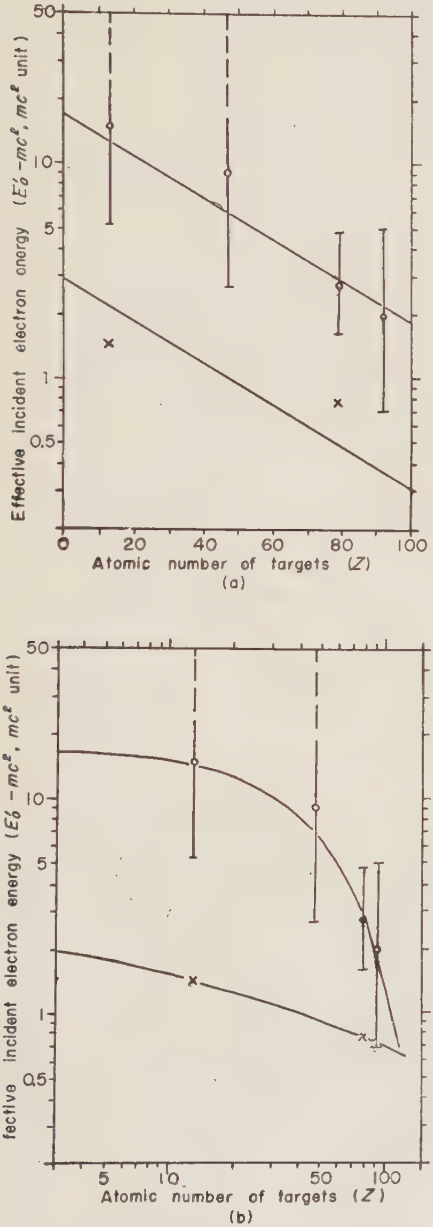


Fig. 12. Z dependence of E_0', the effective incident electron energy for which the theoretical photon energy dependence of polarization without screening correction is equal to the experimental one. ○: The present writer's; ×: Motz's.

Sommerfeld[1)], Kirkpatrick and Wiedmann[2)] showed that in the non-relativistic case the polarization is constant for equal values of V/Z^2, where V is an electron voltage. If one assumes $E_0'-mc^2 \propto V/Z^2$, this is just the relation found in the present experiment for large Z targets as far as Z dependence is concerned. This coincidence may be accidental, because our experiments are not in the non-relativistic region and we can not apply non-relativistic formula. However the same tendencies were also suggested by Motz[17)] in his study on 1 MeV electrons. It will be interesting to disclose such differences between the theory and experiment, but further discussions seem to be inappropriate because of poor statistics in the present experiment.

For thin low Z-targets such as Al, the polarization of bremsstrahlung is considered to be in agreement with theory in all electron energy regions.

Acknowledgement

The author would like to thank Prof. M. Kimura for his interest and encouragement in the course of the present work, and also to thank Dr. K. Okamoto for his kind discussions. Thanks are also due to Miss N. Endo, Miss N. Ito and Miss R. Onuma for scanning many plates. He would like to thank Prof. S. Ogawa and his co-workers of the Research Institute for Iron Steel and Other Metals, and Dr. Y. Amako of the Department of Chemistry, for the operation of microphotometers. Cooperation of the betatron crew is also appreciated. The work was performed under the financial support of the Ministry of Education.

Decay of Rh^{102} and Levels in Ru^{102}

By Kazuo HISATAKE

Tokyo Institute of Technology, Meguro-ku, Tokyo

(Received March 3, 1961)

The decay of Rh^{102} has been investigated using scintillation spectrometers and a magnetic beta-ray spectrometer. The negatron spectrum have the end-point energy of 1.15 Mev and the positron spectrum consists of two groups of end-point energies of 1.30 Mev and 0.82 Mev. All of beta-spectra involved appear to have approximately "the allowed shape of the Fermi plot". 12 gamma transitions were assigned to Ru^{102} from the internal conversion spectrum and the single and coincidence gamma-ray spectra. Gamma-gamma angular correlations have also been measured. The results are consistent with the following level scheme for Ru^{102}: 0.476(2+), 1.106(2+), 1.53(3+), 1.85(?), 1.87(1+, 2+, or 3+), 2.06(?), and 2.23(3−) Mev. The transition between the first and second 2+ state was found to consist primary of E2 transition. The branching ratio obtained for the cascade to crossover transition from the second 2+ level is (4.2±0.8).

§1. Introduction

Energy Levels of even-even nuclei of medium weight are very interesting for the study of nuclear structure. Nuclear spectra in the region far from closed shells have well been explained by the collective nuclear model of Bohr and Mottelson1),2). On the other hand, nuclear spectra of even-even nuclei near closed shells have been less described by the present nuclear models. Scharff-Goldhaber and Weneser[3] pointed out some regularities of the first and second excited states of even-even nuclei in this region and succeeded in explaining some of the character of these nuclei by the use of the Bohr-Mottelson collective theory. Since then, several nuclear models for the even-even nuclei in this region (so-called the vibrational region) have been presented and succeeded in explaining only some of characters of the nuclear spectra. The present status between theory and experiment for even-even nuclei in the vibrational region have been summarized by Horie[4] and Stelson[5].

In the present paper the energy levels of Ru^{102}, which is just in the vibrational region, have been studied observing beta-rays and gamma-rays from the decay of Rh^{102}. Rh^{102} was first discovered by O. Minakawa[6] in 1941, by bombarding Rh^{103} with fast neutrons. He observed that Rh^{102} had both positrons and negatrons using a G-M counter with magnetic field. The half-life of Rh^{102} was determined to be 210±6 days. Since then, several people[7-16] including the author have studied the decay of Rh^{102}. The tentative decay scheme of Rh^{102} was given by the author and Kurbatov[16]. In the mean time Coulomb excitation has been giving valuable informations on the low-lying states of the even-even nuclei including Ru^{102} [17,18]. In this situation it is felt that the extensive study of energy levels of Ru^{102} is necessary.

There was a good opportunity to bombard Ru for many hours by protons of the 63″ cycltron at the Institute for Nuclear Study, University of Tokyo, and to get relatively strong Rh^{102} activity. The development of chemistry for the separation of Rh from Ru made possible to have a good beta source. In this paper the extensive study of the decay of Rh^{102} is reported.* After all the experimental work was done, McGowan and Stelson[19] reported their preliminary work on the decay of Rh^{102}. Their result is in fairly good agreement with the present work.

§ 2. Source Preparation

The Rh^{102} used in the present work was prepared by a (p, n) reaction on natural ruthenium and 97% enriched ruthenium 102 powder. The energy of protons was about 13 Mev. Total bombarded protons were 800 μA hours for natural Ru and 2000 μA hours for enriched Ru^{102}. About three months after each bombardment radioactive rhodium was chemically separated. The procedure of the chemical separation is as follows**: After 10 mg of iron as ferric chloride was added as the collector, bombarded ruthenium target was fused with potassium hydroxide and potassium nitrate at about 500°C for 30 min. in a gold crucible. The residue was collected with centrifugation and fused with potassium pylosulfate. Rhodium was coprecipitated with ferric hydroxide. The precipitate was dissolved in hydrochloric acid, and ferric chloride was removed with ether extraction.

The half-life of the bombarded material was followed by a G. M. counter for two years and was found to be (206±3) days. Thus almost all of the bombarded material was found to be Rh^{102}.

§ 3. Total Beta-Spectra

a) *The beta-source and the beta-ray spectrometer*

The beta-source was mounted on 1 mg/cm^2 mylar film by a drop method. The estimated source thickness was about 1 mg/cm^2. The beta spectrometer used was INS III magnetic spectrometer, which is a sector type double focusing beta spectrometer of $\rho=18$ cm. Analyzed beta-particles were detected with a G.M. counter, the window of which was approximately 1.5 mg/cm^2. The beta spectrometer was operated with momentum resolution 0.9% and was calibrated with the conversion lines of I^{131}, Hg^{203}, Cs^{137} and Co^{60}. The reproducibility of the calibration was within 0.5%. (The deviation was caused by the hysteresis of iron material of the spectrometer) The overall performance of the spectrometer was tested with P^{32} and Rb^{86}. The beta spectrum of P^{32} mounted on 1 mg/cm^2 mylar film showed a straight line down to 300 kev, and the beta spectrum of Rb^{86} exhibited " the unique first forbidden type ", as was expected.

b) *The positron spectrum*

Fig. 1 shows the Kurie plot of the positron spectrum of Rh^{102}. It can be seen that the spectrum is complex. The upper energy group (called β_2^+) slightly shows a deviation from the allowed shape but cannot be assigned to be the unique first forbidden type; the experimental shape factor of this positron group is shown in Fig. 2 together with the theoretical shape factor of the unique first forbidden type (a_1). It is concluded from Fig. 2 that the positron spectrum of Rh^{102} cannot be the unique first forbidden type but nearly the allowed shape. The Kurie plot of the second positron group (called β_1^+) approximately shows a straight line as low as 300 kev. The deviation from a straight line below 300 kev is believed to be due to scattering of beta particles mainly in the source and its backing.

---

* Preliminary reports of this present work were given by the author in the 1959 Spring Meeting and in the 1960 Spring Meeting of the Physical Society of Japan.

** The chemical procedure will be described in detail elsewhere by H. Shimojima.

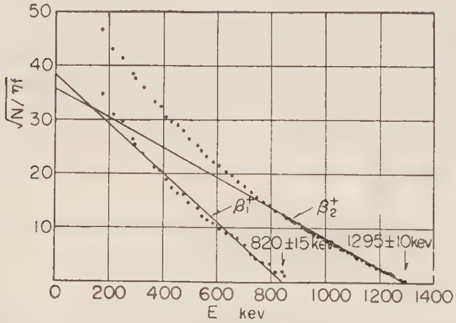

Fig. 1. The Kurie plot of the spectrum of Rh^{102}. The spectrum was taken 110 days after activation.

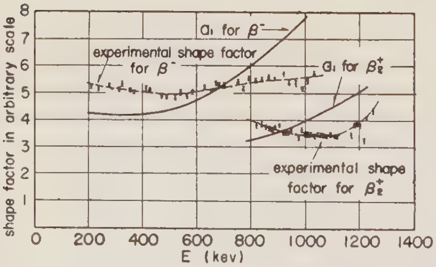

Fig. 2. Experimental shape factors of the positron and negatron spectra. The theoretical shape factors of the unique first borbidden type, a_1, are also shown in the figure by solid curves.

c) *The negatron spectrum*

The Kurie plot of the negatron spectrum of Rh^{102} is shown in Fig. 3. The points of of internal conversion peaks are omitted in the Kurie plot analysis. The Kurie plot of the negatron spectrum approximately shows a straight line down to 250 kev although a slight deviation appears between 600 and 400 kev. The shape factor of the negatron spectrum is shown in Fig. 2. From Fig. 2 it can be seen that the shape factor of negatrons is different from that of the unique first forbidden type (a_1) but nearly that of the allowed type although the shape factors of positrons and negatrons are are a little different. The end-point energies and relative intensities of the two positron groups and the negatron group (callen β^-) are tabulated in Table I. The results are almost in agreement with the previous results[9,10,13] although the 400 kev positron group reported by Marquez[13] was not observed.

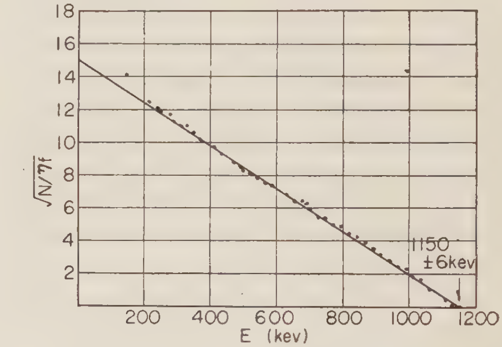

Fig. 3. The Kurie plot of the negatoron spectrum of Rh^{102}, leaving out the conversion electrons. The spectrum was taken 115 days after activation.

Table I. The end-point energy and intensity of each positron and negatron group of Rh^{102}.

Group	End-point energy (kev)	Intensity ($\beta^-=100$)
β_1^+	820±15	21.2±0.5
β_2+	1295±10	54.6+1.0
β^-	1150± 6	100 ±1.5

d) *The internal conversion spectrum*

The internal conversion spectrum of Rh^{102} was studied from 40 kev to 1150 kev carefully. The spectrum is shown Fig. 4. The energy values of the peaks are indicated by arrows in the figure. The three conversion groups below 310 kev and the 533 kev K peak with the 553 kev L peak are attributed to Rh^{101}, as was reported previously[14,17,20]. It is considered that Rh^{101} was produced by the Ru^{102} (p, $2n$) Rh^{101} reaction. The energies and relative intensities of the conversion peaks are

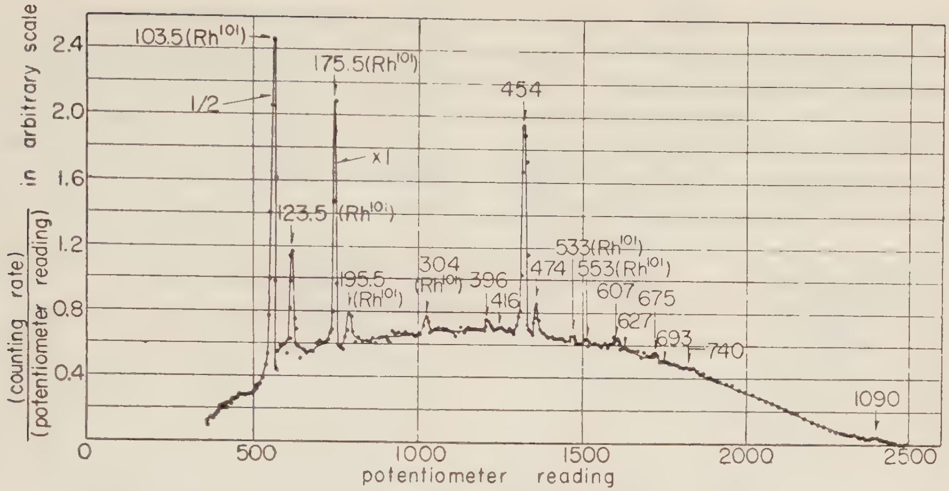

Fig. 4. The internal conversion spectrum of Rh^{102}. Several conversion lines of Rh^{101} also appear in the spectrum. Energies of peaks (kev) are indicated by arrows. The spectrum was taken 120 days after activation.

Table II. Internal conversion spectrum of Rh^{102}.

Energy of conversion electrons (kev)	Origin of conversion electrons	Energy of transition energy (kev)	Intensity of conversion electrons ($\beta^- = 100$)	$\frac{K}{L+M}$	K conversion coefficient	Multiporarity
396 ± 3	K	418 ± 3	0.077 ± 0.019	4.5 ± 2.1		
416 ± 4	L		0.017 ± 0.04			
454 ± 2	K	476 ± 2	1.80 ± 0.06	7.2 ± 0.8	5.2×10^{-3}*	$E2$

* The theoretical K conversion coefficient of Rose is used for the 0.476 Mev transition, which is probably $E2$ transition.

tabulated in Table II together with the $K/L+M$ ratios. Since the 476 kev transition is already known to be $E2$ transition[17,18] which is also consistent with the present $K/L+M$ ratio, the internal conversion coefficients of transitions can be obtained from the combination of the relative intensities of internal conversion electrons with the gamma-ray intensities, which is described in the next section. The K conversion coefficients thus obtained are tabulated in the sixth column of Table II. In the last column of Table II multipole assignments from the K conversion coefficients are given. The K conversion coefficients of the 0.418 and 1.11 Mev transitions are not given because the respective gamma rays were not resolved by the scintillation spectrometer.

§ 4. The Gamma-Ray Spectra of Rh^{102}

The gamma-ray spectra of Rh^{102} were observed with a scintillation spectrometer with $2'' \times 2''$ and $1\frac{1}{2}'' \times 1\frac{1}{2}''$ NaI(Tl) crystals mounted on 6292 DuMont and 6342A RCA photomultiplier tubes. The data were taken with a ten-channel pulse-height analyzer. For the study of the coincidence spectra a conventional fast-slow coincidence circuit with a resolving time 2τ of 0.36μsec was used.

The spectra were taken mainly about 400

days after the bombardments. The single spectrum below 1.4 Mev is shown in Fig. 5. The energies of the observed peaks are indicated in the figure. The peaks of 0.125, 0.190 and 0.315 Mev were already assigned to be Rh^{101} gamma-rays. The 0.48 Mev peak are composed by the 0.476, 0.42 and 0.511 (annihilation radiation) Mev gamma rays; the 0.42 Mev transition was resolved only in the internal conversion spectrum, as is shown in Fig. 4. The small bumps at 0.69 and 0.76 Mev are revealed to be true peaks by coincidence measurements. The broad peaks at ~1 Mev are resolved into three peaks of

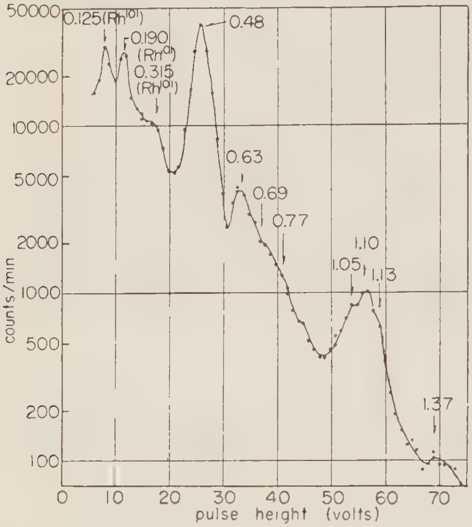

Fig. 5. The gamma ray spectrum of Rh^{102} below 1.4 Mev. Energies of peaks (Mev) are indicated by arrows.

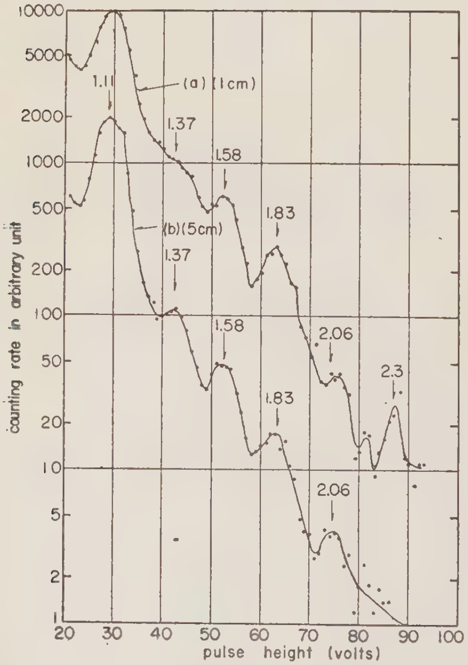

Fig. 6(a) and 6(b). The gamma ray spectrum of Rh^{102} above 1 Mev. Source-to detector distances are 1 cm (a) and 5 cm (b).

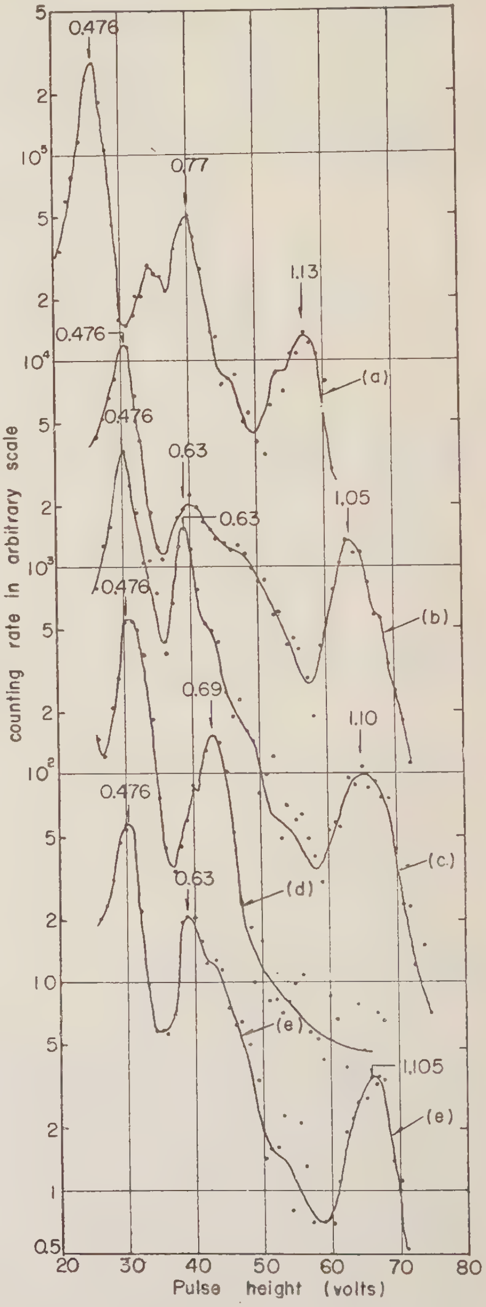

Fig. 7(a)-7(e). The gamma ray spectra of Rh^{102} in coincidence with the (a) 0.63, (b) 0.69, (c), 0.77, (d) 1.05 and (e) 1.13 Mev gamma rays. The energy scale of (a) is different from the others.

Table III. Rh^{102} gamma-ray energies and relative intensities. The data from the internal conversion spectrum are also included. The intensities from the conversion spectrum are obtained from multipole assignments which are indicated in parentheses. The intensities of the beta groups are also listed for comparison. The concluded intensity values summarized from several methods are shown in the last column.

E_r (Mev)	Relative intensity										Concluded intensity
	K internal conversion	Single spectra		Spectra in coincidence with gamma rays of energies (Mev)							
		5 cm	1 cm	0.476	0.511	0.63	0.69	0.76	1.05	1.13	
0.418	3.7(M1)			yes							4
0.476	100(E2)	100			yes	13	8.0	4.0	12	5	100
0.511	45			yes	50						45
0.629	13.2	14		13			1.0	6.4		4.1	13
0.697	7.5(E2) 9.3(M1)	12		8.3		0.5			6.4		8.2
0.762	5.0(E2) 6.3(M1)					6.4					6.3

1.13	7.2(E2)					4.1					5.0
1.37		0.9	0.4	0.5							0.9
1.58		0.5	0.7	0.2							0.5
1.83		0.3	0.9								0.3
2.06		0.2	0.2								0.2
beta group E_{max} (Mev)											
β^- 1.15											29.6
β_1^+ 0.82											6.3
β_2^+ 1.295											16.2

1.05, 1.106 and 1.13 Mev in the coincidence spectra.

The gamma-rays above 1.2 Mev were found to be very weak. The summing peaks could be found in this region. The summing peak efficiencies for various distances were calibrated with the 1.17 and 1.33 Mev gamma rays of Co^{60}. The single gamma-ray spectra above 1 Mev are showo in Figs. 6a and 6b observed with source-to-detector distances of 1 cm and 5 cm, respectively. It is found from the figures that peaks at 1.37, 1.57 and 2.06 Mev are true peaks and the peak at 2.3 Mev is a summing peak; the peak at 1.83 Mev perhaps consists of both kinds.

The intensities of the gamma-rays were determined by measuring the area under the full-energy peak and by correcting for the full-energy peak efficiencies and for Compton continua of high energy gamma-rays. The intensities, which are normalized to a value of 100 for the intensity of the 0.476 Mev gamma-ray, are listed in Table III, together with coincidence and magnetic spectrometer data.

The gamma-ray spectra in coincidence with the 0.476, 0.63, 0.69, 0.76, 1.05, 1.13 and 0.511 (annihilation radiation) Mev gamma rays were investigated. Figs. 7 (a–e) show the spectra show the spectra in coincidence with the 0.63, 0.69, 0.77, 1.05 and 1.13 Mev gamma rays. In Fig. 7a, there appears a predominant peak at 0.77 Mev, which is only a small bump in the single spectrum (Fig. 5). The 1.05 Mev gamma-ray is resolved in Fig. 7b. In Fig. 7d, there is a predominent peak at 0.69 Mev, which exhibits a bump in Fig. 5. The 1.106 gamma-ray, which is found to be a cross-over gamma-ray between the second excited and the ground state of Rh^{102}, can be seen in Figs. 7c and 7e. The intensities in the coincidence spectra corrected for the detector efficiencies, for Compton continua and for gamma-ray summing in the crystal, are tabulated in Table III. The intensity of the annihilation radiation in coincidence with the other annihilation quantum, 50, was obtained by using the annihilation radiation of Na^{22}. In the last column in Table III is shown the concluded intensity values of the gamma rays. The errors of those intensities might be about 10 to 20%. These results are consistent with the decay scheme of Rh^{102} which is shown Fig. 8 and will also be discussed in § 6.

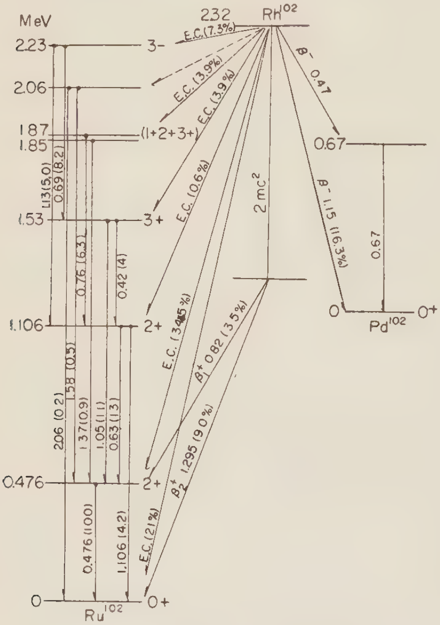

Fig. 8. Decay scheme of Rh^{102} and energy level diagrams of Ru^{102} and Pd^{102}. Energies are given in Mev and intensities are included in parentheses.

§ 5. Gamma-Gamma Angular Correlations in Rh^{102}

For gamma-gamma angular correlation measurements the source was 10 cm from the face of the 2″×2″ NaI crystal and 7.5 cm from the face of the $1\frac{1}{2}''\times1\frac{1}{2}''$ crystal. Data were taken every 22.5° between 90° and 180°. A least-square fit of the data was made to $W(\theta)=1+A_2P_2(\cos\theta)+A_4P_4(\cos\theta)$ following Rose's method[21]. The results were then corrected for the finite angular resolution of the detectors[21,22] and for the Compton continua from the higher gamma rays.

a) *The angular correlation for the 0.63–0.476 Mev cascade*

To obtain the angular correlation for the 0.63–0.476 Mev cascade, a single channel pulse-height analyzer of one detector ($1\frac{1}{2}''\times1\frac{1}{2}''$ NaI) was set with a wide channel width so that almost all the peak area of 0.476 Mev could be detected since no coincidences were observed between the annihilation radiation and the 0.63 Mev gamma ray; the effect from the 0.42–0.63 Mev cascade was estimated to be negligibly small. The other detector (2″×2″ NaI) was connected to a ten-channel pulse-height analyzer to avoid the 0.69 and 0.511 Mev coincidence peaks. The observed coincidences were corrected for the Compton continua from the 1.1 Mev gamma ray group which was in coincidence with the 0.476 Mev gamma ray. The observed correlation function corrected also for the finite angular resolution of the detectors was found to be

$$W_{0\ 0.63-0.476}(\theta)=1+(0{,}049\pm0.012)P_2(\cos\theta)$$
$$+(0.274\pm0.018)P_4(\cos\theta)\ .$$

Since the 0.476 Mev peak detected by the single channel pulse-height analyzer as a gate for coindidences contains the Compton continua of the 0.77 and 1.13 Mev gamma rays which are in coincidence with the 0.63 Mev gamma ray, the above correlation function should be corrected for the 0.63–0.76 and 0.63–1.13 Mev cascades. The observed correlation function of the 0.63–0.76 and 0.63–1.13 Mev cascades were found to be

$$W_{0.76-0.63}(\theta)=1+(0.009\pm0.020)P_2(\cos\theta)$$
$$+(0.022\pm0.028)P_4(\cos\theta)$$

and

$$W_{1.13-0.63}(\theta)=1+(-0.292\pm0.032)P_2(\cos\theta)$$
$$+(-0.0235\pm0.049)P_4(\cos\theta)\ ,$$

respectively. The ratios of the counting rates of these cascades to the counting rate of the 0.476–0.63 Mev cascade are found to be 0.082 for the 0.63–0.76 Mev cascade and 0.040 for the 0.63–1.13 Mev cascade. Thus the final correlation function for the 0.476–0.63 Mev cascade was determined to be

$$W_{0.63-0.476}(\theta)=1+(0.064\pm0.014)P_2(\cos\theta)$$
$$(0.312\pm0.032)P_4(\cos\theta)$$

The experimental correlation function is consistent with the theoretical correlation function for the spin sequence 2 $(D+Q)$ 2 (Q) with $\delta=5.5^{+0.7}_{-0.5}$, where δ is defined as the ratio of the reduced matrix element of quadrupole transition to dipole transition. The determination of δ-values is illustrated in

Fig. 9, where A_2 and A_4 in the correlation functions are taken as the abscissa and the ordinate, respectively, and δ-values are the parameters of the respective ellipses; in Fig. 9 the ellipses of the (3–2–0), (2–2–0) and (1–2–0) correlation functions are shown.

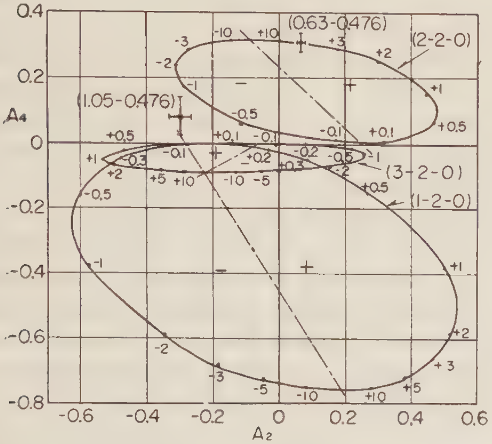

Fig. 9. Coefficients of angular correlation functions for (3-2-0), (2-2-0) and (1-2-0) cascades. δ is taken as a parameter of each ellipse.

b) *The angular correlation for the 1.05–0.476 Mev cascade*

The angular correlation for the 1.05–0.476 Mev cascade was observed similarly. Since the 1.13 Mev gamma ray is also in coincidence with the 0.476 Mev gamma ray, care was taken to select only the 1.05 Mev gamma ray. For this purpose the coincidence spectra in coincidence with the 0.476 Mev gamma ray between 1.0 and 1.2 Mev were carefully taken with the ten pulse-height analyzer at the five angles in which the angular correlation was observed. It was also observed that the coincidence counts for 180° were abnormally high in comparison with the coincidence counts for the other four angles. By changing the source-to-detector distance it was found that the sum coincidence peak between the 0.476 and 0.511 Mev gamma rays was in coincidence with the other annihilation quantum emitting to the opposite direction. For this reason the coincidence counts for 180° were omitted from the data. The observed correlation function for the 1.05–0.476 Mev cascade which was corrected for the finite angular resolution of the detectors was

$$W_{0\,1.05-0.476}(\theta)=1+(-0.252\pm0.028)P_2(\cos\theta)+(0.066\pm0.049)P_4(\cos\theta)\,.$$

This correlation function should be corrected for that of the 0.69–1.05 Mev cascade, which was found to be

$$W_{0.69-1.05}(\theta)=1+(0.122\pm0.038)P_2(\cos\theta)+(-0.222\pm0.061)P_4(\cos\theta)\,,$$

experimentally; the finite angular resolution was corrected for. The ratio of the coincidence counts of the 0.69–1.05 Mev cascade to those of the 0.476–1.05 Mev cascade is observed to be 0.11. The final correlation function was determined to be

$$W_{1.05-0.476}(\theta)=1+(-0.298\pm0.034)P_2+(0.093\pm0.055)P_4(\cos\theta)\,.$$

The unique spin assignment for the 1.53 Mev level of Ru^{102} is difficult only from this correlation function, as is seen in Fig. 9; 3, 1 and 2 are equally probable. 0 and 4 are excluded. However, the data of the relative intensities of the gamma rays give the spin of 3 uniquelly, as will be discussed in the following section. If the spin of the 1.53 Mev level is 3, the δ-value for the 1.05 Mev transition is determined to be 0.3±0.1 from Fig. 9. The reason for the large error in the correlation function for the 0.476–1.05 Mev cascade is probably due to the poor resolution of the 1.05 Mev peak from the 1.13 Mev peak.

c) *The angular correlations for the 0.76–0.63 and the 1.13–0.63 Mev cascades*

The angular correlations for the 0.76–0.63 and the 1.13–0.63 Mev cascades were also studied. The observed correlation functions, which are corrected for the finite angular resolution of the detectors, are described in § 5 (a); the errors mentioned above are only statistical ones. From these correlation functions the spins of the 1.87 and 2.23 Mev levels of Ru^{102} can be obtained since the δ value of the 0.63 Mev transition is already determined. These correlation functions, however, involve other errors than statistical ones because of the poor energy resolution of the detectors. Therefore the unique assignment of those levels is rather difficult. The spin assignment of the 1.87 Mev level is 1, 2 or 3; 0 and 4 are excluded. On the other hand the assignment of the 2.23 Mev level is rather uniquely determined to be 3 even if the error involved are large. The δ-value of the 1.13 Mev transition cannot be determined because of the large experimental error.

§ 6. Discussion

The log ft values of the decay of Rh^{102} to the states of Ru^{102} and Pd^{102} are discussed. In order to obtain the ft value of the transition to the ground states of Ru^{102}, the ratio of orbital electron capture to positron emission is necessary. Since the positron spectrum associated with this transition (β_2^+) exhibits the allowed shape approximately, the capture to positron ratio is considered to be approximately that of the allowed transition[23]. The capture to positron ratio of the allowed transition is found to be 2.3 for the transition to the ground state of Ru^{102} using the Feeberg's chart[24]. In the same way the capture to positron ratio of the transition to the first excited state of Ru^{102} is obtained to be 10. This value is in good agreement with the experimental value of (11±2), which was determined from the relative intensities of the gamma-rays and the total beta-rays. The branching ratio of the transition to each state was obtained from the decay scheme shown in Fig. 8. The values of the branching ratios and the log ft values tabulated in Table IV.

Table IV. Branching ratio and log ft values of Rh^{102} decay.

Terminating level (Mev)		Branching ratio (%)	Log ft
0	Ru^{102}	30	8.6
0.476		38	8.1
1.106		0.6	9.7
1.53		3.9	8.6
1.87		3.9	8.1
2.23		7.3	5.5
0	Pd^{102}	16.3	9.6

All the log ft values obtained are between 8 and 9, except for the transition terminating to the 2.23 Mev state of Ru^{102}. Those transitions are considered to be the first forbidden transitions. Since the parities of the ground states of Ru^{102} and Pd^{102} are positive, the parities of those terminating levels are positive. The log ft of 9.8 for the transition to the second 2+level is compared with the log ft of 8.1 for the transition to the first 2+level. The forbiddeness of the beta transition to the higher 2+state was indicated by M. Sakai[25]. The transition terminating to the 2.23 Mev level of Ru^{102} is considered to be the allowed transition since the log ft value is 5.5.

The spin and parity of the first excited state of Ru^{102}, 2+, was confirmed by the $K/L+M$ ratio of the internal conversion spectrum and the angular correlation function. This state was also studied with Coulomb excitation by Temmer and Hydenberg[17] and by Stelson and McGowan[18]. The half-life of this state was estimeted to be about 2×10^{-11} sec by Coulomb excitation. This half-life value is shorter by 50 than that for a single-particle transition. The collective nature of this state is evident.

The spin of the second level of Ru^{102} was determined to be 2+ by the correlation function for the 0.63–0.476 Mev cascade; the positive parity was already determined by the ft value. The $E2$–$M1$ mixing ratio of the transition between the 1.105 and the 0.476 Mev states was determined to be $\delta=5.5^{+0.7}_{-0.5}$. This value of δ can be compared with those for Ru^{100} and Pd^{106}; δ for Ru^{100} [26] was reported to be $-3.1^{+1.6}_{-2.2}$ and δ for Pd^{106} was to be +30[27]. The $E2$–$M1$ mixing ratios of the transitions between the second 2+ and the first 2+ levels for several even nuclei have been discussed by M. Sakai[28] and S. S. Malik et al.[29] The branching ratio of the cascade to the crossover gamma rays from the second 2+ level is found to be about 5 from the intensity ratio of the 0.63 Mev gamma ray to the 1.106 Mev gamma ray in coincidence with the 0.76 Mev gamma ray and is to be about 3.4 from the same ratio in coincidence with the 1.13 Mev gamma ray; the angular correlation effects have been corrected for. The average of the two values would be 4.2±0.8 if the same level is considered. The difference between these value, however, is just outside of the experimental error and may suggest the doublet of of the 1.106 Mev level which was anticipated by the vibrational model of Sharff-Goldhaber and Weneser[3]. The doublet of this state has also been suggested by McGowan and Stelson[19]. McGowan and Stelson[19] give the value of 1.5±0.3 for the ratio. The ratio $B(E2, 2'\rightarrow2)/B(E2, 2'\rightarrow0)$, which is the ratio of the reduced $E2$ transition probability between the second and the first 2+ level to that between the second 2+ level and the ground state is determined to be (65±15). The theoretical value of this ratio calculated by the formula of Davydov and Filippov[30] is 30. The $E2$ transitions from the second 2+ levels of even-even nuclei was summarized by Van Patter[31]. The second 2+ state of Ru^{102} was also studied with Coulomb excitation by Stelson and McGowan[32].

The spin of the third excited state of Ru^{102} can be determined by the angular correlation function for the 1.05–0.476 Mev cascade and by the intensity ratios of the gamma rays originating from this state. The correlation function suggest 3, 1 or 2 for the spin of this state. The relative intensity of the transition between the 1.53 Mev and the ground state of Ru^{102} was found to be <0.1; the gamma ray of 1.57 Mev is probably different from the 1.55 Mev transition. On the other hand, the relative intensities of the transitions from the 1.53 Mev state to the 1.106 Mev state (2+) and to the 0.476 Mev state (2+) are found to be 4 and 11, respectively. Therefore, the spin assignment of 1 and 2 is excluded for the 1.53 Mev state. Thus the spin assignment of the 1.53 Mev state is concluded to be 3. This spin assignment is in agreement with that of McGowan and Stelson[19]. It is noted that Davydov and Filippov[30] suggest the first 3+ level at 1.58 Mev.

The 1.85 Mev state of Ru^{102} is found by the coincidences between the 0.476 and the 1.37 Mev gamma rays. This state is probably different from the 1.87 Mev state, which is given by the 0.76–0.63–0.476 Mev cascade transition. A weak transition of about (1.83 ± 0.04) Mev was also found in the single gamma ray spectrum, as is shown in Fig. 6b. It is not certain whether the transition may be associated with the 1.85 Mev state or with the 1.87 Mev state. The spin assignment of the 1.87 Mev state is 1, 2 or 3 from the correlation function for the 0.76–0.63 Mev cascade. It is noted that McGowan and Stelson[19] assigned 0+ for the 1.84 Mev level of Ru^{102}.

The 2.06 Mev gamma ray, which was found in the single gamma ray spectrum (Fig. 6b) indicates the 2.06 Mev level of Ru^{102}. It is noted that a faint peak at about 1.6 Mev was found in the gamma ray spectrum in coincidence with the 0.476 Mev. It also confirms the existence of the 2.04 Mev state. McGowan and Stelson[19] also reported the existence of the 2.04 Mev level. Their spin assignment for this state is 2.

No transition which might be associated with Pd^{102} was found either in the single and coincidence gamma ray spectra or in the internal conversion spectrum although the systematics of the first excited states of even-even nuclei expects the first 2+ state of Pd^{102} between 0.65 and 0.7 Mev[33]. Recently beta-gamma coincidences in Rh^{102} have been studied by the author[34]. The preliminary result suggests new transition of 0.67 Mev in coincidence with that beta group, the end-point energy of which is about 0.47 Mev. Since the end-point energy of the main negatron group is 1.15 Mev and the annihilation radiation is in coincidence with no other than the other than the 0.476 Mev gamma ray, the new gamma ray is probably the transition between the first excited and the ground state of Pd^{102}. The gamma ray of 0.68 Mev was also found in the decay of Ag^{102} by Y. Hashimoto et al. University of Tokyo[35].

The spin and parity of the ground state of Rh^{102} is discussed. Since the ground states of Ru^{102} and Pd^{102} are 0+ and the first excited state of Ru^{102} is 2+, the spin and the parity of the ground state of Rh^{102} is considered to be 1− or 2− from the selection rule of the first forbidden beta transition. If the spin and the parity of Rh^{102} were 2−, both the high energy component of the positron spectrum (β_2^+) and the negatron spectrum would show the unique first forbidden spetrum shape. The fact that the experimental spectra approximately show the allowed shape makes the assignment of 1− favourable. The assignment of 1−, however, is against the Nordheims strong rule[36,37] and the spin assignment of the 2.23 Mev level of Ru^{102}. The log ft value of 5.5 is given for the transition terminating the 2.23 Mev level of Ru^{102}, which is already assigned to be 3−. It is inconsistent with the assignment of 1− for Rh^{102} from the selection rule of the allowed beta decay; 2− is more favourable from this point. No consistent assignment for Rh^{102} is not given so far. This may be indication of the existence of a very low energy isomer in Rh^{102}, which is inferred by McGowan and Stelson[19].

Added in Proof

After submitting this paper, the author received a preprint of work by F. K. McGowan and P. H. Stelson (submitted to Phys. Rev.)

Their results are in general agreement with the present one except for one point, although they did not measure any beta-spectra. The only different point is the angular correlation function of the 0.63–0.476 Mev cascade. It is found that the experimental point at 180° of the author is 7% higher than the least square fit for the coincidences of the five angles; the statistical error at 180° is ±1.4%. The coincidences at 180° is considered to be too high probably due to some indirect effect of the annihilation radiation. If one omits the experimental point at 180°, the new least square fit corrected for the finite angular resolution would be

$$W_{0.63-0.476}(\theta)=1+(0.016\pm0.013)P_2(\cos\theta)+(0.158\pm0.021)P_4(\cos\theta)\ .$$

The final correlation function would be

$$W_{0.63-0.476}(\theta)=1+(0.031\pm0.16)P_2(\cos\theta)+(0.179\pm0.025)P_4(\cos\theta)\ ,$$

which is almost in agreement with that of McGowan and Stelson. Thus the consistent δ-value for the 0.630 Mev transition cannot be obtained unless one assumes a 2+ and 4+ doublet at 1.106 Mev, as was done by McGowan and Stelson. On the other hand, no doublet of the 0.630 Mev transition was found in the internal conversion spectrum within the resolution of the spectrometer, say, 1%. Further study will be necessary for this transition.

Acknowledgment

The author wishes to express his sincere thanks to Dr. J. D. Kurbatov for his suggesting this research; Mr. H. Shimojima and Mr. H. Nagao for their chemical separation; Mr. N. Ono, Mr. M. Koike, Mr. Y. Tokita and Mr. H. Arai for their assistance in taking and analyzing experimental data. The author is also thankful to the cycltron crew and the beta group of the institute for Nuclear Study, University of Tokyo, for their kind cooperation.

Ferromagnetic Crystalline Anisotropy of $MeFe_2O_4$-Fe_3O_4 Ferrite Solid Solutions

By Nahonori MIYATA

Department of Physics, Yokohama National University, Yokohama

(Received October 20, 1960)

The ferrite crystals of ternary system $(Mn_xFe_yNi_z)Fe_2O_4$, where $x+y+z=1$, were grown by the Bridgman method in the air. According to the X-ray analysis, they have the spinel structure, except in the region near $NiFe_2O_4$, and their lattice constants depend linearly on the concentration: $a=(8.518-0.125y-0.176z)\pm0.005$ A. The ferromagnetic crystalline anisotropy was measured by the torque method in the temperature range between 90°K and 300°K. In normal specimens K_1 decreases with decreasing temperature. $NiFe_2O_4-Fe_3O_4$ system shows an anomalous temperature dependence for a wide range of concentration: K_1 increases and changes its sign from negative to positive at low temperature. This will be due to the short range order of Fe^{2+} and Fe^{3+} at the octahedral site of the spinel lattice. If such an anomaly is subtracted, K_1 of the ternary system becomes maximum at a certain Fe_3O_4 concentration. This can be attributable to the special contribution of Fe^{2+}-ion.

The crystals of $(Zn_{1-y}Fe_y)Fe_2O_4$ binary system were also investigated. They have the spinel structure with the lattice constant of $a=(8.445-0.052y)\pm0.005$ A. The relation of the anisotropy constant to y also indicates the contribution of Fe^{2+} mentioned above.

§1. Introduction

The interesting characteristics of the dependence of the ferromagnetic crystalline anisotropy of the $MnFe_2O_4$-Fe_3O_4 system on the composition were reported previously by the author and his colaborator[1] and by Penoyer and Shafer.[2] Our knowledge seemed to be insufficient for understanding the mechanism of these phenomena. The study has been extended to the $MnFe_2O_4$-Fe_3O_4-$NiFe_2O_4$ ternary system and $ZnFe_2O_4$-Fe_3O_4 binary one. Ni and Zn were chosen for the third and fourth elements on account of the expectation of their stability of the ionic state (Ni^{2+} and Zn^{2+}) and that of the preference for the lattice site (B- and A-site, respectively) in the spinel type structure. On account of the lack of the phase diagram of these ferrite solid solutions, the method of preparation of the crystals was first investigated. After that, the ferromagnetic crystalline anisotropy of the crystals was measured by the torque method in the temperature range between 90°K and 300°K. Interesting features were observed and discussed from the view point of the theory developed recently.

§2. Crystal Growth and Chemical Analysis

Single crystals were grown by the same method as reported in the previous paper.[1] Fe_2O_3, $MnCO_3$, NiO, ZnO and MgO were used for the raw materials. The ferrite powder, made by the usual ceramic technique, was melted and crystallized by the Bridgman method in the Pt-crucible in the air atmosphere with the speed of 2.8 cm/hr (0.8°C/min). After the cooling at the rates of about 2°C/min (1600~1300°C), 5°C/min (1300~1000°C) and 10°C/min (1000~600°C), the crystal was taken out from the furnace.

Main metallic elements were chemically analysed for all specimen used in the experiment. Larger segregation was observed in $ZnFe_2O_4$-Fe_3O_4 system than in $MnFe_2O_4$-Fe_3O_4-$NiFe_2O_4$ ternary one, as shown in Table I. The analysis could not determine the excess or deficiency of oxygen compared with the stoichiometric composition more accurately than ±5% of the oxygen content. But the measurement of the electric conductivity,[3] which was considered to indicate the number of Fe^{2+}-ions, suggested the realization of the nearly stoichiometry of the oxygen content.

Table I. Examples of chemical analysis. It indicates segregation of crystals.

(a) $MnFe_2O_4$-Fe_3O_4-$NiFe_2O_4$ system

Approximate expression	Element	Position	
		Top	Bottom
$Ni_{0.2}Fe_{2.8}O_4$	Ni Fe	0.21 2.79	0.18 2.82
$Ni_{0.5}Fe_{2.5}O_4$	Ni Fe	0.52 2.48	0.50 2.50
$Mn_{0.4}Fe_{2.6}O_4$	Mn Fe	0.38 2.62	0.37 2.63
$Mn_{0.4}Ni_{0.2}Fe_{2.4}O_4$	Mn Ni Fe	0.41 0.19 2.40	0.42 0.19 2.39

(b) $ZnFe_2O_4$-Fe_3O_4 system

Approximate expression	Element	Position	
		Top	Bottom
$Zn_{0.15}Fe_{2.85}O_4$	Zn Fe	0.12 2.88	0.16 2.84
$Zn_{0.25}Fe_{2.75}O_4$	Zn Fe	0.24 2.76	0.30 2.70
$Zn_{0.45}Fe_{2.55}O_4$	Zn Fe	0.45 2.55	0.48 2.52
$Zn_{0.6}Fe_{2.4}O_4$	Zn Fe	0.56 2.44	0.61 2.39
$Zn_{0.85}Fe_{2.15}O_4$	Zn Fe	0.81 2.19	0.86 2.14

Co-impurity in the specimen was 0.01% or less. Specimens used in the experiment were cut from the bottom of the crystals, because the top was crystallographically less perfect and might be oxidized during the cooling after the crystal growth. The compositions of $(Mn_xFe_yNi_z)Fe_2O_4$ ternary ferrite specimens are shown in Fig. 1 and those of $(Zn_{1-y}Fe_y)Fe_2O_4$ binary system are $y=0.84$, 0.70, 0.52 and 0.39. $(Mg_{1-y}Fe_y)Fe_2O_4$ system was tried, too. But it succeeded only in the case of $y=0.87$, on account of the relatively high melting point of Mg-rich specimens.

§ 3. Crystallographic Investigation

(1) $(Mn_xFe_yNi_z)Fe_2O_4$

The crystal structure and the lattice con-

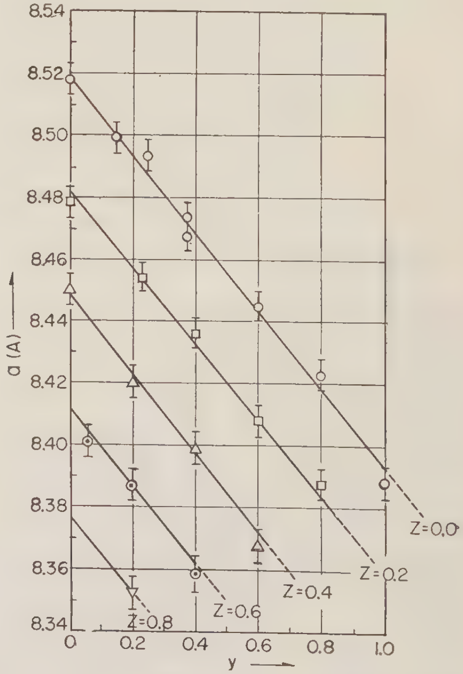

Fig. 2(a). Lattice constants of $(Mn_xFe_yNi_z)Fe_2O_4$ solid solution. (the lattice constant of NaCl, 5.640 A, is chosen as the standard). Lines show $a=(8.518-0.125y-0.176z)$A, in which z is taken as a parameter.

stant were investigated at room temperature by X-ray analysis. Except in the region near Ni-ferrite (shown as × in Fig. 1), where the spinel phase exists together with another phase, all specimens (○ in Fig. 1) have the spinel structure and their lattice constants depend linearly on the composition: the lattice constant of a specimen, the composition of which is expressed as $(Mn_xFe_yNi_z)Fe_2O_4$, where $x+y+z=1$, is approximately shown as

$$a=(8.518-0.125y-0.176z)\pm0.005\text{ A.} \quad (1)$$

Here the lattice constant of NaCl, 5.640A, is chosen as the standard.[4] The comparison between experimental results and the equation (1) is shown in Fig. 2(a).

(2) *$(Zn_{1-y}Fe_y)Fe_2O_4$*

All specimens investigated have also the spinel type structure and their lattice constants are $a=(8.445-0.052y)\pm0.005$A (Fig. 2(b)).

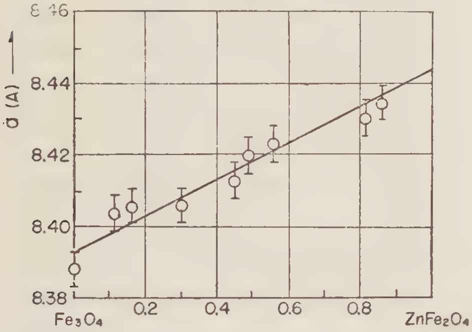

Fig. 2(b). Lattice constants of $ZnFe_2O_4$-Fe_3O_4 system.

§ 4. Experiments on the Ferromagnetic Crystalline Anisotropy

(1) *Method*

Usually the ferromagnetic crystalline anisotropy energy with cubic symmetry is expressed as $E=K_1(\alpha_1^2\alpha_2^2+\alpha_2^2\alpha_3^2+\alpha_3^2\alpha_1^2)+K_2\alpha_1^2\alpha_2^2\alpha_3^2$, where $(\alpha_1, \alpha_2, \alpha_3)$ is the direction cosine of the magnetization. The constants, K_1 and K_2, were measured in the temperature range between 90°K and 300°K by observing the torque exerted on the spherical specimen (about 1 mm in diameter) set in the uniform magnetic field. Specimens were set by the X-ray method so as to rotate about [110]- or [100]-axis within the accuracy of ±1°. The magnetic field was 3500～10500 Oe.

At room temperature the observed torque curve agreed to the curve calculated with K_1-term only, except in the case of small K_1. K_2-term had to be taken into account to explain the torque curve of some specimens at low temperatures.

(2) *Results*

(a) *$(Mn_xFe_yNi_z)Fe_2O_4$*

The dependency of K_1 on the temperature of each specimen and on the concentration of three binary systems, $MnFe_2O_4$-Fe_3O_4,

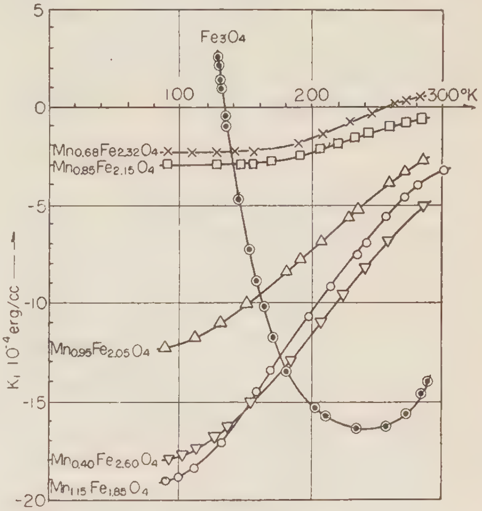

Fig. 3(a). Temperature dependency of K_1 of $MnFe_2O_4$-Fe_3O_4 system.

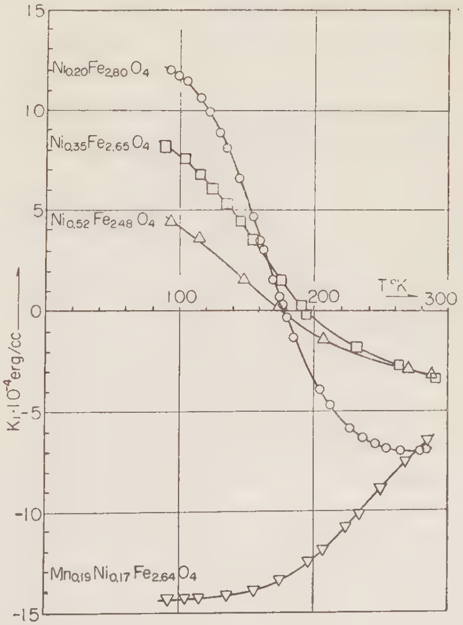

Fig. 3(b). Temperature dependency of K_1 of $NiFe_2O_4$-Fe_3O_4 system, and effect of small Mn addition (▽).

$NiFe_2O_4$-Fe_3O_4 and $MnFe_2O_4$-$NiFe_2O_4$, are shown in Fig. 3(a), (b), (c) and Fig. 4(a), (b), (c). K_1 at 290°K and K_1 and K_2 at 90°K are tabulated in Table II.

In most specimens, except $NiFe_2O_4$-Fe_3O_4 system, K_1 decreases with decreasing temperature. The special character of $NiFe_2O_4$-Fe_3O_4 system, in which K_1 increases with decreasing temperature and goes from negative to positive, will be discussed in § 5. The addition of $MnFe_2O_4$ makes this phenomenon disappear as seen in Fig. 3(b). The application of magnetic field during cooling of the specimens shows no effect on this anomaly.

Penoyer and Shafer's data²⁾ on $MnFe_2O_4$-Fe_3O_4 system accord with ours. It is noticed that K_1 of $Mn_{0.68}Fe_{2.32}O_4$ is positive at room temperature and becomes negative at low temperature. The systematic study on other

ferrite solid solutions has not been presented. Bozorth *et al*[5] reported on $Ni_{0.8}Fe_{2.2}O_4$ that the anisotropy measured by the torque method was nearly the same at room temperature and at 77°K. This is consistent with the character of $NiFe_2O_4$-Fe_3O_4 system mentioned here.

The observed concentration dependency of the anisotropy will be discussed in § 5.

The temperature and concentration dependency of K_1 of $(Zn_{1-y}Fe_y)Fe_2O_4$ system are given in Fig. 5 and 6, respectively. Except the case of $y=0.84$, where the increase of

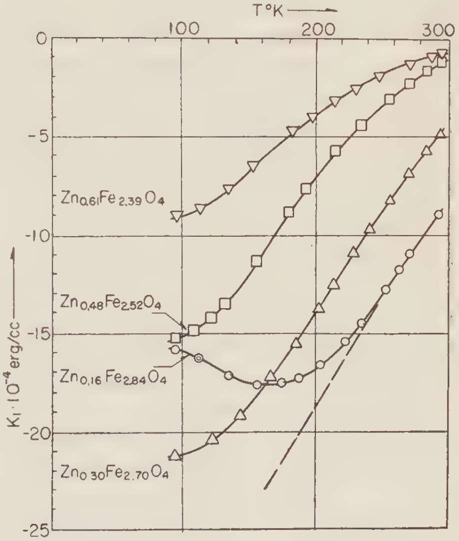

Fig. 5. Temperature dependency of K_1 of $ZnFe_2O_4$-Fe_3O_4 system.

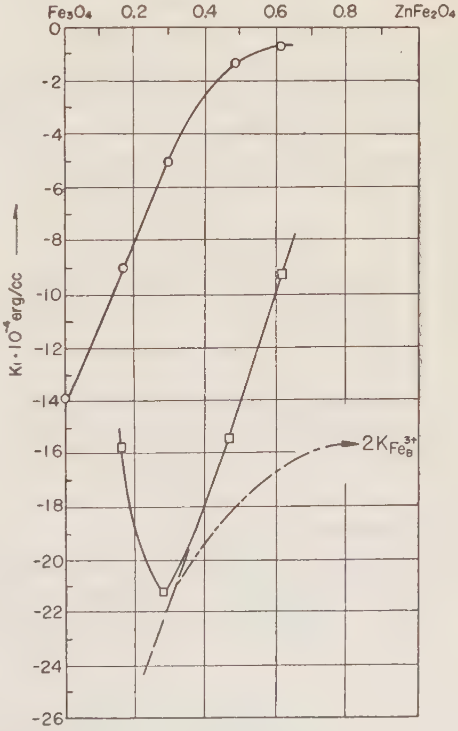

Fig. 6. Concentration dependency of K_1 of $ZnFe_2O_4$-Fe_3O_4 system. ○: 290°K, □: 90°K.

K_1 at low temperatures may be attributed to the short range order of Fe^{2+} and Fe^{3+} (§ 5), all specimens show the normal temperature dependency. If the effect of short range order is neglected (shown as the dashed curve in the figures), $|K_1|$ at a fixed temperature decreases with the decrease of Fe_3O_4 concentration. The cause of this tendency is naturally understood as a result of the breaking of the simple Néel model with increasing of $ZnFe_2O_4$ concentration. $ZnFe_2O_4$ is not ferromagnetic, so that it has no ferromagnetic anisotropy.

(c) *$Mg_{0.13}Fe_{2.87}O_4$*

The temperature dependency of K_1 of $Mg_{0.13}Fe_{2.87}O_4$ is shown in Fig. 7. This specimen is taken out from the furnace at about 1400°C and cooled rapidly in the air. As is shown, K_1 increases and becomes positive at low temperatures. Folen and Rado[6] reported that K_1 *vs.* temperature curve of $Mg_{0.5}Fe_{2.5}O_4$ showed a minimum at 180°K. From these results we conclude that $MgFe_2O_4$-Fe_3O_4 system shows a similar (but smaller) dependence of $K_1(T)$ on the concentration compared with $NiFe_2O_4$-Fe_3O_4 system.

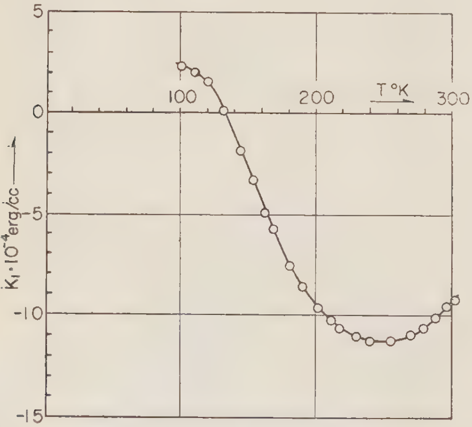

Fig. 7. Temperature dependency of K_1 of $Mg_{0.13}Fe_{2.87}O_4$.

§ 5. Discussions on Anisotropy

It is well known that the one-ion model has been proved successful in the theory of the ferromagnetic crystalline anisotropy of ferrites.[7]

(1) First, *the temperature dependency of K_1 of $NiFe_2O_4$-Fe_3O_4 system* is explained. It is shown by the chemical analysis that the phenemenon is not due to the Co-impurity and can be regarded as the real nature of this system. Ni^{2+}-ions at A-site can contribute to the large positive K_1 like Co^{2+}-ions at B-site, but the magnetization at 0°K is contrary to such a kind of ion distribution.

The abrupt change of the anisotropy of Fe_3O_4, observed at the temperature region just above the transition (about 120°K), is attributed to the electronic short range order of Fe^{2+} and Fe^{3+} on the B-site of the spinel lattice[8]. This character is known to remain as well when the small amount of other ferrite is added to magnetite. $Zn_{0.16}Fe_{2.84}O_4$ in Fig. 5 is an example. The characteristic temperature dependency of K_1 of $NiFe_2O_4$-Fe_3O_4 may also have the same origin. It is reasonably understood from this view point that this character is more remarkable in Fe_3O_4 side than $NiFe_2O_4$ side in this system. Similar character of $MgFe_2O_4$-Fe_3O_4 system, which is stated in § 4(2)(c), can be attributed to the same origin. In order to explain the experimental results (the effect of addition of $MnFe_2O_4$, Fig. 3(b)) completely, it is necessary to assume further that Mn-ion suppresses the growth of the short range order.

In the case of $ZnFe_2O_4$-Fe_3O_4 there are only Fe^{2+} and Fe^{3+} on B-site, since Zn^{2+}-ion is believed to occupy A-site. The ionic distribution of magnetite side of $MnFe_2O_4$-Fe_3O_4 system is, probably, similar to this case. On the contrary, in the case of $NiFe_2O_4$-Fe_3O_4 or $MgFe_2O_4$-Fe_3O_4, there are foreign ions, Ni^{2+} or Mg^{2+}, on B-site. The abnormal character of $K_1(T)$ mentioned here is smallest in $ZnFe_2O_4$-Fe_3O_4 or $MnFe_2O_4$-Fe_3O_4 systems. That is, the short range order of Fe^{2+} and Fe^{3+} is favourable in the circumstances of the presence of foreign ions, Ni^{2+} or Mg^{2+}, on B-site compared with that of Zn^{2+} or Mn^{2+} on A-site. This tendency is consistent with the experimental result obtained by Epstein,[9] in which he reported that the change of the electric conduction during the low temperature transition of magnetite become obscure more rapidly by the addition of $ZnFe_2O_4$ or $MnFe_2O_4$ than by $NiFe_2O_4$ or $CoFe_2O_4$.

(2) *General concentration dependency of the anisotropy of $MeFe_2O_4$-Fe_3O_4 system*

(a) If we substruct from the observed anisotropy the large positive contribution of electronic short range order at low temperature described in (1), the qualitative relation of K_1 *vs.* composition of $NiFe_2O_4$-Fe_3O_4 system may be represented by that at room temperature in Fig. 4(b). It is remarked that the Curie temperature is nearly the same for this system. In such a situation $NiFe_2O_4$-Fe_3O_4 system has qualitatively a common feature as $MnFe_2O_4$-Fe_3O_4 system, which is also the feature of the ternary system $(Mn_xFe_yNi_z)$-Fe_2O_4: with the increase of Fe_3O_4 concentration, K_1 first increases and after passing a maximum it tends to decrease.

(b) In the case of $(Zn_{1-y}Fe_y)Fe_2O_4$, although the break of the simple Néel model should be taken into account, it is well known from the measurement of the magnetization that this model is still correct in the range of $y \gtrsim 0.7$. If the simple Néel model is imagined to hold over the whole range, the anisotropy of *ferromagnetic* $ZnFe_2O_4$ will be $2K_{\mathrm{Fe}^{3+}_{\mathrm{B}}}$, twice of the contribution to the anisotropy of Fe^{3+} on the B-site, compared with the anisotropy of $NiFe_2O_4$, which is given by $K_{\mathrm{Fe}^{3+}_{\mathrm{A}}}+K_{\mathrm{Fe}^{3+}_{\mathrm{B}}}$ (it is concluded theoretically that the contribution of Ni^{2+} on the anisotropy is very small[7]). According to Folen and Rado[6], $K_{\mathrm{Fe}^{3+}_{\mathrm{A}}}>0$ and $K_{\mathrm{Fe}^{3+}_{\mathrm{B}}}<0$. As K_1 of $NiFe_2O_4$ at 90°K is about -9×10^4 erg/cc, the anisotropy of *ferromagnetic* $ZnFe_2O_4$ is estimated as follows:

$$\begin{aligned} K_{\mathrm{ZnFe_2O_4}} &= 2K_{\mathrm{Fe}^{3+}_{\mathrm{B}}} < 2(K_{\mathrm{Fe}^{3+}_{\mathrm{A}}}+K_{\mathrm{Fe}^{3+}_{\mathrm{B}}}) \\ &= 2K_{\mathrm{NiFe_2O_4}} = -18\times10^4 \ \mathrm{erg/cc}. \end{aligned}$$

The chained curve in Fig. 6 indicates the qualitative dependence of the anisotropy on the concentration at 90°K on the assumption of *ferromagnetic* $ZnFe_2O_4$ mentioned above. It shows a maximum like the case of (a).

(c) According to the simplest assumption that each cation at a given lattice site has the specified anisotropy independent of the presence of the other kind of cation and the substitution of metallic ions are made monotonously on each site, it is expected that K_1 depends linearly on the composition. However, contrary to such an expectation, non-linear dependence of K_1 on the concentration of Fe_3O_4 is a general character of the anisotropy of $MeFe_2O_4$-Fe_3O_4 solid solutions as mentioned above. It is suggested[10] that it can be ascribed to a special character of Fe^{2+}-ion in a crystalline field, giving rise to either positive anisotropy or negative one.

(3) *$MnFe_2O_4$-$NiFe_2O_4$ system*

$MnFe_2O_4$ has 80% normal spinel structure as shown by the neutron diffraction experiment. But, for $MnFe_2O_4$-$NiFe_2O_4$ system, there is no data on the ionic distribution. We can see in Fig. 4(c) that the concentration dependency of the anisotropy is monotonic, in contrast to that of ferrite system containing Fe^{2+} ions.

§6. Conclusions

By the analysis of the experimental results on the ferromagnetic crystalline anisotropy of $(MeFe_2O_4)_{1-y}-(Fe_3O_4)_y$ ferrite solid solutions, where Me=Mn, Ni, Mn-Ni, Zn or Mg, two problems are pointed out:

(1) In most cases, the anisotropy constant decreases (increase of the absolute value of negative anisotropy) with decrease of temperature. But, for Fe_3O_4-rich specimens it increases after passing a minimum and this tendency is remarkable in the case of Me=Ni, less remarkable in Me=Mg and least in Me =Mn, Mn-Ni or Zn. This increase of the anisotropy at low temperature is mainly attributed to the electronic short range order of Fe^{2+} and Fe^{3+} on the B-site of the spinel lattice.

(2) If the increase of K_1 at low temperatures mentioned in (1) is substructed, the concentration dependency of the anisotropy shows a maximum and is attributed to the special character of the contribution of Fe^{2+}-ion to the anisotropy.

Acknowledgment

The author wishes to express his hearty thanks to Prof. Z. Funatogawa for his encouragement throughout this work. He is indebted to Mr. T. Karasawa and other members of Tokyo Denki Kagaku Kogyo Co. and Dr. K. Inoue of Nippon Discharge Machining Laboratories, Inc.. Thanks are also due to Dr. M. Tachiki of Osaka University and to Mr. Y. Gondo and Mr. S. Usami in our laboratory for their valuable discussions. This work is partly supported by the Scientific Research Expenditure of the Ministry of Education.

Polarization Waves in Solids

By Tatsumi KUROSAWA*

The Institute for Solid State Physics,
University of Tokyo, Tokyo, Japan

(Received January 30, 1961)

A general theory of the polarization waves in crystals is developed in connection with the optical and the dielectric properties of the crystals. The result includes, in more general form, the relations by Szigeti and Fröhlich about the lattice vibrations in ionic crystals and the theory by Heller and Marcus for the exciton. The theory is applied to the analysis of the infra-red data of $BaTiO_3$-type crystals.

§ 1. Introduction

Polarization waves in solids are concerned with a wide range of phenomena in solid state physics. The transverse modes of the polarization waves interact with light and determine the optical properties of the solids. The longitudinal modes interact with the electric field caused by charged particles are interchange the energy with them. The polarization waves are also responsible for the dielectric properties of the solids. Thus, it is expected that there may be relations between these phenomena, for they come from the same origin, the polarization waves. In fact, several authors, for instance, Szigeti[1], Fröhlich[2),3)] and Mott[4], derived several important relations between them.

In this paper, the polarization waves in solids are treated from the above-mentioned standpoint. Several phenomenological relations unknown previously are derived, and some known facts are interpreted from a viewpoint different from that used hitherto.

In § 2, a general theory of the lattice waves in ionic crystals is developed; the results include the relations derived by Szigeti and Fröhlich, in more general form. In § 3, the theory of § 2 is applied to alkali halide and $BaTiO_3$-type crystals. In the latter cases, the result from the simple ionic model is found to be in large disagreement with the experiment, and a tentative interpretation based upon the ionic model is done in Appendix. In § 4, several problems with respect to the electronic polarization waves are treated similarly as in § 2; for instance, the well-known theory of the exciton by Heller and Marcus is re-interpreted from a different viewpoint.

§ 2. Theory of Lattice Waves in Ionic Crystals

A theory of the lattice vibrations in simple ionic crystals has been developed by Szigeti[1]. We shall extend the theory to more complicated crystals, e.g. perovskite type crystals.

Let the number of atoms (ions) in a unit cell be n, and we enumerate them $1, 2, \cdots, n$. In the first place, we take up a needle-like sample of the crystal. Let us imagine that the ions displace in the direction of the needle. Let the displacements of the ions $1, 2, \cdots, n$ be $x_1, x_2, \cdots, x_n$ respectively. The polarization is induced as the result. If the displacements are small the induced polarization must be represented by a linear function of them[†];

---

* Present address: Faculty of Engineering, Chuo University, 1-1 Koishikawa-cho, Bunkyo-ku, Tokyo.

$$P=N\sum_i e_i^* x_i , \tag{2-1}$$

where N is the number of the unit cells in unit volume. Of course

$$\sum_i e_i^*=0 . \tag{2-2}$$

Generally speaking, e_i^*'s are tensor and the direction of the polarization does not necessarily agree with that of the displacement. However, such a generalization is rather trivial and useless. Hence we assume that e_i^*'s are scalar and the direction of the polarization agrees with that of the needle. Thus, there is no electric field in the crystal.

In the next place, let us consider the case that there exists an electric field E in the crystal. If the ions are held undisplaced at their original positions, the polarization is given by

$$P_0=\frac{1}{4\pi}(\kappa_0-1)E , \tag{2-3}$$

where κ_0 is the high frequency dielectric constant. If the ions displace[††], the polarization is given by

$$P=\frac{1}{4\pi}(\kappa_0-1)E+N\sum_i e_i^* x_i , \tag{2-4}$$

because there is no cross term. This equation does not depend on the shape of the sample; the effect of the shape is represented by the depolarization field and included in E. The first term is purely electronic and the second term is due to the displacements of the ions.

The static dielectric constant κ is determined as follows: We write the energy increment per unit volume due to the displacements $x_1, x_2, \cdots, x_n$ $(E=0)$ as

$$\frac{1}{2}N\sum_{i,j} S_{ij}x_i x_j .$$

When the electric field E exists, the interaction energy between the electric field and the polarization should be added;

$$-(P-P_0)E=-EN\sum_i e_i^* x_i .$$

The equilibrium displacement x_i^0 under the electric field is determined by the condition of minimum energy. Thus x_i^0's are given by

$$\sum_j S_{ij}x_j^0=e_i^*E \qquad i=1, 2, \cdots, n . \tag{2-5}$$

Furthermore, if the electric field oscillates with a frequency ω

$$\sum_j S_{ij}x_j^0(\omega)-M_i\omega^2 x_i^0(\omega)=e_i^*E , \tag{2-6}$$

where M_i is the mass of the i-th ion. $\kappa(\omega)$ is given by

$$\kappa(\omega)=\kappa_0+(1/E)\cdot 4\pi N\sum_i e_i^* x_i^0(\omega) . \tag{2-7}$$

Next, we consider the polar mode lattice waves with sufficiently long wavelength; long compared with the lattice constant but short compared with the size of the sample. In this case, the following relations are well-known[2)]: for the transverse waves[†††]

$$E=0 , \tag{2-8}$$

and for the longitudinal waves

$$E=-4\pi P , \tag{2-9}$$

where P is the polarization due to the wave. Therefore, writing the displacement of the i-th ion as $x_i \exp(i\Omega_t t)$, we have the equation determining the frequency of the transverse waves;

$$\sum_j S_{ij}x_j-M_i\Omega_t^2 x_i=0 , \tag{2-10}$$

and of the longitudinal waves;

$$\sum_j S_{ij}x_j-M_i\Omega_l^2 x_i=-4\pi e_i^* P , \tag{2-11}$$

where

$$P=N\sum_i e_i^* x_i+\frac{1}{4\pi}(\kappa_0-1)(-4\pi P) ,$$

or

$$P=\frac{N}{\kappa_0}\sum_i e_i^* x_i . \tag{2-12}$$

Therefore, Eq. (2-11) is rewritten as

$$\sum_j S_{ij}x_j+\frac{4\pi N}{\kappa_0}e_i^*\sum_j e_j^* x_j-M_i\Omega_l^2 x_i=0 . \tag{2-13}$$

[†] The state of the polarization due to the displacement may be very complicated; the polarization due to the displacement of the i-th ion comes from not only the i-th ion but also the induced polarization on the other ions. If the displacements are small, however, the general form of the polarization is given by Eq. (2-1).

[††] We regard the displacements as variable irrespective of the electric field.

[†††] Here we restrict ourselves to such a case that the long polarization waves can be divided into the longitudinal and the transverse waves.

because the electric field $-4\pi P$ acts as a restoring force, the frequency of the longitudinal waves is generally higher than that of the transverse ones and the difference is proportional to e^{*2}.

We write the eigenfrequencies of Eq. (2-10) as $\Omega_{t1}, \Omega_{t2}, \cdots, \Omega_{tn-1}$ (we ignore another eigenfrequency $\Omega_t=0$ which corresponds to the acoustical mode) and the eigenvector belonging to $\Omega_{t\nu}$ as $x_{1\nu}, \cdots, x_{n\nu}$. The ortho-normal condition is

$$\sum_i M_i x_{i\nu} x_{i\nu'} = A\delta_{\nu\nu'} , \tag{2.14}$$

where A is a constant.

The n-dimensional vector $(x_1{}^0(\omega), \cdots, x_n{}^0(\omega))$ in Eq. (2-6) can be represented by a linear combination of the eigenvectors $(x_{1\nu}, \cdots, x_{n\nu})$'s;

$$x_i{}^0(\omega) = \sum_\nu a_\nu(\omega) x_{i\nu} \qquad \text{for all} \quad i .$$

Inserting this into Eq. (2-6), multiplying $x_{i\nu}$ and summing over i, we find that

$$a_\nu(\omega) = \frac{E}{A(\Omega_{t\nu}{}^2-\omega^2)} \sum_i e_i{}^* x_{i\nu} .$$

By remembering Eq. (2-7), we have the following dispersion relation:

$$\kappa(\omega) = \kappa_0 + 4\pi N \sum_\nu \frac{(\sum_i e_i{}^* x_{i\nu})^2}{\sum_i M_i x_{i\nu}{}^2} \cdot \frac{1}{\Omega_{t\nu}{}^2-\omega^2} . \tag{2-15}$$

If there are only two ions in a unit cell as alkali halide crystals, this is simplified as follows:

$$\kappa(\omega) = \kappa_0 + \frac{4\pi N e^{*2}}{\mu(\Omega_t{}^2-\omega^2)} , \tag{2-16}$$

where μ is the reduced mass of the two ions.

By substituting the expression

$$x_i = \sum_\nu b_\nu x_{i\nu} ,$$

for x_i of Eq. (2-13), we obtain

$$b_\nu = -\frac{4\pi N}{A(\Omega_{t\nu}{}^2-\Omega_l{}^2)\kappa_0} \sum_j e_j{}^* x_j \sum_i e_{i'}{}^* x_{i'\nu} .$$

By multiplying $e_i{}^* x_{i\nu}$ and summing over i and ν, we have the equation giving Ω_l;

$$\frac{4\pi N}{\kappa_0} \sum_\nu \frac{(\sum_i e_i{}^* x_{i\nu})^2}{\sum_i M_i x_{i\nu}{}^2} \cdot \frac{1}{\Omega_{t\nu}{}^2-\Omega_l{}^2} = -1 . \tag{2-17}$$

Comparing (2-17) with (2-15), we see that

$$\kappa(\Omega_l) = 0 . \tag{2-18}$$

This relation can be derived directly from Eq. (2-9) which states that $D=0$[3]. In general, Eq. (2-17) has $n-1$ roots. We write them as $\Omega_{l1}, \cdots, \Omega_{ln-1}$. It is easily found from Eq. (2-17) that

$$\Omega_{t1} \leq \Omega_{l1} \leq \Omega_{t2} \leq \cdots \leq \Omega_{tn-1} \leq \Omega_{ln-1} . \tag{2-19}$$

The equality happens when Ω_t's degenerate.

Let us note that $\kappa(\omega)$ has the following properties: (1) $\kappa(\omega)$ has the poles at $\Omega_{t1}, \cdots, \Omega_{tn-1}$. (2) $\kappa(\omega)$ has the zeros at $\Omega_{l1}, \cdots, \Omega_{ln-1}$. (3) $\kappa(\omega)$ tends to κ_0 for large ω. Therefore, if we take the summation of (2-15) over ν in the following form:

$$\kappa(\omega) = \frac{\sum_{k=0}^{n-1} c_k \omega^{2k}}{\Pi_\nu(\Omega_{t\nu}{}^2-\omega^2)} , \tag{2-20}$$

this must be factorized as follows:

$$\kappa(\omega) = \kappa_0 \prod_\nu \left(\frac{\Omega_{l\nu}{}^2-\omega^2}{\Omega_{t\nu}{}^2-\omega^2}\right) . \tag{2-21}$$

Especially, if we put $\omega=0$,

$$\frac{\kappa}{\kappa_0} = \prod_\nu \frac{\Omega_{l\nu}{}^2}{\Omega_{t\nu}{}^2} . \tag{2-22}$$

This is a generalization of the well-known similar relation in the diatomic case[1].

By comparing the coefficients of ω^{2n-4} of (2-20) and (2-21), we find a relation;

$$4\pi N \frac{\sum_\nu(\sum_i e_i{}^* x_{i\nu})^2}{A} = \kappa_0 \sum_\nu (\Omega_{l\nu}{}^2-\Omega_{t\nu}{}^2) . \tag{2-23}$$

On the other hand, the vector $(e_1{}^*, \cdots, e_n{}^*)$ can be expanded by the vectors $(M_1 x_{1\nu}, \cdots, M_n x_{n\nu})$'s;

$$e_i{}^* = \frac{1}{A} \sum_\nu (\sum_j e_j{}^* x_{j\nu}) M_i x_{i\nu} .$$

By multiplying this by $e_i{}^*/M_i$ and summing over i, we have

$$\sum_\nu (\sum_i e_i{}^* x_{i\nu})^2 = A \cdot \sum_i \frac{e_i{}^{*2}}{M_i} .$$

Thus, Eq. (2-23) becomes

$$4\pi N \sum_i \frac{e_i{}^{*2}}{M_i} = \kappa_0 \sum_\nu (\Omega_{l\nu}{}^2-\Omega_{t\nu}{}^2) . \tag{2-24}$$

Here, we shall comment on the relation between the present $e_i{}^*$ and the effective charge $e_s{}^*$ introduced by Szigeti[1]. We may define his effective charge by writing the polarization in a spherical sample of a diatomic crystal as $Ne_s{}^*x$ when the positive and the negative ions displace homogeneously with the relative displacement x. According to the present viewpoint, the polarization of the spherical sample is given by

$$P = \frac{1}{4\pi}(\kappa_0-1)\left(-\frac{4\pi}{3}P\right) + N\sum e_i{}^* x_i ,$$

from Eq. (2-4), because the depolarization field in the spherical sample is $(-4\pi P/3)$. Or,

$$P=\frac{3}{\kappa_0+2}N\sum e_i^* x_i\,. \tag{2-25}$$

In the diatomic case, writing $x_1-x_2=x$ and $e_1^*=-e_2^*=e^*$, we have

$$e_s^*=\frac{3}{\kappa_0+2}e^*\,, \tag{2-26}$$

and in general

$$e_{si}^*=\frac{3}{\kappa_0+2}e_i^*\,. \tag{2-27}$$

Combining Eqs. (2-16) and (2-26), we get the relation derived by Szigeti;

$$\kappa=\kappa_0+\left(\frac{\kappa_0+2}{3}\right)^2\cdot\frac{4\pi N e_s^{*2}}{\mu\Omega_t^2}\,. \tag{2-28}$$

Similarly, if we write the polarization due to the longitudinal wave as

$$P=N\sum_i e_{li}^* x_i\,,$$

we obtain

$$e_{li}^*=\frac{e_i^*}{\kappa_0}\,. \tag{2-29}$$

This agrees with the effective charge introduced by Callen[5] in the diatomic case.

In some cases, e_s^* is appropriate to discuss the microscopic properties of the polarization. On the other hand, the present e_i^*, which corresponds to the effective charge of the transverse wave, is more directly related to the optical and the dielectric properties of the crystal as seen from Eq. (2-15).

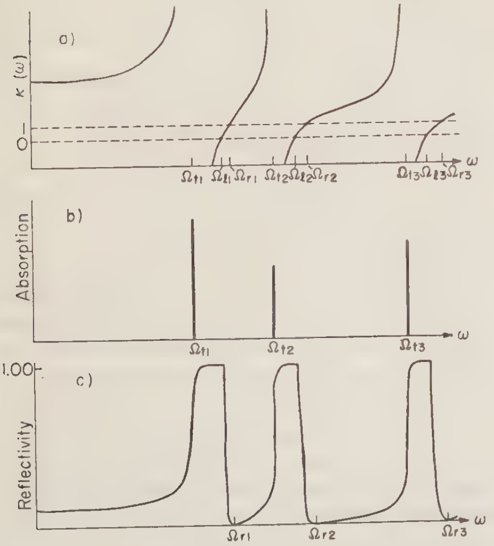

Fig. 1. General features of the dielectric constant, the optical absorption and the reflectivity of crystals.

According to Eq. (2-15), the general features of $\kappa(\omega)$ are schematically as Fig. 1a and the optical properties become as Fig. 1b and 1c; the absorption intensity has peaks at Ω_t's and the peak height is proportional to $(\sum e_i^* x_i)^2/\sum M_i x_i^2$, the crystal shows the metallic reflection when $\kappa(\omega)<0$ and the reflectivity is zero at Ω_r where $\kappa(\Omega_r)=1$.

§ 3. Application of the Theory

Alkali halide and other simple ionic crystals

For these crystals, the analysis by Szigeti[1] and Fröhlich[2] has been known, and we have little to be added to them. We tabulated the values of e^* and e_s^* in Table I for reference. As Szigeti has pointed out, e_s^*/e should be an integer if the simple ionic model were a good approximation†. We have shown that the deviation of e_s^*/e from an integer may be interpreted as brought by the short range

† Through the present paper, we mean by the term "simple ionic model" that the binding is perfectly ionic and the interaction between the polarizations can be expressed only by the Lorentz correction, and by "ionic model" we take into account the short range interaction energies between the polarizations especially the cross terms like $B_{ij}x_i p_j$, where p_j is the electronic polarization of the j-th ion.

interaction energy due to the interionic overlapping which causes cross terms between the ionic displacement and the electronic polarization, at least in the case of the alkali halide crystals[6].

In order to verify the theory of § 2, we compare in Table II the dielectric constant κ obtained experimentally and that calculated from the following relation:

$$\kappa-1=(\kappa_0-1)\frac{\Omega_r^2}{\Omega_t^2}\,,$$

and from the observed values of κ_0, Ω_t and Ω_r,[7]† where the above relation is a special case of the more general relation;

$$\kappa(\omega)-1=(\kappa_0-1)\prod_\nu \frac{\Omega_{r\nu}^2-\omega^2}{\Omega_{t\nu}^2-\omega^2}\,, \qquad (3\text{-}1)$$

this can be derived similarly as Eq. (2-21).

$BaTiO_3$ and the related crystals

We take up these crystals, because of the comparatively satisfactory experimental data about them as well as their peculiar dielectric properties.

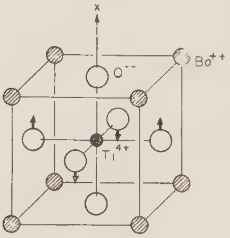

Fig. 2. The crystal structure of $BaTiO_3$ crystal.

These crystals have five ions in a unit cell and have fifteen independent modes of the lattice waves; three acoustical and twelve optical. However, three optical modes illustrated in Fig. 2 (two oxygen ions oscillate to the opposite direction with the same amount) have no dipole moment and are optically inactive. Thus, there remain three longitudinal modes and 3×2 transverse modes for sufficiently long waves. Last[8] has observed two absorption peaks (Ω_t) and two reflection minima†† (Ω_r) for $BaTiO_3$, $SrTiO_3$ and $PbTiO_3$ crystals. Furthermore, we can guess that the one more Ω_t may be nearly zero from their quite large κ. The one more Ω_r has not been observed. We tabulated them in Table III. If Ω_{r1} were observed, we could determine $(\sum_i e_i^*x_i)^2/\sum_i M_ix_i^2$'s of three modes using Eq. (2-15)†††. Furthermore, if a quite precise measurement using the isotopes were performed, it would be possible to determine the e_i^* of each ion separately. Although it is also possible to estimate the $(\sum e_i^*x_i)^2/\sum M_ix_i^2$ from the absorption intensity, practically the reliable determination is difficult.

Table III. (cm⁻¹).

	$SrTiO_3$	$BaTiO_3$	$PbTiO_3$
Ω_{t1}	~0	~0	~0
Ω_{r1}	?	?	?
Ω_{t2}	395	400	405
Ω_{r2}	490	475	455
Ω_{t3}	610	545	590
Ω_{r3}	890	800	(800)

Table IV. The values of $4\pi N\sum_i e_i^{*2}/M_i$ (10^6 cm⁻²).

	From the infra-red data	From the simple ionic model
$SrTiO_3$	2.26~2.96	17.4
$BaTiO_3$	1.95~2.71	10.6
$PbTiO_3$	2.02~3.00	12.3

Nevertheless, we can derive an inequality about the effective charges. In the same way as the derivation of Eq. (2-24), we have

$$4\pi N\sum_i \frac{e_i^{*2}}{M_i}=(\kappa_0-1)\sum_\nu(\Omega_{r\nu}^2-\Omega_{t\nu}^2)\,. \qquad (3\text{-}2)$$

On the other hand, clearly

$$\Omega_{t2}>\Omega_{r1}>\Omega_{t1}\simeq 0\,.$$

Thus we have the upper and lower limits of the $\sum e_i^{*2}/M_i$ (Table IV).

---

† We have used Ω_r, because it can be more easily determined than Ω_l from usually available experimental data.

†† The reflection is not perfectly zero because of the absorption tail at Ω_r.

††† In the case of $BaTiO_3$ crystal, it may help the understanding to imagine the following process: When the $BaTiO_3$ crystal is compressed the curie point T_c is lowered because of the increased interionic repulsive forces. If the compression is continued, the T_c will be lowered down to 0°K and the crystal will lose its ferroelectricity. We may expect, however, that rather a small contraction of the lattice constant (about 2~3%) and rather a small increase of the repulsive force is sufficient to remove the ferroelectricity on the one side and causes no appreciable change of the other properties; Ω_t, Ω_l, Ω_r and e_i^* on the other side.

For comparison, we calculate the $\sum e_i^{*2}/M_i$ assuming the simple ionic model, where e_i^*'s can be calculated by the following process:

$$e_i^* = Z_i e + \sum_j \varepsilon_{ji} \tag{3-3}$$

and

$$p_i = \sum_j \varepsilon_{ij} x_j \,, \tag{3-4}$$

where Z_i, x_i, p_i are the valency (e.g. $Z_{\mathrm{Ti}} = +4$), the displacement and the electronic polarization of the i-ion respectively. p_i is given by

$$p_i = \alpha_i F_i \tag{3-5}$$

and

$$F_i = N\{\sum_j L_{ij} p_j + \sum_j L_{ij} Z_j e(x_j - x_i)\}\,, \tag{3-6}$$

where α_i and F_i are the polarizability and the local field. The coefficients L_{ij}'s are given by many authors[9], for instance when $i = \mathrm{Ti}^{4+}$ and $j = \mathrm{O}_{\iota}^{--}$, $L_{ij} = 4\pi \times 2.727$. We calculated $\sum e_i^{*2}/M_i$'s (Table IV), by substituting for α_i the following values: 0.2 (Ti^{4+}), 1.6 (Sr^{++}), 2.5 (Ba^{++}), 3.1 (Pb^{++}) and 2.2×10^{-24} cm^3 (O^{--}).[†] The values of $\sum e_i^{*2}/M_i$ from the infra-red data are only 1/5~1/4 times of those from the simple ionic model, although the above polarizabilities are consistent with κ_0. On the other hand, in the case of alkali halide crystals, if we assume the simple ionic model as above and take the polarizabilities as consistent with κ_0, e^* is given by

$$e^* = \left(\frac{\kappa_0 + 2}{3}\right) e\,.$$

Thus the ratio of the infra-red value to the simple ionic model value of $\sum e_i^{*2}/M_i$ is $(e_s^*/e)^2$, that is about 0.5~0.9. In this case, we have interpreted the difference by the effect of the short range interaction energy between the ionic displacement and the electronic polarization of ions; the displacement works to induce the electronic polarization with the opposite direction through the overlapping between ions. However, the ratios 1/5~1/4 seem too small to be interpreted by the same effect.

The experiments about the spontaneous polarization of $\mathrm{BaTiO_3}$ are also consistent with the present analysis about the effective charge. The spontaneous polarization is given by

$$P_s = N \sum_i e_i^* x_i^s \,, \tag{3-7}$$

where x_i^s is the spontaneous displacement of the i-th ion and has been determined from the experiments of the neutron[11] or the x-ray diffraction[12]. Although e_i^* of each ion is not known, we have an inequality;

$$P_s^2 = (N \sum_i e_i^* x_i^s)^2 \leq N^2 \sum_i \frac{e_i^{*2}}{M_i} \sum_i M_i x_i^{s2} \,. \tag{3-8}$$

By substituting for x_i^s's the values from the neutron diffraction experiment, we have

$$P_s < 31 \text{ microcoulomb/cm}^2 \,.$$

The x_i^s's from the x-ray diffraction give nearly the same result. The direct experimental value of P_s by Merz[13] is 26 microcoulomb/cm^2. The spontaneous displacement x_i^s can be regarded as brought by the instabilized transverse vibration mode with the lowest frequency Ω_{t1} and as again stabilized by unharmonicity. Therefore, if the $(\sum e_i^* x_i)^2/\sum M_i x_i^2$ of the Ω_{t1} mode were known, the P_s could be estimated more precisely;

$$P_s^2 = N^2 \left[\frac{(\sum_i e_i^* x_i)^2}{\sum_i M_i x_i^2} \right]_{\Omega_{t1}\,\text{mode}} \times \sum M_i x_i^{s2} \,. \tag{3-9}$$

Nevertheless, the inequality (3-8) is consistent with the experiment.

There may be two possible standpoints in interpreting the difference between calculated (simple ionic model) values and the observed (infra-red) values of the effective charge; one attributes the disagreement to the homopolar-binding, and another interprets it within the range of the ionic model. Although it is not within the scope of the present analysis to discuss this problem, a trial upon the latter standpoint is done in Appendix.

It may be allowable to interpret a ferroelectric crystal as a crystal of which the polar mode lattice wave of $\vec{k}=0$ is unstable (in the first approximation) and an antiferroelectric crystal as a crystal of which a lattice wave of $\vec{k} \neq 0$ (e.g. at the zone boundary) is unstable, in the case of the ionic crystals. Generally speaking, the $\vec{k}$-dependence of the frequency of the polar mode lattice wave is rather small and has complicated properties, therefore the theoretical prediction whether a crystal is ferroelectric or antiferroelectric is a delicate problem.

[†] The values for Ti^{4+}, Sr^{++} and Ba^{++} are taken from the paper of Tessman, Kahn and Shockley[10], that of O^{--} ion is adjusted to give the optical dielectric constant κ_0 of $\mathrm{BaTiO_3}$ and $\mathrm{SrTiO_3}$ and that of Pb^{++} ion is taken to be consistent with κ_0 of $\mathrm{PbTiO_3}$.

§4. The Electronic Polarization Waves

It is possible to apply the viewpoints in §2 to the case of the electronic polarization waves in some degree.

Notes on the theory of Heller and Marcus

Let us suppose an atom (or an ion or a molecule) under an oscillating electric field F with a frequency ω. The induced dipole moment is

$$m=\alpha(\omega)F\,, \tag{4-1}$$

where let the polarizability $\alpha(\omega)$ be scalar and given by

$$\alpha(\omega)=\frac{e^2}{m_e}\sum_i\frac{f_i}{\omega_i^2-\omega^2}\,. \tag{4-2}$$

The oscillator strength f_i satisfies the sum rule;

$$\sum_i f_i=n\,, \tag{4-3}$$

where n is the number of the electrons belonging to the atom.

In the next place, let us suppose a crystal consisting of these atoms and the polarization waves propagating in it. The electronic polarization of the i-th atom is given by

$$\vec{m}_i=\vec{m}_0\cdot\exp(i\vec{k}\vec{R}_i-i\omega_k t)\,. \tag{4-4}$$

The relations (2-8) and (2-9) for sufficiently long waves are valid also in this case. If we neglect the overlapping between the atoms, the interaction between the polarizations is only the dipole-dipole one. This interaction can easily be taken into account merely by considering the local field acting on each atom due to the dipole moments on the other atoms. For instance, in the case of the polarization waves of $k=0$ in a cubic crystal, the local field F is given by

$$F=E+\frac{4\pi}{3}P\,. \tag{4-5}$$

Therefore, by combining the Eqs. (2-8), (4-1), (4-2) and (4-5), we find that the frequency Ω_t of the transverse wave in this case must satisfy the following relation:

$$\frac{4\pi}{3}N\alpha(\Omega_t)=\frac{\omega_p^2}{3}\sum_i\frac{f_i}{\omega_i^2-\Omega_t^2}=1\,, \tag{4-6}$$

where

$$\omega_p^2=\frac{4\pi Ne^2}{m_e}\,. \tag{4-7}$$

Similarly, the frequency of the longitudinal wave is given by

$$-\frac{2\omega_p^2}{3}\sum_i\frac{f_i}{\omega_i^2-\Omega_l^2}=1\,. \tag{4-8}$$

On the other hand, under the same assumptions the dielectric constant $\kappa(\omega)$ is given by

$$\kappa(\omega)=1+\frac{4\pi N\alpha(\omega)}{1-(4\pi/3)N\alpha(\omega)}\,. \tag{4-9}$$

Comparing Eqs. (4-6) and (4-8) with (4-9), we can ascertain that Ω_t's and Ω_l's correspond to the poles and the zeros of $\kappa(\omega)$ respectively, as in §2.

Eqs. (4-6) and (4-8) can be transformed as follows: e.g. in the case of $i=1$

$$\Omega_{t1}^2-\omega_1^2=-\frac{f_1\omega_p^2}{3}\cdot\frac{\kappa^{(1)}(\Omega_{t1})+2}{3} \tag{4-10}$$

and

$$\Omega_{l1}^2-\omega_1^2=\frac{2f_1\omega_p^2}{3}\cdot\frac{3\kappa^{(1)}(\Omega_{l1})}{\kappa^{(1)}(\Omega_{l1})+2}\,, \tag{4-11}$$

where $\kappa^{(1)}(\omega)$ is given by

$$\kappa^{(1)}(\omega)=1+\frac{4\pi N\alpha^{(1)}(\omega)}{1-(4\pi/3)N\alpha^{(1)}(\omega)} \tag{4-12}$$

and

$$\alpha^{(1)}(\omega)=\frac{e^2}{m_e}\sum_{i\neq1}\frac{f_i}{\omega_i^2-\omega^2}\,,$$

that is, $\kappa^{(1)}(\omega)$ is the dielectric constant due to the oscillators other than the ω_1-oscillator. Eqs. (4-10) and (4-11) represent the shift of the atomic levels due to the dipole interaction in the crystal.

If we put $\kappa^{(1)}(\omega)=1$ (i.e. neglect the effect of the other levels) and take only the first order term of f_1, (4-10) and (4-11) can be simplified as

$$\Omega_{t1}=\omega_1-\frac{f_1\omega_p^2}{6\omega_1}$$

and

$$\Omega_{l1}=\omega_1+\frac{f_1\omega_p^2}{3\omega_1}\,. \tag{4-13}$$

These results agree with the energy of the exciton of $k=0$ by Heller and Marcus[14].

If there are many excited states, however, each mode of the polarization waves should be represented by a mixture of various atomic excitations; the dipole moment due to an atomic excitation induces that corresponding to the other atomic excitations. The latter is superposed on the former and the resultant dipole moment is $\{\kappa^{(1)}(\Omega_t)+2\}/3$ times the original one in the case of the transverse waves. The local field, that is the variation in the restoring force, is proportional to the dipole moment, thus we have the factor $\{\kappa^{(1)}(\Omega_t)+2\}/3$ of Eq. (4-10).

The frequency of the polarization wave with an arbitrary $\vec{k}$ is to be easily found, if we perform the dipole sum as Lyddane and Herzfeld[15)] have done and calculate the local field at an atom.

If we express the dielectric constant $\kappa(\omega)$ as

$$\kappa(\omega)=1+\frac{4\pi Ne^2}{m_e}\sum_i \frac{F_i}{\Omega_{ti}^2-\omega^2}, \qquad (4\text{-}14)$$

F_i corresponds to the oscillator strength of the i-th excitation mode *in the crystal*; it is proportional to the optical absorption intensity and (4-14) has the same form as the expression of $\kappa(\omega)$ neglecting the local field correction;

$$\kappa(\omega)=1+4\pi N\alpha(\omega)=1+\frac{4\pi Ne^2}{m_e}\sum_i \frac{f_i}{\omega_i^2-\omega^2}.$$

Comparing (4-9) and (4-14), we have a relation after simple manipulations;

$$F_1=f_1\left\{\frac{\kappa^{(1)}(\Omega_{t1})+2}{3}\right\}^2 \Big/ \left\{1+\frac{f_1\omega_p^2}{9}\left[\frac{d\kappa^{(1)}(\omega)}{d(\omega^2)}\right]_{\omega=\Omega_{t1}}\right\} \simeq f_1\left\{\frac{\kappa^{(1)}(\Omega_{t1})+2}{3}\right\}^2. \qquad (4\text{-}15)$$

This represents the change of the absorption intensity in the crystal. The change is caused by the mixing of the other atomic excitation modes. The relation with a similar property has been derived by Dexter[16)]. Furthermore, the following relations are readily found:

$$\sum_i F_i=\sum f_i=n, \qquad (4\text{-}16)$$

this is natural,

$$\kappa(\omega)=\prod_i\left(\frac{\omega^2-\Omega_{li}^2}{\omega^2-\Omega_{ti}^2}\right) \qquad (4\text{-}17)$$

and

$$\frac{1}{2}\sum_i(\Omega_{li}^2-\omega_i^2)=\sum_i(\omega_i^2-\Omega_{ti}^2)=\frac{n}{3}\omega_p^2. \qquad (4\text{-}18)$$

In the above discussions, we adopted a semi-classical approach. However, so far as the interaction between the atoms is the dipole-dipole one and the response of the atom to the electric field is given by (4-1) and (4-2), the above discussions would hold even if the motion of the system were governed by any mechanics; the relations (4-10), (4-11) and (4-15) are to be equivalent to the results calculated quantum mechanically up to the higher order terms of the interaction. The response (4-1), however, holds only for sufficiently weak electric fields except the case of the harmonic oscillator. On the other hand, an atomic transition causes finite electric fields on the neighbouring atoms, namely, the electric field due to the electronic polarization wave fluctuates up to finite values even if it is sufficiently small on an average, such a situation differs from the classical polarization waves. Thus the deviations from the above relations are expected in quantum mechanics. It is not difficult to verify that the above relations agree with the quantum mechanical results up to the terms of f_i's and f_if_j's $(i\neq j)$ in the power series expansions with respect to f_i's. It is supposed, however, that both do not agree for higher order terms in general.†

On the other hand, the level scheme given by Eqs. (4-10) and (4-15) is equivalent to the expression of $\kappa(\omega)$ given by (4-9), therefore the deviation from the so-called Lorentz correction is expected in quantum mechanics from the order of f^3 even if the interaction is only the dipole-dipole one.††

---

† Although it is difficult to investigate quantum mechanically the higher order terms than f^2 in general, we can verify this supposition for special cases, for instance; (1) Two atom system. (2) A crystal composed of the atoms with three atomic levels; s (ground state), p and d levels. In this case, the exact polarization waves should include d-component as well as s- and p-components at the same time differing from the classical polarization waves. (3) In the case of the extremely strong interaction, Ω_{t1} becomes zero or imaginary (see Eq. (4-10)), but such a behaviour cannot be expected in general.

†† The same conclusion has been independently obtained by T. Izuyama (private communication).

The above discussions are more suitably applied to molecular crystals rather than to ionic crystals. In most molecular crystals, however, the crystal structure is complicated and the local field is not simply given by (4-5). In order to apply the above theory to these crystals, it is necessary to perform the complicated dipole sum. It is rather trivial, however, to generalize the theory to these cases unless the practical problems are treated.

Similarly as above, the dipole moment due to the excitation of an impurity atom in a crystal induces the dipole moments of the surrounding atoms, therefore the absorption spectra of the impurity atom change from those of the free atom; the shift of the frequency and the change of the intensity are caused[16].

General electronic polarization waves

The properties of the more general electronic polarization waves have been discussed by many authors[3),4),17)], therefore we briefly summarize them from the present standpoint.

The frequency of the longitudinal polarization wave of $k=0$ satisfies again the relation;

$$\kappa(\Omega_l)=0\ . \tag{4-19}$$

So that, if $\kappa(\omega)$ is represented by the expression like (4-14),

$$\Omega_{l1}{}^2-\Omega_{t1}{}^2=\left(\frac{4\pi Ne^2F_1}{m_e}\right)\Big/\left\{1+\frac{4\pi Ne^2}{m_e}\sum_{i\neq 1}\frac{F_i}{\Omega_{ti}{}^2-\Omega_{l1}{}^2}\right\}=\frac{4\pi Ne^2F_1}{m_e\kappa^{(1)}(\Omega_{l1})}\ . \tag{4-20}$$

Particularly, in the case of $\Omega_{t1}=0$, that is in metals, Ω_{l1} becomes the plasma frequency of the electron system shielded by the dielectric constant $\kappa^{(1)}(\Omega_{l1})$.

In general, however, crystals have continuous absorption spectra, hence the roots of Eq. (4-19) are complex. In this case, it is appropriate to investigate the relation between the response of the system to the electric field $E(t)$ and that to the electric displacement $D(t)$. The electric current in a crystal induced by microscopically homogeneous $E(t)$ and $D(t)$ is generally given by

$$\begin{aligned} J(t)&=\int_{-\infty}^{\infty}\Phi(t-t')E(t')\,dt' \\ &=\int_{-\infty}^{\infty}\Psi(t-t')D(t')\,dt'\ . \end{aligned} \tag{4-21}$$

Clearly, the response functions $\Phi(t)$ and $\Psi(t)$ have the following properties: (1) $\Phi(t)=\Psi(t)=0$, for $t<0$. (2) $\Phi(t)$ and $\Psi(t)$ are real. (3) $\Phi(0)=Nne^2/m_e$, where Nn is the total number of the electrons per unit volume, $\Phi(0)$ is the current which is induced instantly by the electric field of $\delta(t)$ type. By noting that

$$D(t)=E(t)+4\pi\int_{-\infty}^{t}J(t')\,dt'\ , \tag{4-22}$$

we have

$$\Psi(t)=\Phi(t)-4\pi\int_0^t dt'\Phi(t-t')\int_0^{t'}dt''\Psi(t'')\ . \tag{4-23}$$

If we write

$$\Phi(t)=\frac{1}{2\pi}\int_{-\infty}^{\infty}\sigma(\omega)\,e^{i\omega t}\,d\omega$$

and

$$\Psi(t)=\frac{1}{2\pi}\int_{-\infty}^{\infty}s(\omega)\,e^{i\omega t}\,d\omega\ , \tag{4-24}$$

(where $\sigma(\omega)=\sigma^*(-\omega)$ and $s(\omega)=s^*(-\omega)$ because of the reality of $\Phi(t)$ and $\Psi(t)$), we have from Eq. (4-23)

$$s(\omega)=\frac{\sigma(\omega)}{1-4\pi i\sigma(\omega)/\omega}\ . \tag{4-25}$$

From the definitions of $\sigma(\omega)$ and $s(\omega)$, it is clear that their physical meaning is that the current due to the oscillating E and D with the frequency ω is given by

$$J=\sigma(\omega)E=s(\omega)D\ . \tag{4-26}$$

Moreover, because

$$1-\frac{4\pi i\sigma(\omega)}{\omega}=\kappa(\omega)\ , \tag{4-27}$$

the relation (4-25) is equivalent to

$$s(\omega)=\frac{\sigma(\omega)}{\kappa(\omega)}\ . \tag{4-28}$$

This is rather trivial.

On the other hand, if we put $t=0$ in Eq. (4-23), we have

$$\Psi(0)=\Phi(0)=\frac{Nne^2}{m_e}\ . \tag{4-29}$$

By comparing this with (4-24), we have the sum rules;

$$\int_0^{\infty}\sigma_r(\omega)\,d\omega=\int_0^{\infty}s_r(\omega)\,d\omega=\frac{\pi Nne^2}{m_e}\ , \tag{4-30}$$

where σ_r and s_r are the real parts of σ and s respectively. Furthermore, from Eq. (4-25)

$$s(\omega)-\sigma(\omega)=4\pi i\,\frac{\sigma(\omega)s(\omega)}{\omega}\,,$$

therefore

$$\begin{aligned}0&=\int_{-\infty}^{\infty}\frac{\sigma(\omega)s(\omega)}{\omega}\,d\omega\propto\int_{-\infty}^{\infty}\omega\,\frac{(\kappa-1)^2}{\kappa}\,d\omega\\&=\int_0^{\infty}\omega\left(\kappa-\kappa^*+\frac{1}{\kappa}-\frac{1}{\kappa^*}\right)d\omega\\&\propto\int_0^{\infty}\left\{\sigma_r(\omega)-\frac{\sigma_r(\omega)}{|\kappa(\omega)|^2}\right\}d\omega\end{aligned}$$

or

$$\int_0^{\infty}\sigma_r(\omega)\,d\omega=\int_0^{\infty}\frac{\sigma_r(\omega)}{|\kappa(\omega)|^2}\,d\omega=\frac{\pi Nne^2}{m_e}\,. \tag{4-31}$$

On the other hand, the rate of the energy loss per unit volume of the crystal, if $E=E_0\cos\omega t$ and $D=D_0\cos\omega t$, is given by

$$\text{Loss}=\frac{1}{2}\sigma_r(\omega)E_0^2=\frac{\sigma_r(\omega)}{2|\kappa(\omega)|^2}D_0^2\,. \tag{4-32}$$

Thus the relations (4-30) and (4-31) are the sum rules concerning the electric current and the energy loss due to E and D respectively. The conductivity $\sigma_r(\omega)$ determines the intensity of the optical absorption and the $\sigma_r(\omega)/|\kappa(\omega)|^2$ does the energy loss[†] of a high energy charged particles[3)], for the charged particle acts as a source of D rather than of E.

The oscillator strength of the exciton in alkali halide crystals

As stated in § 3, we can determine $(\sum e_i^* x_i)^2/\sum M_i x_i^2$'s which correspond to the oscillator strength in the electronic case, from Ω_t (absorption peak) and Ω_r (reflection minimum) instead of the absorption intensity. The similar method is applicable to the electronic case, if the absorption peak is isolated. For instance, in the case of the so-called exciton absorption in alkali halide crystals, $\kappa(\omega)$ is given by

$$\kappa(\omega)=\frac{4\pi Ne^2}{m_e}\frac{f}{\Omega_t^2-\omega^2}+\kappa'(\omega)\,,$$

near the exciton peak, where f is the oscillator strength of the exciton level and N is the number of unit cells per cm³, $\kappa'(\omega)$ is the dielectric constant coming from the other levels. The reflection minimum arises when $\kappa(\Omega_r)=1$. We estimate $\kappa'(\omega)$ from the reflectivity of the region over $(\hbar\Omega_t-0.2\,\text{ev})\sim(\hbar\Omega_t-0.5\,\text{ev})$, since it may be approximately regarded as a constant within the narrow frequency range from $(\hbar\Omega_t-0.5\,\text{ev})$ to $\hbar\Omega_r$. The results are summarized in Table V. The oscillator strength of the exciton level is rather small, if we remember that there are at least six electrons participating in the exciton level in a unit cell. The contribution to κ_0 from the exciton level is about 0.1. This method may be useful to estimate the oscillator strength when the quantitative data of the absorption intensity are not available, although it is not new in principle.

Appendix. The Effective Charge of BaTiO$_3$ Crystal

As stated in § 3, the ratio;

$$\frac{(\text{the experimental value of }\sum_i e_i^{*2}/M_i\text{ from the infra-red data})}{(\text{the calculated value of }\sum_i e_i^{*2}/M_i\text{ from the simple ionic model})} \tag{A-1}$$

is 1/5~1/4 in BaTiO$_3$ and the related crystals. We investigate here whether such a great difference may be interpreted by the ionic model or not. In the case of alkali halide crystals, the ratio (A-1) is 0.5~0.9, and we can interpret[6)] the difference by assuming the short range interaction energy between the polarization due to the ionic displacement and the electronic polarization, although we cannot explain it by the simple ionic model only.

[†] Of course, the weight with respect to the final states of the particle must be multiplied to this.

In the case of $BaTiO_3$ and the related crystals, we attempt to bring the ratio (A-1) from $1/5 \sim 1/4$ to 0.5 within the range of the simple ionic model and expect that the remaining difference may be interpreted by the similar mechanism as in alkali halide crystals.

The large calculated values of $\sum e_i^{*2}/M_i$ come mainly from the large polarizability of the oxygen ions. However, the polarizabilities assumed in § 3 are not well-founded, although they are consistent with the experimental κ_0. Therefore we regard them as the adjustable parameters and examine whether the above ratio can be brought to the expected value ($\simeq 0.5$) or not with the reasonable values of them.

It is a way to this purpose to decrease the polarizability of the O^{--} ions and increase that of the divalent metal ion. The polarizability of Ti^{4+} ion is too small to influence the result. It is necessary, however, to compensate the decrease of the polarizability of three O^{--} ions with the increase of that of only one metal ion to hold the κ_0 unchanged, so that unreasonably large polarizability of the metal ion is necessary to bring the ratio (A-1) to the expected range. For instance, if we put the polarizability of Sr^{++} ion as 3.4 A^3 instead of 1.6 A^3 in § 3 the above ratio for $SrTiO_3$ becomes 0.5. This value of the polarizability is inconsistent with κ_0 of SrO crystal, in which the *total* polarizability is to be 3.5 A^3.

Another way is to assume the anisotropic polarizability of the O^{--} ions. It is well-known that the polarizability of O^{--} ion fluctuates from compound to compound and generally increases with the volume per O^{--} ion[10]. In the $BaTiO_3$ type crystals, the ionic configuration is close-packed in the Ti–O direction and loose-packed in the Ba–O direction (Table VI), so that, it is probable that the polarizability of the O^{--} ion is small in the Ti–O direction and large in the Ba–O direction. Since the most important contribution to the calculated values of $\sum e_i^{*2}/M_i$ comes from the electronic polarization of the so-called O_a ion, the above assumption is favorable to our purpose. For instance, in the case of $BaTiO_3$ crystal, the following polarizabilities bring the above ratio to 0.5 and are also consistent with κ_0: O^{--} ion (Ti–O direction) 1.7 A^3, (Ba–O direction) 2.5 A^3, Ba^{++} ion 2.5 A^3 and Ti^{4+} ion 0.2 A^3 (the last two values are equal to those in § 3). The circumstances are nearly the same in the other titanates. The polarizability of O^{--} ion varies considerably from compound to compound, e.g. 1.6 A^3 in MgO and 3.0 A^3 in BaO crystals, so that the anisotropy as above is possible. Of course, the above discussions only suggest a possibility of the ionic model and do not deny the possibility of the homopolar binding.

Cleavage Fracture in Single Crystals of Silicon Iron

By Ryūkichi HONDA

National Research Institute for Metals
2-300, *Nakameguro, Meguro-ku, Tokyo*

(Received February 1, 1961)

Sheet specimens of single crystal of 2.9% silicon iron with {110} surface have been extended in the ⟨100⟩, ⟨110⟩ and ⟨111⟩ directions respectively at −196°C, until they have fractured. The twins and slip lines have been observed in the course of extension as well as after the fracture. The following two mechanisms by which slip or twinning causes the cleavage have been confirmed. In ⟨100⟩ extension, a twin stopped intersecting with another twin along the ⟨110⟩ direction causes a cleavage on the {100} plane parallel to the intersection line. In ⟨110⟩ extension, two {110} slip systems intersecting along the ⟨100⟩ direction cause a cleavage on either of two {100} planes parallel to the intersecting line. Cleavage in ⟨111⟩ extension seems to be understood by extended applications of the latter mechanism.

§1. Introduction

Generally, the cleavage stress actually observed in materials is less than that estimated for ideal crystals by two orders of magnitude or so.[1),2)] This discrepancy is the central problem on which emphasis has been laid so far in the theory of brittle facture in metals and other crystals at low temperature, because the cleavage fracture is the most characteristic feature of the brittleness. Microscopic defects such as inclusions or pre-existing microcracks are not sufficient to explain this discrepancy except in special cases. Grain boundaries might be responsible for it in some cases. But there must be other causes of cleavage fracture, because single crystals are more brittle and have more tendency to cleavage under the stress in certain directions than polycrystals.

To overcome this difficulty, many possible mechanisms of cleavage fracture have been discussed. Twins and cleavages occur frequently in the similar conditions, that is, at low temperature,[2)–4)] at high strain rate[2),3)] and so on. Also, prestrain often decreases both tendencies towards twinning and cleavage.[2),3),5),6)] But the role of the twin as the cause of cleavage fracture remained ambiguous until recent days. Hull[7)] reported recently fine observations about the twins and cracks in single crystals of silicon ions. He showed that almost all cleavage cracks observed after the facture at −196°C were located at the intersecting points of certain twin pairs. Perhaps these cracks were actually initiated by the intersecting twins. But the mechanism by which the intersecting twins cause a cleavage fracture was not clear, together with the answer to the question whether other important causes of the cleavage facture do exist or not.

According to many reports so far published, cleavage fracture is preceded by plastic deformation, especially in certain cases by slip.[8)] Several authors have discussed and calculated the large concentrated stress produced by a pile-up group of dislocations which are forced to stay by a strong obstacle.[9),10)] This large stress field has often been considered in relation to the cleavage crack. In line with this, Stroh[1),11)] elaborated a theory of cleavage fracture. As the strong barrier in b. c. c. metals, Cottrell[12)] has suggested a sessile dislocation which can be formed by coalescence of a pair of two suitable dislocations. Following his suggestion, a calculation was made recently about the magnitude of the stress produced by a double dislocation pile-up on two intersecting slip planes.[13)] Theoretically, these discussions and calculations support the great possibility of cleavage initiation by the mechanism of pile-up dislocations. The observations of the regular row of pile-up dislocations itself were reported by several workers. Especially Smith[14] reported recently an observation of this row on one {110} plane in α-iron. But the direct experimental evidence that the cleavage fracture is caused by pile-up group or groups of dislocations was very meager as yet.

There have also been proposed other mechanisms of cleavage fracture, including Allen's consideration[15] by which no yielding is necessary for the initiation of cleavage. The present purpose is to reply to the following questions, concerning the cleavage in b.c.c. metals.

1) Does the twin actually cause the cleavage fracture? In what case and by what mechanism?
2) Does the slip actually cause the cleavage fracture? In what case and by wheat mechanism?
3) Does any other mechanism remain to be considered?

§ 2. Experimental Procedure

Single crystals of silicon iron have been extended in the [001], [110] and [111] directions respectively in liquid nitrogen (−196°C) by a hard tensile machine, until they have fractured. Twins and slip lines which have appeared on the two surfaces and two sides of the specimens have been observed mainly by optical microscope. These observations have been made at the room temperature at the several points in the course of extension as well as after the fracture, by interrupting the extension and removing the specimens from the tensile machine. The cleavage faces also have been examined.

Single crystal sheets used were prepared by strain-annealing method from polycrystalline sheets and kindly supplied by Dr. Taoka and his group in our institute. The initial polycrystalline sheets contained 2.9 wt. % Si and 0.017 wt. % C but these elements are though to have slightly diminished during the recrystallization in the atmosphere of dry hydrogen. The surfaces of these single crystal sheets coincide with the {110} plane, which will be designated as (1$\bar{1}$0) in this work, with the deviation less than 5 degrees according to the result of X-ray analysis.

From these sheets, three kinds of specimens were cut by the use of wheel cutter. The longitudinal direction, that is, tensile axes of them coincide with the [001], [110] and [111] directions respectively with the deviation less than 5 degrees. They were shaped with fine file by hand. Their surfaces and sides were made flat and strain-free by electropolishing following the method of Jacque. The size and shape of these specimens are shown in Fig. 1. The width of the narrowest region of each specimen was not the same for all specimens. But the effect of this divergence was trivial.

The rate of extension was about 3×10^{-4}/sec. Nine specimens of each kind were examined. The time elapsed during the microscopic examination in the course of extension was about 20 minutes to 1 hour in each observation at room temperature.

§ 3. Results

3.1 Case of [001] extension.

A typical stress-strain curve observed in the case of extension in [001] direction is shown in Fig. 2. The characteristic feature of this curve is straightness interrupted by several abrupt load drops. Accompanying the abrupt load drop, a click was usually heard. Fracture took place always suddenly and total plastic elongation up to the fracture was 1 to 2 percent.

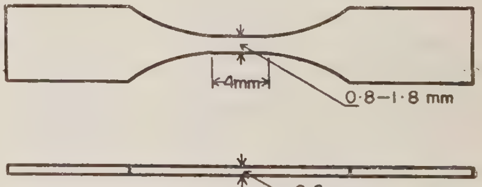

Fig. 1. Size and shape of specimens.

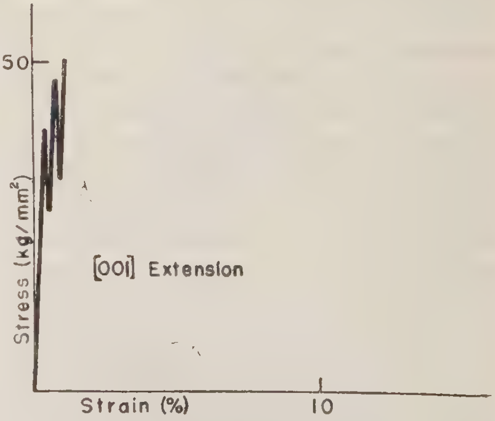

Fig. 2. Stress-strain curve in [001] extension.

In the case [001] extension, after any one abrupt load drop during the extension, a number of traces of twins have been observed as shown in Fig. 3(a) and (b). These traces are thin regions with finite width, the boundaries of which are straight in major part. Sometimes zig-zag markings are observed along the boundaries of them. Their orientations examined geometrically are parallel to the traces of the {112} planes. These features accord with the characteristic ones reported about the deformation twins in α-iron and other b.c.c. metals. With each

abrupt load drop, these twins were found to increase in their number and width. The deformation twins observed are classified by their orientations into four groups. Each group corresponds to one of the four {112} planes, on which resolved shear stress along ⟨111⟩ direction is maximum among all twelve {112} planes as shown in Appendix. These four planes are (112), $(\bar{1}12)$, $(11\bar{2})$ and $(1\bar{1}2)$ planes, and their traces on the surface and the side of [001] specimens are shown in Fig. 4 (a) and (b) to be compared with Fig. 3 (a) and (b).

The intersections of these four groups of twins are classified geometrically into two types. The intersecting line of twins on the (112) and $(11\bar{2})$ planes is parallel to the $[1\bar{1}0]$ direction and that of twins on the $(\bar{1}12)$ and $(1\bar{1}2)$ planes to the [110] direction, as exemplified in Fig. 5. these twin pairs may be shortly called ⟨110⟩ type. Other four pairs among four groups intersect along ⟨012⟩ lines. The intersections of these pairs may by called ⟨012⟩ type.

The microscopic observations show a characteristic difference between these two types of intersections. In a intersection of ⟨110⟩ type, one of two twins is usually stopped at the intersecting point, as seen in Fig. 6(a). Sometimes two twins which form the

⟨110⟩ intersection on the cleavage face seem as if they had run through each other. But the one half of either twin is thought to have been formed after the cleavage had been initiated. Indeed, this situation has been shown in some observations. On the other hand, in more than one third of observed intersections of ⟨012⟩ type, two intersecting twins have run through each other as shown in Fig. 6(b).

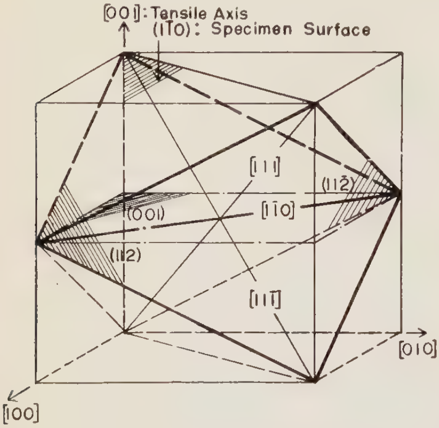

Fig. 5. Twin intersection of ⟨110⟩ type in [001] extension. ——: twinning plane, ——·——: intersecting line, ——·——: cleavage plane.

At the neighboring regions of the intersections of ⟨110⟩ type, short traces considered to be slip lines have been often observed, as seen in Fig. 6(a). They run from the intersecting points along the trace of {110} plane which involes the intersecting line of two twins. Their length is about 0.01–0.1 mm and they fade away at one end. Sometimes other localized slip lines have also been observed around twins and cleavage faces.

The specimens extended in [001] direction have always fractured by cleavage on (001) plane. The cleavage face, as shown in Fig. 7(a), is a plane face with many steps along twins. Also many fine patterns sometimes called river patterns[16] are observed on them. As an important fact, it could be pointed out that always one and only one intersection of two twins of ⟨110⟩ type is observed on the cleavage face as shown in Fig. 7(b). Not all the twin intersections of ⟨110⟩ type have caused cleavage fractures but many intersections of ⟨110⟩ type have been observed already in the course of extension. In a few specimens, the only one ⟨110⟩ intersection detected on cleavage face coincides with one of ⟨110⟩ intersections observed in advance in the course of extension. Sometimes cleavage face deflects from (001) plane and runs for a short distance along twin-matrix interface, as seen in Fig. 8.

3.2 Case of [110] extension.

A typical stress-strain curve is shown in Fig. 9. Several abrupt load drops usually accompanying audible click are observed also in each [110] extension. But here, more or less continuous flow occurs in the later stage of extension and after the elongation from a few to about ten percent the specimens have suddenly fractured by cleavage.

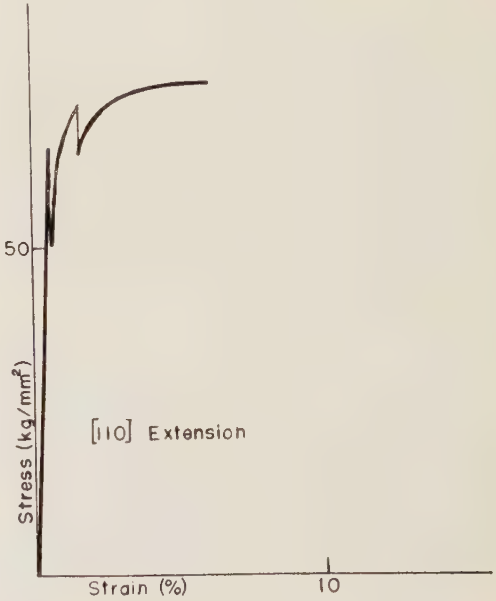

Fig. 9. Stress-strain curve in [110] extension.

The observation in the course of extension shows a distinct difference from the case of [001] extension. That is, no twins have been detected in advance to the occurrence of fracture, although many lines have appeared and increased with abrupt load drops, see Fig. 10(a) and (b). These lines are surely slip lines, for they are parallel to the traces of four {110} planes which have maximum resolved shear stress in the [111] or the [111̄] direction on them among all {110} slip systems, as shown in Appendix.

Traces of these planes on the surface and side of the specimen are shown in Fig. 11(a) and (b), to be compared with Fig. 10(a) and (b). The slip lines on the surface have appeared perhaps due to the small deviation of that face from the exact (1$\bar{1}$0) plane, in spite of the fact that the slip directions must be parallel to this plane. Slip lines appeared after the first abrupt load drop or after the first and second were parallel to one {110} plane. Until the fracture occurred, slip lines appeared usually on two {110} planes in each specimen. In two specimens, many cross slips were observed on the sides.

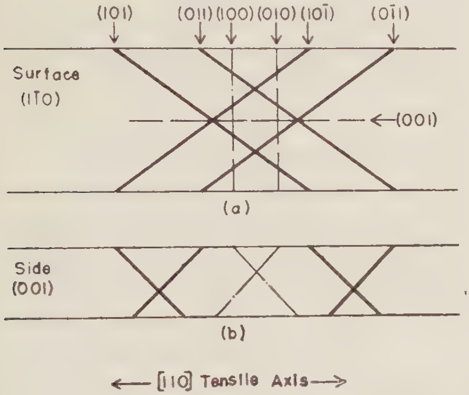

Fig. 11. Traces of operative slip planes and cleavage planes on [110] specimen.
(a) Surface.
(b) Side. ——: slip plane, ——·——: cleavage plane.

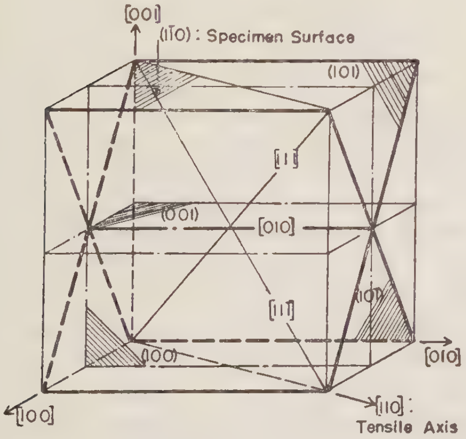

Fig. 12. Slip intersection of ⟨100⟩ type in [110] extension. ——: slip plane, ——·——: intersecting line, ---·——: cleavage plane.

Geometrically intersections among these four slip systems are classified into two types. The pair of (101) [11$\bar{1}$] and (10$\bar{1}$) [111] and that of (011) [11$\bar{1}$] and (0$\bar{1}$1) [111] intersect along the ⟨100⟩ lines, as exemplified in Fig. 12. The other four pairs intersect along the ⟨111⟩ directions. It has been found that the fracture has occurred only after the intersections of ⟨100⟩ type. The fracture took place not always immediately after the first ⟨100⟩ intersections but usually after the succeeding elongation of several percent. In seven specimens, the slip lines remained parallel on the side until the fracture, though the intersections of slip lines were observed on the surface, as shown in Fig. 10. That is, in each of these specimens, only either one of two kinds of ⟨100⟩ intersections has occurred until the fracture.

A remarkable fact is the appearance of large or small longitudinal cracks on (001) plane parallel to the tensile axis. In four specimens, these cracks of length more than 1 mm have been detected in each specimen as shown in Fig. 13(a) and (b).

The specimen fractured finally by transversal cleavage on (100) or (010) plane. It has been also found that the transversal cleavage planes correspond to the kinds of intersections of ⟨100⟩ type in the following way. When the intersecting line between the two slip planes is [010], the transversal cleavage plane is (100) and when the intersecting line is [100], the transversal cleavage plane is (010). As illustrated in Fig. 12, the traces on the (001) plane of transversal cleavage plane and of intersecting slip planes must be all parallel if the above correspondence is actually correct. In each specimen in which the observed ⟨100⟩ intersections were confined to only one kind, this correspondence has been distinctly verified by the observation of the sides which is the (001) plane, as seen in Fig. 14.

After the fracture, some twins have been observed around the cleavage face but no definite configuration was detected which suggests the function of these twins in the initiation of the cleavage. These twins are thought to have taken place as sequential products at the instant of the cleavage fracture. Localized slip lines which are also thought to be the sequential products have been detected occasionally after the fracture. The longitudinal and transversal cleavage faces have also a number of steps along twins and river patterns between them. Transversal cleavage face is shown in Fig. 15.

3.3 Case of [111] extension.

A typical stress-strain curve is shown in Fig. 16. The characteristic feature is a round load drop with which a sharp neck is formed. The ductility was fairly large. Several little abrupt load drops have been observed in many specimens. The click was heard with the abrupt load drop but not with the round one. The fracture took place after the round load drop with or without succeeding elongation of several percent and still pretty suddenly.

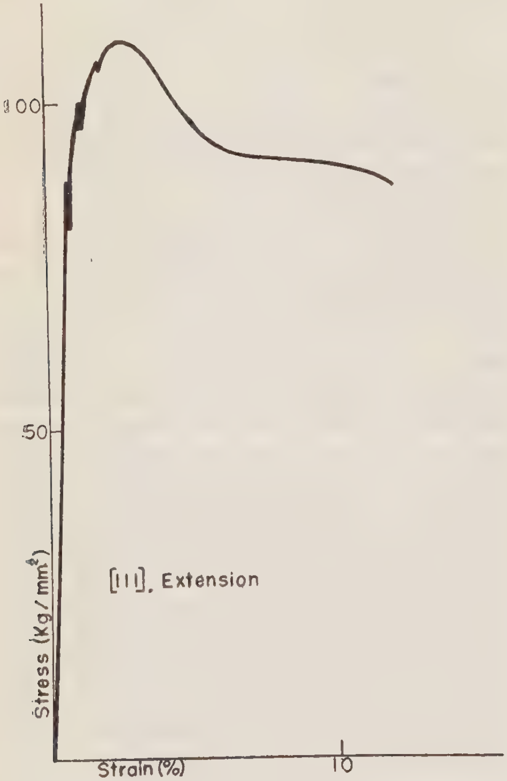

Fig. 16. Stress-strain curve in [111] extension.

Many slip lines have appeared with the abrupt load drops and during the continuous flow. But no twins have been detected in advance to the fracture. Geometrically there exist six {110} slip systems on three {110} planes which have maximum resolved shear stress, as listed in Appendix. The slip lines observed in the early stage of extension or outside the neck almost lie on these three {110} planes and many cross slips are observed, as shown in Fig. 17(a), (b) and Fig. 18(a), (b). In severe neck, on the other hand, slip lines which might be on {112} or {123} planes have been observed, together with closely distributed slip lines on the above {110} planes. But, there the slip lines are so complicated that unquestionable identification of slip systems was rather difficult. Also, a configuration or configurations which have the appearance of kinks have been formed in or around the neck. A bend plane appeared in the kinks is shown in Fig. 19.

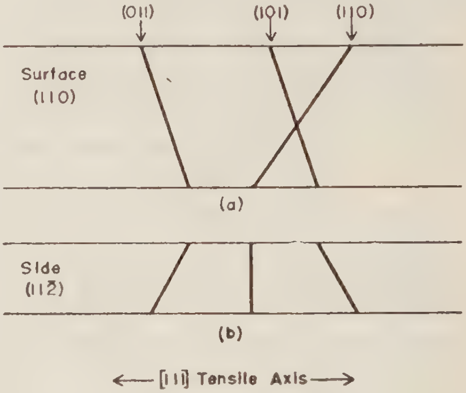

Fig. 18. Traces of operative slip planes on [111] specimen.
(a) Surface. (b) Side.

The fracture occurred through the neck but is still due to the cleavage as seen in Fig. 20. In almost every specimen, not only one but two or three cleavage faces, usually intersecting perpendicularly, have been observed. Nearly all of the observed cleavage faces are thought to be on the {100} planes from their orientation and their structures are more or less similar to those of cleavage faces appeared in [001] and [110] extension. But two of them are pretty deviated from any one of the {100} planes and might be on the {110} planes. These two have somewhat different surface structures and are curved in their boundary regions as shown in Fig. 21. The indices of these planes were difficult to decide exactly due to the heavy deformation even with X-ray analysis. A number of twins have been observed only after the fracture but they do not seem to have played the significant role for the initiation of cleavage.

§ 4. Discussions

4.1 Case of [001] extension.

In the case of [001] extension, twins will be mainly discussed because slip is not observed except that located in special zones. Prior to the analysis of cleavage fracture, the difference between two types, ⟨110⟩ and ⟨012⟩, of twin intersections will be made clear. We have already recognized that in the ⟨110⟩ intersections, one twin is stopped by the other and in ⟨012⟩ intersections, many two twins run through each other, as shown in Fig. 6. Consideration of a characteristic property of twinning leads us naturally to the understanding of this situation. Twinning can operate in one direction but not in the opposite direction. This property will be easily understood from the configuration of atom displacement in twinning. Fig. 22 shows twinning on the (112) and (11$\bar{2}$) planes seen on the (1$\bar{1}$0) plane in b.c.c. crystals. The twinning can occur in the directions pointed by arrows. The shear stress components in these possible twinning directions is positive when the external tension is in the [001] direction or negative when the tension is in the [110] direction. Thus, it is reasonable that the twins on the (112) or (11$\bar{2}$) planes have been observed only in the [001] extension but not in the [110] extension.

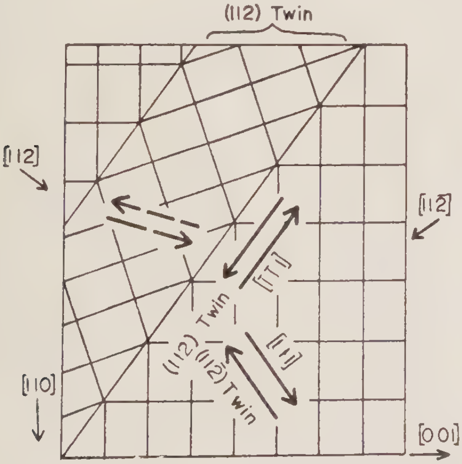

Fig. 22. Possible twinning directions on (1$\bar{1}$0) plane are shown by solid arrows in original lattice and by dotted arrows in (112) twin region.

Returning to the case of [001] extension, let us consider an example of ⟨110⟩ twin intersections in which a (11$\bar{2}$) twin grows and meets with a (112) twin, as shown in Fig. 23. In this case, (11$\bar{2}$) twin cannot penetrate into the (112) twin region by twinning, because the orientation of the new {112} plane within the (112) twin region is deviated from that of the original (11$\bar{2}$) plane and moreover the component of shear stress in the possible twinning direction on that {112} plane is negative, as shown by dotted arrows in Fig. 22. On the other hand, in the ⟨012⟩ twin intersection, there is a {112} plane in either twin, on which the other twin can penetrate into the former twin, though some difficulty should be accompanied by the penetration because of a deflection of the twinning plane.

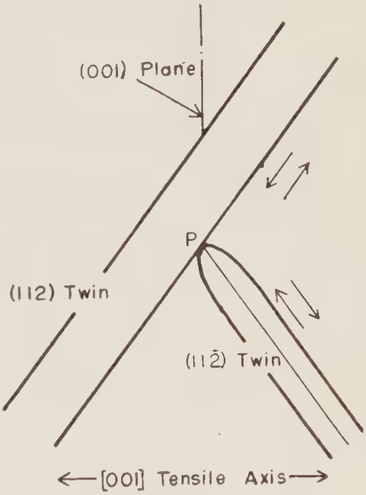

Fig. 23. ⟨110⟩ type twin intersection seen on (1$\bar{1}$0) plane.

Thus, the difference of two types of twin intersections can be understood. Beside the intersections on cleavage faces mentioned in 3.1, there have been observed a few exceptional examples of ⟨110⟩ intersections, in which two twins seem to have run through each other. In these intersections, perhaps the stopped twin has produced a new twin just at the opposite side of stopping twin. But this process is naturally rare, because a twin will be hardly generated in a region without suitable defects.

Now, the mechanism by which the ⟨110⟩ twin intersection causes a cleavage fracture is argued as follows. In Fig. 23 a twinned region is supposed to be stopped at the top *P* by another twin. Then, the outer part of that stopped twin will be pushed to the obstacle and cause a large stress around the top. By comparing the work done by the external stress with the work done by the concentrated shear stress at the top in the process of virtual advance of the top P by twinning, the concentrated shear stress τ_c is estimated as

$$\tau_c = n\tau , \qquad (1)$$

where n is the number of twinning layers in that twin, and τ is the external shear stress. In the stable configuration, this shear stress must be compensated by the elastic stress in the obstacle region and this compensation stress will appear as tensile and compressive stress on the upper and lower side of the twinning plane through P respectively. The direction of them is considered to be nearly parallel to the twinning direction and their magnitude will be of the order of τ_c or $n\tau$. These situations are very analogous to the case of pile-up dislocations.

This concentrated stress will cause a cleavage if it is sufficiently large. When the external tension is σ, the thickness of the stopped twin is d and the normal component of the concentrated tensile stress on the (001) plane is S,

$$\tau = 0.472\sigma \text{ (Appendix)} , \qquad (2)$$

$$n = \sqrt{6}\, d/a , \qquad (3)$$

and

$$S = n\tau/\sqrt{3} = 0.668\sigma d/a , \qquad (4)$$

where a is the lattice constant. For the observed order of $\sigma = 50\,\text{kg/mm}^2$ and $d = 0.5\,\mu$, S is estimated to be $6\times10^4\,\text{kg/mm}^2$. This roughly estimated value is considered to be enough to cause a cleavage fracture. Since the concentrated stress is produced along the intersecting line, cleavage can occur only on a plane parallel to that line. Here the (001) plane satisfies this condition, as understood from Fig. 5.

The localized short slip lines observed at the intersecting points of ⟨110⟩ type give an evidence of localized stress concentration. In the ⟨012⟩ type of intersection, large stress concentration is not produced, because each twin, owing to the possibility of mutual penetration, does not act as a strong barrier to the other and hence no cleavage occurs. The observed one-to-one correspondence between the (001) cleavage and the ⟨110⟩ twin intersection shows conclusively that the cleavage fracture in [001] extension has always been caused by the mechanism of the twin intersection of ⟨110⟩ type mentioned above.

4.2 Case of [110] extension.

Here, the slip is observed to be the main mode of deformation. On the (112) and (11$\bar{2}$) planes, resolved shear stress is fairly large but it is negative to the twinning direction, as shown in Fig. 22. Actually, twins have not been observed on these planes. After the fracture a number of twins on other {112} planes have been observed, but they do not seem to have played significant role in the initiation of cleavage fracture. Therefore, only the function of slip will be discussed in the following analysis.

Cottrell[12)] has suggested that in b.c.c. metals certain two {110} dislocations, for example, (101)$a/2[\bar{1}\bar{1}1]$ and (10$\bar{1}$)$a/2[111]$ can coalesce to form one dislocation, Burger's vector of which is $a[001]$ and the energy of which is lower than the sum of energies of two dislocations to be coalesced. This coalescence occurs along the [010] direction in which the two slip planes intersect. The succesive dislocations which follow the already coalesced dislocations on both slip planes pile up before or run into the coalesced dislocation, because it is sessile. The (001) plane which involves the intersecting line receives a large normal tension under this circumstance. In this way Cottrell has explained the cleavage fracture in b.c.c. metals.

The observed slip systems in the case of [110] extension are predominantly confined on the {110} planes in accordance with other report concerning the slip systems of silicon iron.[4)] Moreover, the intersections of two slip systems of ⟨100⟩ type mentioned in 3.2 are essentially equivalent to those proposed by Cottrell. The direction of slip in the case of [001] extension considered by him is opposite to that in the case of [110] extension now under consideration. But this difference can be thought as trivial, for the same dislocations can cause an opposite shear moving to the opposite directions. Of course, a slip shear in one direction itself can be caused by either of two kinds of dislocations with opposite signs moving to the opposite directions. Hence the combination of Burger's vectors of dislocations running towards the intersecting line is not necessarily suitable for the coalescence. But this situation exists both in Cottrell's case and in the present case. Anyway, about half of the pairs of intersecting slip systems are expected to be caused by dislocation groups suitable for the coalescence.

The cleavage fracture in [110] extension has always taken place after the occurrence of the slip intersections of ⟨100⟩ type. This behavior is in accord with the first requirement of Cottrell's mechanism.

It is easily checked up that by the Cottrell's mechanism, the cleavage must take place on the (001) plane, even in the case of [110] extension, no matter which kind of intersections of ⟨100⟩ type is responsible. Actually, cleavages on the (001) plane have frequently been observed as large or small longitudinal cracks, as shown in Fig. 13.

In the above argument, the numbers of pile-up dislocations were implicity assumed as nearly equal in both slip planes. If the number is extremely small on one plane compared with that on the other, the concentrated tensile stress is directed nearly parallel to ⟨111⟩ direction, and the two {100} planes parallel to the intersecting line receive equally a large normal tension. One of these two is again the (001) plane on which the observed longitudinal cracks exist. The other is the (100) or (010) plane, if the intersecting line is [010] or [100] respectively. The transversal cleavage planes actually observed are found to be in full agreement with this consideration.

Thus, the mechanism of pile-up dislocations before a coalesced one is entirely conformable to every feature observed. Hence, the cleavage fracture in [110] extension is concluded to have occurred always by this mechanism.

4.3 Case of [111] extension

Here, the six {110} slip systems operative in the early stage of extension intersect along ⟨111⟩ lines, if they are not on the same plane and many cross slips have been observed as expected naturally. Then, the formation of sessile dislocation and the pile-up of many dislocations are probable, if any, only along the ⟨111⟩ direction. The large ductility observed in this case seems natural because the ⟨111⟩ lines are not parallel to any {100} plane. For, the observed cleavage planes are predominantly the {100} planes in b. c. c. metals and other crystallographic planes seem to have higher surface energy considering the elastic anisotropy and shapes of etching pits.

The mechanism of cleavage fracture itself is not clear in this case, though the slip seems to play the important role here again. As one possible mechanism, it is proposed that cleavages are caused by the intersections of {112} or {123} slip systems as well as of {110} slip systems. All the slip dislocations in b.c.c. metals have the Burger's vectors of $a/2\langle 111\rangle$ and any pair of these vectors sums to $a\langle 100\rangle$ or $a\langle 110\rangle$ according to their relative sign. Thus, when two slip planes intersect, the formation of coalesced and sessile dislocation is always probable excluding the case of cross slip. Hence, if the intersecting line of two slip systems is on one {100} plane, pile-up group or groups of dislocations may cause a cleavage on this plane. In fact, it seems that several pairs of slip systems observed in the neck of [111] specimens might be those in which two slip system intersect on the {100} plane. These pairs might be the cause of cleavage fracture on the {100} planes in [111] extension, because the cleavage fracture has taken place through the neck. On the other hand, {110} slip systems intersecting along the ⟨111⟩ direction might cause occasionally a cleavage on a plane parallel to this intersecting line also by the mechanism of pile-up dislocations. The cleavage which seems to have occurred on the {110} plane might be caused by this mechanism. The {110} cleavage planes are also reported in tantalum[17)] and niobium[18)].

Finally, it will be suggested that the present mechanisms of cleavage fracture do not conflict with the ductile-brittle transition. Twins are not formed and hence do not cause a cleavage in higher temperature. The concentrated stress caused by intersecting slip systems may also be easily released by the occurrence of other slips at higher temperature. In the case of twin intersections, this release has been observed as localized slip lines. Dissociation of coalesced dislocation might also occur frequently in the higher temperature. There might be some intermediate temperature region in which the formation of twins is not possible but intersecting slips can still cause a cleavage fracture under the tension in the [001] direction.

These two mechanisms of cleavage fracture mentioned above, one by intersecting twins and the other by intersecting slips, stand obviously in close parallelism in their essential points. At first, the plastic flow is blocked by the intersection in both mechanisms, although the mechanisms of blockage are different in them, and a large concentrated stress is consequently produced along the intersecting line. Secondly, the interesting line lies on the {100} plane which has the weakest resistance against the cleavage among all other crystallographic planes. Thirdly, the concentrated stress acts as a large normal tension on this weak plane and causes a cleavage fracture.

The cleavage behavior in the silicon iron will be considered to have common feature to some extent with that of other b. c. c. metals, because the behavior of twinning or slip is pretty similar in other b.c.c. metals.

§ 5. Conclusions

In the cleavage fracture of single crystals of silicon iron extended at −196°C, two mechanisms of cleavage fracture have been experimentally confirmed. One is a mechanism by which a definite type of twin intersections causes a cleavage fracture on the {100} plane. The other is that by which a definite type of the {110} slip intersections causes a cleavage fracture on the {100} planes.

The cleavage fracture of specimens extended in the ⟨100⟩ direction is always explained by the former mechanism and that of specimens extended in the ⟨110⟩ direction is always explained by the latter mechanism. The cleavage fracture of specimens extended in the ⟨111⟩ direction may be explained by extended applications of the latter mechanism.

These two mechanisms, one by twins and the other by slips, are similar in their essential points.

Acknowledgement

The author wishes to express his hearty thanks to Dr. U. Hashimoto, Director of National Research Institute for Metals, and Prof. S. Kaya, President of the University of Tokyo, for their continual encouragement throughout this work. He is grateful to Dr. T. Kawada and Dr. T. Taoka for their cordial guidance in this work. Also his thanks are due to Dr. Taoka and his group for the kind supply of single crystal sheets of silicon iron.

Some Remarks on the Phenomenological Theory of Ferroelectricity

By Shozo SAWADA and Ikushi YOSHIDA*

Tokyo Institute of Technology, Tokyo

(Received February 16, 1961)

The free energy of a ferroelectric was expanded as an even power-series of polarization in the customary phenomenological theory. For the case of the transition of the second order, the condition was examined under which the well-known relation holds that the temperature-gradients of reciprocal susceptibility immediately below and above the transition point stand in the ratio $-2:1$, and it was shown that this relation is valid regardless of the number of terms taken in the expansion and the temperature-dependence of their coefficients. When the transition is of the first order, on the contrary, this ratio was found to be very sensitive to them, though a simple ratio $-8:1$ is obtained by postulating the temperature-independent coefficients of fourth- and sixth-powers and neglecting terms of higher powers. A similar result was also obtained concerning the antiferroelectricity.

§1. Introduction

To explain the ferroelectricity of $BaTiO_3$ Devonshire[1] expanded the free energy A in an even power-series of polarization P and postulated a linear temperature-dependence on the coefficient of the term of second power only, and succeeded in deriving several important thermodynamical relations and in accounting for the occurrence of phase transitions. A fair success was also due to him in a theoretical reasoning of the temperature-dependencies of quantities such as spontaneous polarization or susceptibility. Merz[2] was able to explain why a single crystal of $BaTiO_3$ describes a double hysteresis-loop just above the transition from the tetragonal ferroelectric- to the cubic paraelectric-phase on the groucd of Devonshire's phenomenological theory. Kittel[3], on the other hand, suggested a possibility of antiferroelectricity applying a similar phenomenological theory to a crystal composed of two sub-lattices, and indeed soon afterwards Shirane *et al*[4] found that $PbZrO_3$ is antiferroelectric. Cross[5] extended the theory to that of a three-dimensional case.

A closer fit of results derived from the phenomenological theory to experimental facts will necessarily require much more terms of expansion and much more coefficients which are temperature-dependent. In fact, a series of works have been made along this line of development. In the phenomenological theory of $BaTiO_3$, Kholodenko[6] and Drougard *et al*[7] postulated a temperature dependence on the coefficient of fourth power also, and moreover added other terms of sixth power not taken into account by Devonshire. A temperature dependence on the coefficient of sixth power was postulated by Kawabe[8]. Terms of eighth- and tenth-powers were added by the same author for a better explanation of the lowest phase-transition of $BaTiO_3$.

Here we examined generally the effect of increasing the number of terms of expansion and allowing complex temperature dependencies for the coefficients on the temperature depencence of susceptibility, in the phenomenological theory of a uniaxial ferroelectric. The susceptibility is a more directly and more precisely measurable quantity than others such as spontaneous polarization (determined by the observation of hysteresis loop or by the measurement of pyrocurrent) or a bias effect of phase transition. This was the main reason why we adopted the susceptibility as a quantity to judge the propriety of theory. Discussions on the other quantities will similarly be made.

§2. General Formulation

The free energy per unit volume of a ferroelectric is expanded as follows;

---

* Now at the Central Research Institute, Fuji Iron and Steel Co., Ltd.

$$A(P,T)=A_0(T)+2\sum_{n=1}^{\infty}h_n(T)P^{2n}\,, \tag{1}$$

where P is the electric polarization and T is the absolute temperature. The external field E and hence the susceptibility η are obtained by successive differentiation of Eq. (1) with respect to P, as

$$E=\left(\frac{\partial A}{\partial P}\right)_T=4P\sum_{n=1}^{\infty}nh_n(T)P^{2(n-1)}\,, \tag{2}$$

$$\frac{1}{\eta}=\left(\frac{\partial E}{\partial P}\right)_T=4\sum_{n=1}^{\infty}nh_n(T)P^{2(n-1)}+8P^2\sum_{n=2}^{\infty}n(n-1)h_n(T)P^{2(n-2)}\,. \tag{3}$$

The spontaneous polarization P_s is obtained as a root of the equation

$$\sum_{n=1}^{\infty}nh_n(T)P_s^{2(n-1)}=0\,, \tag{4}$$

which comes from Eq. (2) for $E=0$. As $A_F=A_P$ is required at $T=T_c$,

$$\sum_{n=1}^{\infty}h_n(T)P_s^{2n}=0 \qquad (T=T_c) \tag{5}$$

is readily obtained from Eq. (1). Combined with Eq. (4), Eq. (3) gives the paraelectric and ferroelectric susceptibilities as

$$\frac{1}{\eta_P}=4h_1(T)\,, \tag{6}$$

$$\frac{1}{\eta_F}=8P_s^2\sum_{n=2}^{\infty}n(n-1)h_n(T)P_s^{2(n-2)}\,. \tag{7}$$

Here the "ratio of temperature gradients of reciprocal susceptibility" p is defined by

$$p=\frac{d}{dT}\left(\frac{1}{\eta_F}\right)\Big]_{T=T_c-0}\Big/\frac{d}{dT}\left(\frac{1}{\eta_P}\right)\Big]_{T=T_c+0}\,. \tag{8}$$

Eqs. (6) and (7) give

$$p=\frac{2}{\{dh_1(T)/dT\}}\left\{P_s^2\sum_{n=2}^{\infty}n(n-1)\frac{dh_n(T)}{dT}P_s^{2(n-2)}+\sum_{n=2}^{\infty}n(n-1)^2h_n(T)P_s^{2(n-2)}\frac{dP_s^2}{dT}\right\}\Big]_{T=T_c-0}\,, \tag{9}$$

or by Eq. (4) p is further rewritten as

$$p=\frac{2}{\{dh_1(T)/dT\}}\left\{P_s^2\sum_{n=2}^{\infty}n(n-1)\frac{dh_n(T)}{dT}P_s^{2(n-2)}\right.$$
$$\left.-\frac{\left(\sum_{n=1}^{\infty}n\frac{dh_n(T)}{dT}P_s^{2(n-1)}\right)\left(\sum_{n=2}^{\infty}n(n-1)^2h_n(T)P_s^{2(n-2)}\right)}{\sum_{n=2}^{\infty}n(n-1)h_n(T)P_s^{2(n-2)}}\right\}\Bigg]_{T=T_c-0}\,. \tag{10}$$

Values of p of several substances known as ferroelectrics are listed in Table I. It is noticed that there are three groups, i.e., the first group with p of about -10, the second group with p of about -2 and the third group with p considerably smaller than -2 in the absolute values.

§ 3. The Second-Order Transition

As is well-known, the phase transition is of the second order under the conditions

$$h_1(T)=h_1^0(T-T_0) \qquad (h_1^0>0)\,, \tag{11a}$$

$$h_2=\text{const.}>0\,, \tag{11b}$$

and

$$h_n=0 \qquad (n\geq 3)\,, \tag{11c}$$

and the following equations are readily obtained, giving the two linear relations of $1/\eta$ *vs* T as shown in Fig. 1:

$$1/\eta_P=4h_1\,, \tag{12}$$

$$1/\eta_F=-8h_1\,. \tag{13}$$

The ratio of their gradients is always $-2:1$.

Now, the conditions (11a)~(11c) are too severe and following two conditions will be sufficient for the transition to be of the second order;

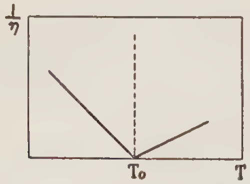

Fig. 1. Schematic variation of reciprocal susceptibility *vs* temperature for the second-order transition under the conditions (11).

(i) $h_1(T)$ has a positive temperature dependence and vanishes at a temperature T_0; and

(ii) $h_2(T_0)>0$ ($h_2(T)$ may have any temperature dependence).

We now take into account every terms of Eq. (1) and give arbitrary temperature dependencies to every coefficients under the single condition that the transition be of the second order.

Since the transition is of the second order we have $P_s^2(T_c)=0$ at $T=T_c=T_0$, and hence from Eq. (10) it is readily seen that

$$p=-2\,. \tag{14}$$

It has been well-known that Eq. (14) holds under the severe conditions (11a)~(11c), but now it should be stressed-on that Eq. (14) is really a universal relation valid very generally with a sole restriction that the transition is of the second order, no matter how many number of terms of expansion may be taken into account or whatever temperature dependence may be postulated for each coefficient.

As is seen from Eq. (6) $1/\eta_P$ is independent of the coefficients higher than $h_1(T)$, and hence $1/\eta_P$ *vs* T is always a straight line as far as the linear temperature dependence (11a) is postulated for $h_1(T)$. $1/\eta_F$ *vs* T will generally deviate from a straight line, but, if the expansion is stopped at the fourth-power term, Eq. (13) will hold even when the coefficient of the fourth-power term is temperature-dependent, as is seen by introducing Eq. (4) into Eq. (7), and hence $1/\eta^F$ *vs* T gives a straight line as far as Eq. (11a) is valid.

§ 4. The First-Order Transition

It is well-known that the transition is of the first order under postulations

$$h_1(T)=h_1^0(T-T_0) \qquad (h_1^0>0)\,, \tag{15a}$$

$$h_2=\text{const.}<0\,, \tag{15b}$$

$$h_3=\text{const.}>0\,, \tag{15c}$$

and

$$h_n=0 \qquad (n\geq 4)\,, \tag{15d}$$

and that then the jump of the susceptibility at the transition follows the rule

$$\eta_F\Big]_{T=T_c-0}\Big/\ \eta_P\Big]_{T=T_c+0}=1/4\,. \tag{16}$$

$1/\eta_F$ is now no longer a linear function of T even in this simplified case. Eq. (7) can be rewritten by use of Eq. (4) as

$$1/\eta_F=-16h_1(T)+\frac{16}{3}\frac{h_2^2}{h_3}\left(1+\sqrt{1-\frac{h_3}{h_2^2}3h_1(T)}\right) \tag{17}$$

and its temperature coefficient is given by

$$d(1/\eta_F)/dT=-32\frac{dh_1(T)}{dT}\left(\frac{1}{2}+\frac{1}{4}\frac{1}{\sqrt{1-\frac{h_3}{h_2^2}3h_1(T)}}\right). \tag{18}$$

From Eq. (18) it is readily seen that the value $\{d(1/\eta_F)/dT\}/\{dh_1(T)/dT\}$ decreases with decreasing temperature, the lower limit of which being given by an inequality

$$\frac{d(1/\eta_F)/dT}{dh_1(T)/dT} < -16\,. \tag{19}$$

As Eqs. (4) and (5) give

$$4h_1(T_c) = h_2^2/h_3 \tag{20}$$

at $T=T_c$, Eq. (18) readily gives

$$d(1/\eta_F)/dT\Big]_{T=T_c-0} = -32 dh_1(T)/dT\Big]_{T=T_c-0}$$

and, needless to say, Eq. (12) holds also for the first-order transition. Hence we have a remarkable result

$$p = -8 \tag{21}$$

which is valid independently of h_2 and h_3. The relation $1/\eta$ *vs* T is schematically shown in Fig. 2.

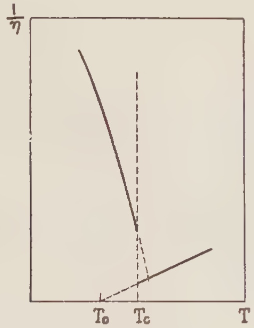

Fig. 2. Schematic variation of reciprocal susceptibility *vs* temperature for the first-order transition under the conditions (15).

Eq. (21) does not generally hold if the conditions (15) are loosened when the transition is of the first order. If temperature dependencies are postulated on h_2 and h_3, as an example of loosening the conditions (15b) and (15c), Eq. (10) gives

$$\left. p = -8\left\{1 - \frac{3}{4}\frac{dh_2(T)/dT}{dh_1(T)/dT}\frac{h_2(T)}{h_3(T)} + \frac{3}{8}\frac{dh_3(T)/dT}{dh_1(T)/dT}\left(\frac{h_2(T)}{h_3(T)}\right)^2\right\}\right]_{T=T_c}. \tag{22}$$

In another example in which a positive temperature-independent coefficient h_4 is introduced, while h_2 and h_3 are still assumed temperature-independent, we have

$$p = -10 + \frac{2}{\sqrt{1-3h_2h_4/h_3^2}}\,. \tag{23}$$

It can generally be said that p is rather sensitive to the form of the expansion of free energy when the transition is of the first order.

§ 5. Special Transitions

According as $h_2(T_c) \gtrless 0$, the transition becomes of the second order or of the first order, respectively. In this section, the intermediate case, i.e., $h_2(T_c)=0$ will be discussed.

(i) The second-order transition:

$$h_2(T_0) = 0\,, \tag{24a}$$

$$h_3(T_0) > 0\,, \tag{24b}$$

$$\text{no restriction on } h_n(T_0) \quad (n \geq 4)\,. \tag{24c}$$

Eq. (10) reduces to

$$p = -2\left.\frac{\sum_{n=2}^{\infty} n(n-1)^2 h_n(T) P_s^{2(n-2)}}{\sum_{n=2}^{\infty} n(n-1) h_n(T) P_s^{2(n-2)}}\right]_{T=T_c-0}, \tag{25}$$

for $P_s^2(T_c)=0$ when the transition is of the second order. Under the conditions (24), this equation results in

$$p = -4\,. \tag{26}$$

Under the more general conditions

$$h_n(T_0) = 0 \qquad (n = 1, 2, \cdots, N-1)\,, \tag{27a}$$

$$h_N(T_0) > 0\,, \tag{27b}$$

$$\text{no restriction on } h_n(T_0) \quad (n \geq N+1)\,, \tag{27c}$$

we have the generalized rule

$$p = -2(N-1)\,. \tag{28}$$

(ii) The first-order transition:

$$h_2 = 0\,, \tag{29a}$$

$$h_3 = \text{const.} < 0\,, \tag{29b}$$

$$h_4 = \text{const.} > 0\,, \tag{29c}$$

$$h_n = 0 \qquad (n \geq 5)\,. \tag{29d}$$

Although $P_s^2(T_0) \neq 0$ for the first-order transition, the fact that $dh_n/dT=0$ $(n \neq 1)$ makes Eq. (25) hold for this case, too. As Eqs. (4) and (5) give

$$P_s^2 = -\frac{2h_3}{3h_4} \qquad (T = T_c - 0)\,, \tag{30}$$

p can be readily calculated as

$$p = -12\,. \tag{31}$$

Under the more general conditions

$$h_n = 0 \qquad (n \neq N, n \neq M, M > N), \tag{32a}$$

$$h_N = \text{const.} < 0\,, \tag{32b}$$

$$h_M = \text{const.} > 0\,, \tag{32c}$$

Eqs. (4) and (5) give

$$P_s^{2(M-N)}(T_c) = -\frac{(N-1)h_N}{(M-1)h_M}, \tag{33}$$

and hence p is calculated as

$$p = -2(N+M-1). \tag{34}$$

It seems rather unlikely that the term next to the second-power one is not the fourth but the higher one in the expansion of the free energy, but there seems to be no reason for excluding such a postulation as a conventional expression for a *steep* potential in a phenomenological discussion. It is noteworthy that the absolute value of p is always increased in such a steep potential, compared to a usual one of non-vanishing fourth-power term, for both first- and second-order transitions.

§ 6. Antiferroelectricity

Kittel[3] phenomenologically treated the antiferroelectricity considering polarizations P_1 and P_2 of two equivalent sublattices. A discussion parallel to the preceding sections is possible for this case, being almost unaltered. The free energy per unit volume of an antiferroelectric is now expanded as

$$A(P_1, P_2, T) = A_0(T) + f(P_1^2 + P_2^2) + gP_1P_2 + \sum_{n=2}^{\infty} h_n(P_1^{2n} + P_2^{2n}). \tag{35}$$

When $g > 0$ a solution $P_1 = -P_2$ gives a lower free energy than the solution $P_1 = P_2$, causing an antiferroelectricity.

According as $h_2(T_c) \gtrless 0$, the transition is of the second or the first order respectively, provided that $2f - g$ has a positive temperature dependence. The magnitude of g is an index of the dominance of antiferroelectricity over ferroelectricity, and if it has a temperature dependence no simple relation is obtained for p.* For a discussion of antiferroelectricity, g is now postulated as temperature-independent, and then it can be shown again that the rule $p = -2$ holds for the second-order transition even when any number of terms are taken into account in the expansion and any temperature dependence is postulated for every coefficients. For the first-order transition, on the contrary, an expression of p is complex in general, but Eq. (21) holds under the conditions (15), whereas Eq. (16) does not.

§ 7. Discussions

It has been found that p is always equal to -2 when the transition is of the second order except in the very special cases discussed in § 5. This is indeed supported by the fact that values of p of the second group in Table I are near -2. It can be concluded, therefore, that the value of p is very insensitive to the functional form of free energy for the second-order transition. This result suggests that little will be gained by elaborating the functional form of free energy in a phenomenological discussion of a ferroelectric with the second-order transition.

In the case of the first-order transition, on the other hand, the situation is quite different and p is very sensitive to the functional form of free energy, and it takes the ideal value -8 only when the severe conditions (15) are imposed. Values of p of the first group in Table I are, nevertheless, rather close to -8. In the present stage it is uncertain whether this fact shows the validity of the severe conditions (15) or it is merely an "accidental" result of canceling of the deviations from Eq. (15) in several coefficients. Whichsoever the true explanation may be, it seems difficult to seek the physical meaning of each term of such an expansion because of at least two facts; i.e., that the value of p is affected very sensitively by the functional form of expansion, and that each term of the expansion has the same order of magnitude showing no tendency of convergence. The circumstance that many terms are needed to reasonably explain the various relations at the phase transition seems to show an evidence of a limit of phenomenological theory in this direction of progress.

It is interesting to note that p of the second group in Table I have a general tendency of deviating from -2, the theoretical value, towards larger side in the absolute value. Hoshino *et al*[14] insisted that the absolute value of p of $(CH_2NH_2COOH)_3 \cdot H_2SO_4$ is larger than 2 because of the domain clamping which reduces the dielectric constant in the ferroelectric phase, and a similar deviation in the case of $CaB_3O_4(OH)_3 \cdot H_2O$ was attributed by Wieder[12] to a thermodynamical fact that the adiabatic dielectric constant is smaller than the isothermal one in the ferroelectric phase. A variety of reasons causing the deviation

---

* In this case, p is defined by

$$p = d(1/\eta_{AF})/dT \Big]_{T=T_c-0} \Big/ d(1/\eta_P)/dT \Big]_{T=T_c+0}.$$

of p from -2 may be considered. The values of p of the third group in Table I are less than 2 in the absolute value. These values do not seem to have a simple explanation.

Fermi Momentum for Free Electron Metals Perturbed by Localized Imperfections

By Akira SUGIYAMA

Nagoya Technical College, Nagoya

(Received June 4, 1960)

The Fermi momentum k_m and the interior density ρ_i are calculated for free electron metals perturbed by localized imperfections, and the Thomas-Fermi relation $\rho_i = k_m^3/3\pi^2$ is verified up to the higher order. Then it is shown that the Friedel theorem can be based on the above relation. When the Fermi momentum k_m is expressed in terms of the phase shift η of the free electron wave function, the charge neutrality condition in the interior leads to the Friedel sum rule for the case of the plane surface as well as of the point imperfection.

§1. Introduction

As for the heap up charge of free electrons around a localized imperfection in metals, Friedel[1-3] suggested a theorem, which plays an important role in the theory of imperfections[4-8].

In treating the heap up charge he did not discuss directly the complicated behaviour of the electron density around the imperfection, but took account of the effect of the imperfection on the almost uniform density in the region far from the imperfection where the perturbation potential due to the imperfection vanishes but the effect is integrated to give the phase shift of the electron wave function.

It is important in his treatment that the uniform density in the interior should be discussed up to higher orders. But he based his theorem on the Weyl-Laue theorem[9], which is not valid up to the higher order that he required. And therefore his verifications are not considered to be rigorous. Plaskett[10] investigated the validity of the Friedel theorem for the one-dimensional metal, but he made use of a somewhat ambiguous averaging process.

The main purpose of the present paper is to verify the Friedel theorem based upon the Thomas-Fermi relation between the interior density ρ_i and the Fermi momentum*) k_m for the perturbed electron gas, because the Thomas-Fermi relation in the interior, not the Weyl-Laue theorem, can be proved to be valid up to the required higher order. Some of the relations of which use were made beforehand in the previous paper[11] (hereafter referred to as I) are verified in this paper.

§ 2. Model and Formulation of the Problem

The notations and the model in the present paper are the same as those in I; we regard the metal as the system composed of the jelly of positive charge having the volume V_0 and the uniform density ρ_0 and of the assembly of N_0 $(=\rho_0 V_0)$ free electrons. For the free electron gas in a potential box bounded by the infinite wall the ordinary Weyl-Laue theorem is true; the number $N(k)$ of the electronic states of momentum smaller than k is given as $k^3V/3\pi^2$, where V is the volume of the box, independently of its concrete shape.

Now we consider the effect of a localized imperfection on the distribution of the free electrons. It can be studied, without so great loss of generality, by investigating the influence of some appropriate surface potential barrier; for example, even the potential due to an atomic vacancy can be regarded as the one due to a cavity surface.

In this case, as was pointed out in I, we make use of the more precise expression for the Weyl-Laue theorem $N(k)\simeq k^3V/3\pi^2-k^2S/8\pi$, where S is the area of the boundary surface. From this expression it appears that we can straightforwardly conclude the relation

$$N(k_m)=\rho_i V-Q_0 S\ , \tag{2.1}$$

where the interior density $\rho_i=k_m{}^3/3\pi^2$ and the charge expelled from unit area of the infinite wall $Q_0=k_m{}^2/8\pi$; the validity of the relation (2.1), however, is not self-evident, but is required to be verified.

When the infinite wall is replaced by a more realistic potential barrier, the situation is more complicated, where we have no clear-cut definition of the volume and of the Fermi momentum. The volume is clearly defined only in the case of a step potential barrier. The potential barrier gives rise to a phase shift in the electron wave, and results in deforming the quantized points in the $\boldsymbol{k}$-space. The exact Fermi momentum k_m must be calculated for this deformed lattice.

Accordingly we must consider the following points:

(1) Order of the validity of the Thomas-Fermi relation in the interior for the electron gas bounded by the infinite wall.

(2) The relation between the Fermi distribution in the case of the infinite wall and that in the case of any other potential barrier.

(3) The validity of the Thomas-Fermi relation for the electron gas bounded by any surface potential barrier.

(4) The explicit expressions both for the Fermi momentum and for the interior density in terms of the phase shift.

(5) The rigorous verification of the Friedel theorem and his sum rule.

For simplicity we shall discuss mainly the the system bounded by the plane surface, say the plate metal with the finite width L_0 in the x-direction and infinite in the other two directions.

We start with the case of the infinite wall potential $V^{(1)}(x)$ which is infinite on the edge planes $x=0$ and L_0. Imposing the usual cyclic boundary condition of the period L_1 in the y and the z directions, we get the wave function $\psi^{(1)}(\boldsymbol{k},\ \boldsymbol{r})$, for the free electron, which is obtained by replacing L in Eq. (2.17) of I by L_0, as $\chi^{(1)}(k_x,\ x)\ =\sqrt{2/L_0}\sin(k_x x)$ etc.

Then we consider the case of the surface potential barrier $V^{(*)}(\boldsymbol{r})=V^{(*)}(x)$, which has the symmetry with respect to the midpoint $x_c=L_0/2$ and vanishes in the sufficient interior of the system and exceeds the Fermi energy $k_m{}^2/2$ outside the system. The wave function is expressed as

$$\psi^{(*)}(\boldsymbol{k},\ \boldsymbol{r})=\{1+\delta(k_x)\}\cdot\chi^{(*)}(k_x,\ x)\cdot(1/L_1)\cdot\exp i(k_y y+k_z z)\ , \tag{2.2}$$

---

*) Atomic units are used.

where

$$\delta(k_x) = -\frac{1}{L_0}\frac{\partial}{\partial k_x}\eta(k_x)\ , \tag{2.3}$$

and $\eta(k_x)$ is the phase shift. In terms of $\eta(k_x)$, $\chi^{(*)}$ is expressed as $\sqrt{2/L_0}\cdot\sin\{k_x x+\eta(k_x)\}$ in the interior of the metal. The relation (2.3) is deduced in the appendix.

§ 3. The Thomas-Fermi Relation in the Case of the Infinite Wall

In the case of the infinite wall the wave vector is quantized to be $\boldsymbol{k}^{(1)}(\boldsymbol{n})$; $k_x^{(1)}=(\pi/L_0)\cdot n_x$, $n_x=+1,\ +2,\ \cdots$, $k_y^{(1)}=(2\pi/L_1)n_y$, $n_y=0,\ \pm1,\ \pm2,\ \cdots$, etc. The Fermi momentum $k_m^{(1)}$ is determined by the equation

$$N^{(1)}(k_m^{(1)}) = N_0(=k_F^3 L_0 L_1^2/3\pi^2)\ , \tag{3.1}$$

where $N^{(1)}(k)$ represents the number of states of momentum smaller than k in this case and $k_F=(3\pi^2\rho_0)^{1/3}$, defined by the positive charge density ρ_0 or by the total number N_0 of free electrons, is the Fermi momentum for the uniform electron gas. Since $N^{(1)}(k_m)$ has been obtained as Eq. (2.19) in I, we have

$$k_m^{(1)} = k_F + \frac{\pi}{4L_0} = k_F\left(1+\frac{\pi}{4L_0 k_F}\right). \tag{3.2}$$

The density of the electron gas $\rho^{(1)}(\boldsymbol{r})$ is obtained by replacing L in Eq. (2.21) of I by L_0. And we get the interior density

$$\rho_i^{(1)} = \frac{k_F^3}{3\pi^2}+\frac{k_F^2}{4\pi L_0} = \rho_0+\frac{k_F^2}{4\pi L_0}\ ,$$

and then

$$= k_m^{(1)3}/3\pi^2\ . \tag{3.3}$$

Thus the Thomas-Fermi relation is verified up to the first order in $1/L_0 k_F$ $(=S/V\cdot k_F)$, and therefore the validity of the relation (2.1) is verified.

§ 4. The Thomas-Fermi Relation in the Case of Any Surface Potential Barrier

Now we consider the case of any potential barrier $V^{*}(x)$. The wave vector is expressed as the lattice point $\boldsymbol{k}^{(*)}(\boldsymbol{n})$ deformed from $\boldsymbol{k}^{(1)}(\boldsymbol{n})$;

$$\boldsymbol{k}^{(*)}(\boldsymbol{n}) = \boldsymbol{k}^{(1)}(\boldsymbol{n})+\Delta\boldsymbol{k}\ ,$$

where

$$(\Delta\boldsymbol{k})_x = -\frac{2}{L_0}\eta(k_x^{(*)}) \simeq -\frac{2}{L_0}\eta(k_x^{(1)})\ , \qquad (\Delta\boldsymbol{k})_y=(\Delta\boldsymbol{k})_z=0\ . \tag{4.1}$$

Further we assume that the potential does not trap any electrons; and then

$$\eta(0)=0\ . \tag{4.2}$$

4.1 Fermi momentum

In the approximation of the first order in $1/L_0 k_F$, we obtain

$$\begin{aligned} N^{(*)}(k) &= \frac{L_1^2}{2\pi}\sum_{n_x=1}^{n_1}\{k^2-k_x^{(*)2}(n_x)\} \\ &= \frac{k^3}{3\pi^2}L_0 L_1^2-\frac{k^2}{4\pi}L_1^2+\frac{2L_1^2}{\pi^2}\int_0^k \eta(k_x)\cdot k_x\,dk_x\ , \end{aligned} \tag{4.3}$$

where n_1 is given by $k_x^{(*)}(n_1)=k$. Similarly to $k_m^{(1)}$, we can determine the Fermi momentum

$k_m^{(*)}$ from $N^{(*)}(k_m^{(*)})=N_0$ as

$$k_m^{(*)}=k_m^{(1)}(1+\mathcal{E}) ,$$

where

$$\mathcal{E}\fallingdotseq-\frac{2}{L_0k_F^3}\cdot\int_0^{k_F}\eta(k_x)\cdot k_x\,dk_x ,$$

or

$$k_m^{(*)}=k_F+\frac{2}{L_0}\left\{\frac{\pi}{8}-\frac{1}{k_F^2}\int_0^{k_F}\eta(k_x)\cdot k_x\,dk_x\right\} . \tag{4.4}$$

Then we investigate the relation between the Fermi distributions in the cases of $V^{(1)}(x)$ and of $V^{(*)}(x)$, and examine the correctness of the usual assumption that the Fermi distribution in the $\boldsymbol{n}$-space is preserved when we replace $V^{(1)}$ by $V^{(*)}$.

A lattice point $\boldsymbol{n}$ corresponds to $\boldsymbol{k}^{(1)}(\boldsymbol{n})$ and to $\boldsymbol{k}^{(*)}(\boldsymbol{n})$, respectively in the case of $V^{(1)}$ and $V^{(*)}$. If the Fermi distribution in the $\boldsymbol{n}$-space be preserved, the one-to-one correspondence can hold between the lattice points in the $\boldsymbol{k}$-space in the Fermi distribution for $V^{(1)}$ and those for $V^{(*)}$. But this is not true, since the Fermi distribution is spherical in the $\boldsymbol{k}$-space in both cases. In fact, the Fermi top in the $\boldsymbol{n}$-space is not preserved; it is $n_1^{(1)}=L_0k_m^{(1)}/\pi$ in the n_x-direction and $n_2^{(1)}=L_1k_m^{(1)}/2\pi$ in the n_y and n_z-directions in the case of $V^{(1)}$, but $n_1^{(*)}=n_1^{(1)}[1+\mathcal{E}+\{2\eta(k_F)/L_0k_F\}]$ and $n_2^{(*)}=n_2^{(1)}(1+\mathcal{E})$ in the case of $V^{(*)}$.

To the approximation of the first order in $1/L_0k_F$, however, the one-to-one correspondence holds, and then the Fermi distribution in the $\boldsymbol{n}$-space is preserved. It can be verified as follows.

If we assume the validity of the one-to-one correspondence, the Fermi surface in the $\boldsymbol{k}$-space for $V^{(*)}$ is obtained from the Fermi sphere for $V^{(1)}$ by the correspondence of $\boldsymbol{k}^{(1)}(\boldsymbol{n})$ to $\boldsymbol{k}^{(*)}(\boldsymbol{n})$. Therefore the perturbation energy ΔE_p is obtained conventionally by summing the energy change $\boldsymbol{k}^{(1)}\Delta\boldsymbol{k}$ over the preserved Fermi distribution in the $\boldsymbol{n}$-space;

$$\Delta E_p=\frac{L_0}{\pi}\cdot\int_0^{k_F}k_x\cdot(\Delta\boldsymbol{k})_x\cdot\frac{L_1^2}{2\pi}(k_F^2-k_x^2)\cdot dk_x=-\frac{L_1^2}{\pi^2}\int_0^{k_F}\eta(k_x)\cdot k_x(k_F^2-k_x^2)\cdot dk_x . \tag{4.5}$$

On the other hand, we can obtain ΔE_p more exactly as the difference between the ground state energy $E^{(1)}$ in the case of $V^{(1)}$ and that $E^{(*)}$ in the case of $V^{(*)}$, which are calculated from the expressions for $N^{(1)}(k)$ and $N^{(*)}(k)$ as

$$\left.\begin{aligned}
E^{(1)}&=\int_0^{k_m^{(1)}}\frac{1}{2}k^2\frac{\partial N^{(1)}}{\partial k}dk=\frac{k_F^5}{10\pi^2}L_0L_1^2+\frac{k_F^4}{16\pi}L_1^2 ,\\
E^{(*)}&=\int_0^{k_m^{(*)}}\frac{1}{2}k^2\frac{\partial N^{(*)}}{\partial k}dk=\frac{k_F^5}{10\pi^2}L_0L_1^2\\
&\qquad+2L_1^2\left\{\frac{k_F^4}{32\pi}-\frac{1}{2\pi^2}\int_0^{k_F}\eta(k_x)\cdot k_x(k_F^2-k_x^2)\cdot dk_x\right\} ,
\end{aligned}\right\} \tag{4.6}$$

where we use Eqs. (3.2) and (4.4) respectively. The difference $E^{(*)}-E^{(1)}$ agrees with the conventionally calculated ΔE_p. Thus the assumption has been proved to be valid, and then we can regard the deformed sphere as an approximate Fermi distribution in the case of $V^{(*)}$.

Although it seems rather artificial to consider such deformed Fermi sphere, it is convenient to calculate ΔE_p and advantageous in the point; (i) we can replace the summation by an approximate integral over the preserved Fermi distribution in the $\boldsymbol{n}$-space, (ii) we can apply to the case of the point imperfection.

Then we shall give the definition of the average Fermi momentum over the deformed Fermi sphere. We start with a simple deformation, a uniform expansion, of the lattices caused by the addition of Z electrons or by the contraction of the potential box in the x-direction by $2b$. Such perturbation causes the Fermi sphere to expand uniformly by Δk_m and the interior density to increase by $\Delta\rho_i$. These changes are connected by the relation

$$\Delta\rho_i = \frac{k_m^{(1)2}}{\pi^2}\Delta k_m \simeq \frac{k_F^2}{\pi^2}\Delta k_m\,, \tag{4.7}$$

where

$$\Delta\rho_i = Z/L_0L_1^2\,, \quad \text{and} \quad 2b\rho_i/L_0\,,$$

respectively in the case of the addition and of the contraction. In order to generalize Eq. (4.7) to more complicated deformations, we rewrite $\Delta\rho_i$ as

$$\Delta\rho_i = \frac{1}{2\pi^3}\cdot\Delta k_m\iint d\omega = \frac{1}{2\pi^3}\cdot\iint(\Delta\boldsymbol{k}_m)_n d\omega\,,$$

where $d\omega$ is the surface element on the Fermi (hemi-) sphere and $(\Delta\boldsymbol{k}_m)_n$ is the component of the displacement normal to the Fermi surface, the integral being carried out over the Fermi surface. Then it is reasonable to define the average displacement $\langle\Delta k_m\rangle$ and consequently the average Fermi momentum $\langle k_m^{(*)}\rangle$ as

$$\langle\Delta k_m\rangle = \frac{\iint(\Delta\boldsymbol{k}_m)_n\,d\omega}{\iint d\omega} = \frac{1}{2\pi k_F^2}\iint(\Delta\boldsymbol{k}_m)_n d\omega \tag{4.8}$$

and

$$\langle k_m^{(*)}\rangle = k_m^{(1)} + \langle\Delta k_m\rangle\,, \tag{4.9}$$

in a general case where $(\Delta\boldsymbol{k}_m)_n$ may depend on the directions. The validity of the definition is proved as follows: Since $(\Delta\boldsymbol{k}_m)_n = -(2/L_0)\cdot\eta(k_x)\cdot k_x/k_F$ and the surface element between k_x and k_x+dk_x is $2\pi k_F dk_x$, we have

$$\langle\Delta k_m\rangle = -\frac{2}{L_0k_F^2}\int_0^{k_F}\eta(k_x)k_x dk_x\,.$$

This gives the same expression for $\langle k_m^{(*)}\rangle$ as $k_m^{(*)}$ given by Eq. (4.4). Thus the validity has been verified.

The relation (4.7) is also valid for $\langle\Delta k_m\rangle$ as well as for Δk_m. In terms of $\rho_i^{(*)} = \rho_i^{(1)} + \Delta\rho_i$, it is rewritten as $\rho_i^{(*)} = \langle k_m^{(*)}\rangle^3/3\pi^2$, which will be verified in the next section.

4.2 Interior density

The free electron density $\rho^{(*)}(\boldsymbol{r})$ in the case of $V^{(*)}$, defined as

$$\rho^{(*)}(\boldsymbol{r}) = \rho^{(*)}(x) = \frac{1}{2\pi}\sum_{n_x=1}^{n_1^{(*)}}\{1+\delta(k_x^{(*)}(n_x))\}^2|\chi^{(*)}(k_x^{(*)}(n_x),\ x)|^2\{k_m^{(*)2} - k_x^{(*)2}(n_x)\}\,,$$

cannot be expressed in a simpler form. But the asymptotic behaviour $\rho_i^{(*)}$ in the interior can be reduced to a simple expression in terms of the phase shift up to the first order in $1/L_0k_F$ as follows.

Making use of the approximation

$$\{1+\delta(k_x^{(*)})\}^2\cdot|\chi^{(*)}|^2 \simeq |\chi^{(1)}|^2 + (|\chi^{(*)}|^2 - |\chi^{(1)}|^2) + 2\delta(k_x^{(*)})\cdot|\chi^{(*)}|^2\,,$$

we divide the summation into three parts. The first part including $|\chi^{(1)}|^2$,

$$\frac{1}{\pi L_0}\sum\{k_m^{(*)2} - k_x^{(1)2}(n_x) + \frac{4}{L_0}k_x^{(1)}(n_x)\cdot\eta(k_x^{(1)})\}\cdot\sin^2\{k_x^{(1)}(n_x)\cdot x\}$$

is reduced in the interior to

$$\frac{k_m^{(*)3}}{3\pi^2} + \frac{2}{\pi^2L_0}\cdot\int_0^{k_F}\eta(k_x)\cdot k_x dk_x - \frac{2}{\pi L_0^2}\cdot\sum\eta(k_x^{(1)})\cdot k_x^{(1)}(n_x)\cdot\cos(2k_x^{(1)}x)\,,$$

and the second and the third parts are approximated by

$$\frac{1}{\pi L_0}\cdot\sum\left(k_m^{(1)2}-k_x^{(1)2}\right)\cdot\sin\left\{\eta(k_x^{(1)})\cdot\left(1-\frac{2x}{L_0}\right)\right\}\cdot\sin\left\{2k_x^{(1)}x+\eta(k_x^{(1)})\cdot\left(1-\frac{2x}{L_0}\right)\right\},$$

and

$$\frac{1}{\pi^2}\int_0^{k_F}\delta(k_x)\cdot(k_F^2-k_x^2)\cdot dk_x-\frac{1}{\pi L_0}\sum\delta(k_x^{(1)})\cdot(k_m^{(1)2}-k_x^{(1)2})\cdot\cos\left\{2k_x^{(1)}x+2\eta(k_x^{(1)})\left(1-\frac{2x}{L_0}\right)\right\}.$$

Then we investigate $\lim_{x\to\infty}\rho^{(*)}(x)$, where x/L_0 is kept to be a constant C. In these three parts, we meet terms of the type

$$S(N)=\sum_{n=1}^{N}f\left(\frac{n}{N}\right)\cdot\sin\left\{2\pi Cn+g\left(\frac{n}{N}\right)\right\}$$

with smooth functions $f(x)$ and $g(x)$. This sum has the properties

$$\left.\begin{aligned}&\lim_{N\to\infty}S(N)/N=0\,,\\ \text{and, when } f(0)=f(1)=0\,,\quad&\\ &\lim_{N\to\infty}S(N)=0\,.\end{aligned}\right\}\tag{4.10}$$

Making use of Eqs. (2.3), (4.2) and (4.10), we obtain

$$\rho_i^{(*)}=\lim_{x\to\infty}\rho^{(*)}(x)=k_m^{(*)3}/3\pi^2\,,\tag{4.11}$$

or, from Eq. (4.4), rewrite this as

$$\rho_i^{(*)}=\rho_i^{(1)}-\frac{2}{\pi^2L_0}\int_0^{k_F}\eta(k_x)\cdot k_xdk_x=\rho_0+\frac{2}{\pi^2L_0}\left\{\frac{\pi}{8}k_F^2-\int_0^{k_F}\eta(k_x)\cdot k_xdk_x\right\}.\tag{4.12}$$

Thus the Thomas-Fermi relation has been verified in the interior up to the first order in $1/L_0k_F$.

§ 5. Rigorous Verification of the Friedel Theorem

So far we have considered the effect of the perturbation potential of a given form upon the electron density and the Fermi distribution. However, a localized imperfection is specified not by a perturbation potential but by an arrangement of the positive ions, or by an approximate distribution of the positive jelly. And the perturbation potential due to the imperfection ought to be determined by taking account not only of change in the positive jelly but also of the screening effect of the electron gas self-consistently.

Friedel investigated the condition under which the perturbation on the free electron should be localized around the imperfection, and could formulate the condition as the Friedel theorem, which can be stated as follows:

(i) *Localization.* Far from the imperfection, the density of the free electron gas tends to a (almost) constant value $\rho_i=k_m^3/3\pi^2$.

(ii) *Preservation of the Fermi momentum.* The coulomb field due to a localized imperfection should be completely screened by the perturbed electron gas. The charge of the electron gas, therefore, should be neutralized in the region far from the imperfection by the charge of the positive jelly; $\rho_i=\rho_0$, or $k_m=k_F$. The latter is called the Friedel theorem in a strict sense.

(iii) *Sum rule.* For a (isotropic) point imperfection in a spherical metal of large radius R, the heap up charge Q of the electrons around the imperfection is expressed as

$$Q=\frac{2}{\pi}\cdot\sum_{l=0}^{\infty}(2l+1)\cdot\eta_l(k_F)\,,\tag{5.1}$$

where η_l is the phase shift of the electrons in the l-state.

This theorem has been explained by Friedel in various ways[1-3]. But he did not consider so carefully to which order the equations $\rho_i=k_m^3/3\pi^2$ and $k_m=k_F$ are valid. In order to deduce the sum rule he developed two different methods.

(a) He expressed[2] the contribution $(\varDelta Q)_l$ of the l-electrons to Q as

$$(\varDelta Q)_l=\frac{1}{R}\frac{\partial}{\partial k}\eta_l(k)\,. \tag{5.2}$$

Summing this over all electrons, he derived Eq. (5.1). Although Eq. (5.2) has a wide applicability, his deduction was not rigorous, since he did not relate $\partial\eta_l/\partial k$ with the change in the normalization factor.

(b) As another proof, he showed[1] that Eq. (5.1) can be obtained by summing $(2R/\pi)\cdot(\eta_l(k_F)/R)\cdot(2l+1)$ over all l-states, where $\eta_l(k_F)/R$ is the displacement of the Fermi momentum for the l-electrons and $2R/\pi$ is the state density in regard to k for $l\ll Rk$. In this method, however, the ordinary Weyl-Laue theorem is implicitly assumed to be valid up to the higher order.

We shall now attempt a more rigorous verification of the Friedel theorem. From the preceding discussion about the plane surface it follows that the relation $\rho_i=k_m^3/3\pi^2$ is valid up to the first order in $S/V\cdot k_F$. This will be generalized to any localized imperfections. And the long-range nature of the coulomb force also requires the validity of $k_m=k_F$ at least up to the first order*) in $S/V\cdot k_F$. The preceding discussion also shows that it is possible to replace the Fermi momemtum in (i) and (ii) by the average Fermi momentum. For detailed treatment of (iii) we classify the imperfections into two types.

5.1 Plane surface potential

Now we assume that the Friedel formula (5.2) is applicable also to the surface potential barrier. Then the contribution $\varDelta Q$ of the electron of momentum $\boldsymbol{k}$ to the heap up charge Q per unit area of the surface will be expressed as

$$\varDelta Q=\frac{1}{L_0}\frac{\partial}{\partial k_x}\eta(k_x)\,, \tag{5.3}$$

and then

$$Q=\varSigma\varDelta Q=\frac{1}{2\pi^2}\int_0^{k_F}\frac{\partial\eta}{\partial k_x}\cdot(k_F{}^2-k_x{}^2)dk_x=\frac{1}{\pi^2}\int_0^{k_F}\eta(k_x)k_xdk_x\,,$$

where we use Eq. (4.2).

Since the infinite wall expels $Q_0=k_F{}^2/8\pi$ per unit area, the total heap up charge is $Q-Q_0$. The charge neutrality condition in the interior requires $Q=Q_0$, and is expressed as

$$\int_0^{k_F}\eta(k_x)\cdot k_xdk_x=\pi k_F{}^2/8\,. \tag{5.4}$$

This is correct, because this is derived by substituting $\rho_i{}^{(*)}=\rho_0$ in Eq. (4.12) and also by inserting $k_m{}^{(*)}=k_F$ in Eq. (4.4). Accordingly the formula (5.3) has been verified.

5.2 Point imperfection

The verification of the Friedel theorem proceeds similarly to the case of the plane surface barrier, except that the sums of trigonometrical functions in the latter case are replaced by those of Bessel functions. The summation involves more complicated calculations. And then we shall investigate only the outline of the verification.

We start with a free electron metal bounded by a spherical infinite wall of radius R. The radial part of the wave function is given by $N_l(k)\cdot J_{(l+1/2)}(k\cdot r)$, where N_l is the normalization factor and J_ν is the Bessel function of ν-th order. Then we introduce an isotropic imperfection at the center of the metal. The radial part of the wave function in the region far from the center and the outer boundary becomes

---

*) More exactly, $\lim\limits_{L_0\to\infty}(\rho_i-\rho_0)\cdot L_0{}^{3/2}=0$ for the plane surface and $\lim\limits_{R\to\infty}(\rho_i-\rho_0)\cdot R^{5/2}=0$ for the point imperfection.

$$N_l(k)\left\{1-\frac{1}{R}\cdot\frac{\partial}{\partial k}\eta_l(k)\right\}\{J_{(l+1/2)}(k\cdot r)-(-)^{l+1}\cdot\tan\eta_l\cdot J_{-(l+1/2)}(k\cdot r)\},$$

just as in the case of the plane surface barrier.

The imperfection changes the Fermi momentum of the l-electrons by $(\varDelta k_m)_l$. Since the state density of the l-electrons with regard to k is $(2R/\pi)\cdot\sin\tau(k)$, where $\cos\tau(k)=(2l+1)/2Rk$, the average Fermi momentum should be defined as

$$\langle k_m\rangle=k_F+\langle\varDelta k_m\rangle,$$

where

$$\langle\varDelta k_m\rangle=\frac{\Sigma(2l+1)\sin\tau(k_F)\cdot(\varDelta k_m)_l}{\Sigma(2l+1)\sin\tau(k_F)}=\frac{3}{2}\frac{1}{(R\cdot k_F)^2}\sum_{l=0}^{Rk_F}(2l+1)\{\sin\tau(k_F)\}\cdot(\varDelta k_m)_l\,. \tag{5.5}$$

The displacement $(\varDelta k_m)_l$ for an isotropic imperfection is expressed in terms of the phase shift $\eta_l(k)$ as $(\varDelta k_m)_l=-\eta_l(k_m)/R\simeq-\eta_l(k_F)/R$. The linear dimension D of the imperfection is assumed to be far smaller than R. This, together with the properties $\eta_l\simeq 0$ for $l\gg Dk_F$, permits the approximation

$$\sum_{l=0}^{Rk_F}(2l+1)\cdot\eta_l(k_F)\sin\tau(k_F)\simeq\sum_{l=0}^{Dk_F}(2l+1)\cdot\eta_l(k_F)\simeq\sum_{l=0}^{\infty}(2l+1)\cdot\eta_l(k_F)\,,$$

and then

$$\langle\varDelta k_m\rangle=-\frac{3}{2R^3k_F^2}\sum_{l=0}^{\infty}(2l+1)\cdot\eta_l(k_F)\,. \tag{5.6}$$

Just as in the case of the plane surface potential barrier, we assume the validity both of the Thomas-Fermi relation in the region far from the center and the boundary and of the relation (5.6). Then we can get $\varDelta\rho_i=k_F^2\langle\varDelta k_m\rangle/\pi^2$ again. Since the decrease in the interior density should be attributed to the heap up of electrons around the localized imperfection at the center, we get the heap up of electrons as

$$Q=-V\cdot\varDelta\rho_i=-\frac{4}{3\pi}\cdot R^3k_F^2\langle\varDelta k_m\rangle=\frac{2}{\pi}\sum_{l=0}^{\infty}(2l+1)\cdot\eta_l(k_F)\,, \tag{5.7}$$

verifying the Friedel sum rule.

When an impurity atom with $(1+Z)$ valency is introduced in monovalent metals, the Friedel theorem requires that $\langle\varDelta k_m\rangle=0$. This is rewritten as the usual Friedel sum rule

$$Z=\frac{2}{\pi}\sum_{l=0}^{\infty}(2l+1)\cdot\eta_l(k_F)\,, \tag{5.8}$$

because the displacement $\langle\varDelta k_m\rangle$ is composed of two terms; the first $\langle\varDelta k_m\rangle_1$, caused by the increase of Z free electrons, is

$$\langle\varDelta k_m\rangle_1=\frac{\pi^2}{k_F^2}\frac{Z}{V}=\frac{3}{2R^3k_F^2}\cdot\frac{\pi}{2}\cdot Z\,,$$

and the second $\langle\varDelta k_m\rangle_2$, caused by the screened potential due to Z valency impurity ion, is given by Eq. (5.6). Equation $\langle\varDelta k_m\rangle_1+\langle\varDelta k_m\rangle_2=0$ leads to Eq. (5.8), and therefore the Friedel sum rule in the form (5.8) is proved to be an expression of the Friedel theorem in terms of the phase shift.

§ 6. Conclusion

The definite answers to five problems in § 2 have been given for the case where the localized imperfection is a plane surface. The effect of the surface potential barrier is integrated into the phase shift of the free electron wave in the interior. The phase shift affects both the Fermi momentum and the interior density. Eliminating the phase shift from the expressions for the Fermi momentum and for the interior density, we can find the familiar Thomas-Fermi relation between them.

The Friedel theorem can be based on the higher order validity of the Thomas-Fermi relation. The Friedel theorem and his sum rule are proved to be the results from the charge neutrality in the interior in terms of the Fermi momentum and of the phase shift, respectively.

The Friedel sum rule given by Eq. (5,4) for a plane surface, together with the expression (4.6) for the ground state energy, has played an important role in I. Strictly speaking, the present verification is restricted to the case of the plane surface. Therefore it is desirable that treatments[12] based on the orthodox perturbation theory should be carried out in the case of general imperfections.

Acknowledgement

Appendix. Deduction of Eq. (2.3)

From the symmetry of $\chi^{(*)}$ with respect to $x_c=L_0/2$, it follows that

$$\{1+\delta(k_x)\}^2\int_{-\infty}^{L_0/2}|\chi^{(*)}(k_x,\ x)|^2dx=\frac{1}{2}\,. \tag{A.1}$$

Since the perturbation is localized around the surface, we have $|\delta|\ll 1$ and then

$$\delta(k_x)\simeq\frac{1}{2}-\int_{-\infty}^{L_0/2}|\chi^{(*)}(k_x,\ x)|^2dx\,. \tag{A.2}$$

The integration can be carried out, in the way similar to Friedel's. The wave equation for $\chi^{(*)}$ is

$$\frac{1}{2}\frac{\partial^2}{\partial x^2}\chi^{(*)}(k_x,x)+\{E(\boldsymbol{k})-V^{(*)}(x)\}\cdot\chi^{(*)}(k_x,\ x)=0\,, \tag{A.3}$$

where

$$E(\boldsymbol{k})=|\boldsymbol{k}|^2/2\,.$$

Provided L_0 is so large that the eigen values are distributed almost continuously, we differentiate Eq. (A.3) with regard to k_x;

$$\frac{1}{2}\frac{\partial^3\chi^{(*)}}{\partial k_x\partial x^2}+\{E(\boldsymbol{k})-V^{(*)}(x)\}\frac{\partial\chi^{(*)}}{\partial k_x}+k_x\chi^{(*)}=0\,. \tag{A.4}$$

By subtracting $\chi^{(*)}$ times (A.4) from $\partial\chi^{(*)}/\partial k_x$ times (A.3) we get

$$\frac{1}{2}\frac{\partial}{\partial x}\left\{\frac{\partial\chi^{(*)}}{\partial x}\frac{\partial\chi^{(*)}}{\partial k_x}-\frac{\partial^2\chi^{(*)}}{\partial x\partial k_x}\chi^{(*)}\right\}=k_x\cdot\chi^{(*)2}\,. \tag{A.5}$$

Integrating Eq. (A.5) with regard to x, we have

$$k_x\int_{-\infty}^{L_0/2}|\chi^{(*)}|^2dx=k_x\left\{\frac{1}{2}+\frac{1}{L_0}\frac{\partial}{\partial k_x}\cdot\eta(k_x)\right\}, \tag{A.6}$$

where we use the behaviour of $\chi^{(*)}$ for $x\to-\infty$ and $x=L_0/2$. Then, from Eq. (A.2) it follows that

$$\delta(k_x)=-\frac{1}{L_0}\frac{\partial}{\partial k_x}\eta(k_x)\,. \tag{A.7}$$

Finally we treat a more general case where the surface barrier depends not only on x but also on $\boldsymbol{k}$. Now the potential has non-vanishing values in the interior. We obtain the phase shift $\eta(\boldsymbol{k})$ and energy eigen values $E(\boldsymbol{k})$ as somewhat complicated functions of $\boldsymbol{k}$. The previous results, however, are only little modified. We get

$$\delta(\boldsymbol{k})=-\frac{1}{L_0}\frac{\partial}{\partial k_x}\eta(\boldsymbol{k})\,,\qquad\text{and}\qquad(\Delta\boldsymbol{k})_x=-\frac{2}{L_0}\cdot\eta(\boldsymbol{k})\,,\qquad(\Delta\boldsymbol{k})_y=(\Delta\boldsymbol{k})_z=0\,,$$

as the generalization of Eqs. (2.3) and (4.1). The definitions (4.8) for $\langle\Delta k_m\rangle$ and (4.9) for $\langle k_m^{(*)}\rangle$ are still valid. For the charge neutrality condition (5.4), we obtain

$$\frac{1}{2\pi}\iiint\frac{\partial\eta}{\partial k_x}dk_xdk_ydk_z=\frac{\pi}{8}k_F^2\,,$$

where the integral is carried out over all occupied states, or, by making use of the Gauß theorem for the surface integral, we get

$$\frac{1}{2\pi k_F^2}\iint_{\text{Fermi surface}}(\Delta k_m)_n d\omega+\frac{\pi}{4L_0}=0$$

for the condition $\langle k_m^{(*)}\rangle=k_F$.

Antiferromagnetic Resonance in $CoCl_26H_2O$

By Muneyuki DATE
Department of Physics, Faculty of Science, Osaka University, Osaka

(Received March 8, 1961)

Antiferromagnetic resonance experiment was performed on a single crystal of $CoCl_26H_2O$ in the frequency range of 9.5 to 47 kMc/sec at liquid helium temperature. The result can be understood by the theory of antiferromagnetic resonance developed by Nagamiya and Yosida and also by Ubbink et al., except for certain systematic deviations from the theory. These deviations can be removed by introducing a large anisotropic exchange interaction of the symmetric tensor form in place of the ordinary small anisotropy energy. Thus, the effective fields acting on sublattice magnetizations, M^+ and M^-, are assumed to be of the form

$$H_E{}^{\pm}=-AM^{\mp}-\Gamma M^{\pm}-A'M^{\mp}-\Gamma'M^{\pm}\ ,$$

where A and Γ are the isotropic molecular field constants and A' and Γ' are newly introduced anisotropic molecular field tensors. It was found that the symmetry axes of A' and Γ' coincide with those of the g-tensor and their components are given by

$$A_x'=0.25\text{ A}\ ,\qquad A_y'=0.20\text{ A}\ ,\qquad A_z'=-0.45\text{ A}\ ,$$
$$\Gamma_x'=0.19\text{ A}\ ,\qquad \Gamma_y'=0.18\text{ A}\ ,\qquad \Gamma_z'=-0.37\text{ A}\ ,$$

where x, y and z correspond to the c-, b- and a'-axes, respectively. Line width measurements were also performed in the para- and antiferromagnetic regions and a rapid narrowing was observed at low temperatures.

§1. Introduction

Since theoretical studies[1] of antiferromagnetic resonance and observations[2] of such a resonance in $CuCl_22H_2O$ were made, attempts to find similar resonances in other antiferromagnetic substances have been made by several researchers. Unlike the case of para- or ferromagnetic resonance, however, the possibility to observe antiferromagnetic resonance under ordinary resonance conditions is confined to a relatively few number of antiferromagnetic substances for the reason that the required frequency or magnetic field is too high in most of antiferromagnetic substances. Let us consider the simplest case of uniaxial anisotropy energy. The resonance frequency ω in this case is given by

$$\frac{\omega}{\gamma}=\sqrt{2H_AH_E}\pm H\ ,\qquad H_E\gg H_A,\ H\ ,$$

where γ is the gyromagnetic ratio, H_A the anisotropy field, H_E the exchange field and H is the external magnetic field applied along the easy axis. H_A may range between 10^3 and 10^5 Oe, and for antiferromagnetics with Néel temperature of $\sim10^2$°K, H_E may be $\sim10^6$ Oe. Therefore, a high frequency or a strong external magnetic field will be required to satisfy the resonance condition. Substances in which antiferromagnetic resonance was observed up to the present time are $CuCl_22H_2O$ by the Leiden group[2], $CuBr_22H_2O$ by the present author[3], MnF_2 by Johnson and Nethercot[4] and Foner[5], Cr_2O_3 by Dayhoff[6] and Foner[7], $CuCl_22D_2O$ by the present author[8], FeF_2 by Tinkham and Ohlman[9], and NiO by Kondoh[10]. The latter two observations were made with far-infrared technique, and Foner used high pulse magnetic fields.

So far as the author is aware of, no experiment has been reported on the antiferromagnetic resonance in cobaltous compounds. In the antiferromagnetic resonance in compounds containg Co^{++} ions, the contribution of the orbital angular momentum should play a role. Usually, the effect of orbital angular momentum can be expressed in terms of the effective g-tensor. However, in the phenomenon of antiferromagnetic resonance, this g-tensor can be reduced further to an isotropic tensor by introducing a modified external field, as was discussed by Ubbink[2] and Nagamiya[1] in the case of $CuCl_22H_2O$. In $CoCl_26H_2O$, however, the deviation of the g-

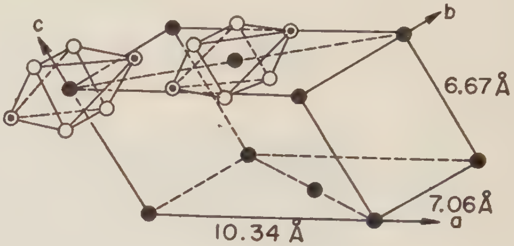
value from the free spin value is so large and the exchange interaction so small that it is interesting to check whether such a reduction alone is sufficient or not. It is also interesting to investigate the resonance line width, because the presence of the orbital angular momentum will give rise to a short spin-lattice relaxation time and a large anisotropic exchange interaction, both of which will broaden the resonance line, especially in the paramagnetic resonance.

Among the cobaltous compounds, $\mathrm{CoCl_2 6H_2O}$ is one of the most stable hydrated salts and can be easily obtained from the saturated aqueous solution. The antiferromagnetic behavior of the salt was first discovered by Haseda and Kanda[11] from the measurement of the powder susceptibility. The x-ray analysis of the crystal structure[12], the specific heat measurement[13] and the single crystal susceptibility[14],[15] were reported recently. It has become clear that this salt is antiferromagnetic below 2.29°K, and this has been also confirmed by a proton resonance experiment[16].

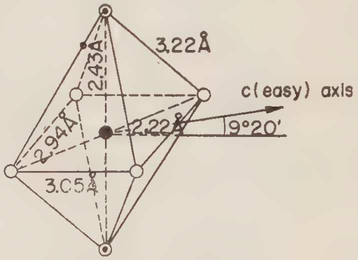
As was reported in a previous short note[17], the present author observed the antiferromagnetic resonance in $\mathrm{CoCl_2 6H_2O}$. In the present paper, detailed results and discussion of the experiment will be given.

§ 2. Crystal Structure and Spin Orientation

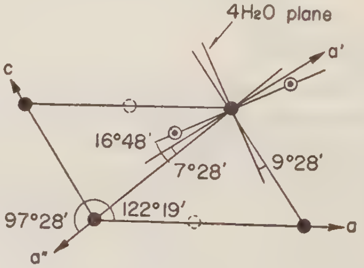
The X-ray analysis of $\mathrm{CoCl_2 6H_2O}$ was performed by Mizuno, Ukei and Sugawara[12]. The crystal structure is monoclinic ($\beta=122°19'$) and the lattice constants were determined to be $a=10.34$ Å, $b=7.06$ Å and $c=6.67$ Å. The space group is C_{2h}^3-C2/m and the unit cell contains two $\mathrm{Co^{++}}$ ions which form a base-centered structure. Two $\mathrm{Cl^-}$ ions and four water molecules are octahedrally coordinated to each $\mathrm{Co^{++}}$ ion so as to form a $\mathrm{CoCl_2 4H_2O}$ group. The crystal has a layer structure parallel to (001) and shows a perfect cleavage along this plane. A simplified model of the arrangement is shown in Fig. 1 (a) and (b). As is seen in Fig. 1 (a), there are two equivalent slightly distorted octahedrons in a unit cell, whose principal axes are perfectly parallel, so that the magnetic analysis of this crystal can easily be compared with that of $\mathrm{CuCl_2 2H_2O}$. The angular relation between the octahedrons and the unit cell is shown in Fig. 1 (c), in which we introduced two new axes a' and a'' for convenience.



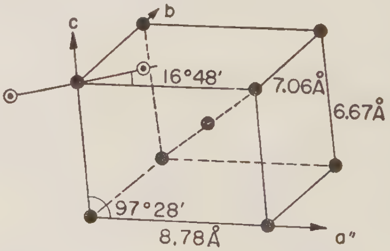
(a) Schematic view of the unit cell. Two free water molecules are not drawn. There are two octahedrons in a unit cell having equivalent crystallographic orientations.



(b) A unit octahedron.



(c) Angular relations between the axes in ac-plane.



(d) Modified unit cell showing a slightly deformed body centered structure.

● ---- $\mathrm{Co^{++}}$ ion
⊙ ---- $\mathrm{Cl^-}$ ion
○ --- $\mathrm{H_2O}$ molecule

Fig. 1. Crystal structure of $\mathrm{CoCl_2 \cdot 6H_2O}$.

The a'-axis was defined to be perpendicular to both the b- and c-axes; the new rectangular coordinate axes, a', b and c are convenient to analyse experimental data as will be shown in the following sections. On the other hand, the a''-axis is profitable for some calculations such as those of dipolar width and dipolar sum, because the unit cell can be regarded as a slightly deformed body-centered structure. The schematic view of the unit cell is shown in Fig. 1 (d).

The spin orientation at low temperature was determined to be parallel to the c-axis from the susceptibility, proton resonance and antiferromagnetic resonance experiments. It is interesting to note that the spin direction does not coincide with any of the principal axes of the unit octahedron as in $CuCl_22H_2O$. Moreover, it should be mentioned that the spin direction in $NiCl_26H_2O$[18], which is isomorphous to $CoCl_26H_2O$, is not along the c-axis but it is along the b-axis.

Unfortunately, no neutron diffraction experiment is reported so that we do not know the super-structure of spins. As is shown in Fig. 1 (b), there are slight differences among the H_2O–H_2O distances in the unit octahedron, which may produce an orthorhombic crystalline electric field upon the Co^{++} ion. However, the g-values determined by susceptibility measurement show tetragonal symmetry so that small orthorhombicity may not be important. Accordingly, we shall hereafter not care about this orthorhombicity. Throughout the present paper, we do not use the unit octahedron coordinate system, which is inclined by about 9°20′ to the cba,-coordinate system. One of the reasons for this is the fact that the magnetic easy axis is the c-axis which is not in the 4–H_2O plane, as is shown in Fig. 1 (b). The other reason concerns with our experimental accuracy: the paramagnetic resonance line width is so broad that it is not possible to discriminate which of the coordinate systems coincides with the principal axes of the g-tensor. In other words, we encounter no practical contradiction when we use the cba'-coordinate system.

§ 3. Experimental Method

(1) Preparation of the specimen

The specimens used in this experiment were grown from the saturated aqueous solution of pure cobaltous chloride at room temperature. Dark red single crystals having well developed (100) faces were obtained, which show a perfect cleavage along the (100) plane. To prevent deliquescence, single crystals were preserved in pure clock oil. The volume of the single crystals used in the experiment was 1∼10 mm³, varying with the frequency used, i.e. 47∼9.5 kMc/sec.

(2) Microwave equipments and cryostats

Microwave oscillator tubes used for the experiment are klystrons 2K25, 2K33, 35V10 and 50V10 which can be used in the range of 10, 24, 34 and 50 kMc/sec, respectively. Usual experimental apparatus and techniques were used to observe the paramagnetic and antiferromagnetic resonance absorption in $CoCl_26H_2O$.

The cut view of the cryostats are shown in Fig. 2 (a) and (b). Microwave transmission method was used for 34 and 47 kMc/sec, and wave guide and coaxial cable reflection method were respectively adopted for the 24 and 10 kMc/sec regions. German silver wave guide with a wall thickness of 0.3 mm was useful to prevent fast evaporation of liquid helium. Specimens were always immersed in the liquid helium bath in order to secure the precise temperature of the specimens. The microwave loss and frequency shift of the resonant cavity due to the filling up of liquid helium are practically negligible. A cylindrical doubly tuned resonant cavity was used for the resonance in the 10 and 24 kMc/sec regions. This cavity was originally designed for a three level maser in the 10 GC region[19] and the cut view of it is shown in Fig. 2 (b). Cu–Ni alloy was used for all the metal parts of the coaxial cable and RG–55U polyethylene pipe was utilized as a dielectric spacer. Under these conditions, one liter liquid helium can be maintained for more than ten hours, during which experiments in the 10 and 24 kMc/sec regions could be carried out.

Microwave power levels are of the order of milliwatts, and no saturation effect of the antiferromagnetic resonance was yet observed at this power level.

§ 4. Paramagnetic Resonance

The paramagnetic resonance measurement was performed above T_N using microwaves

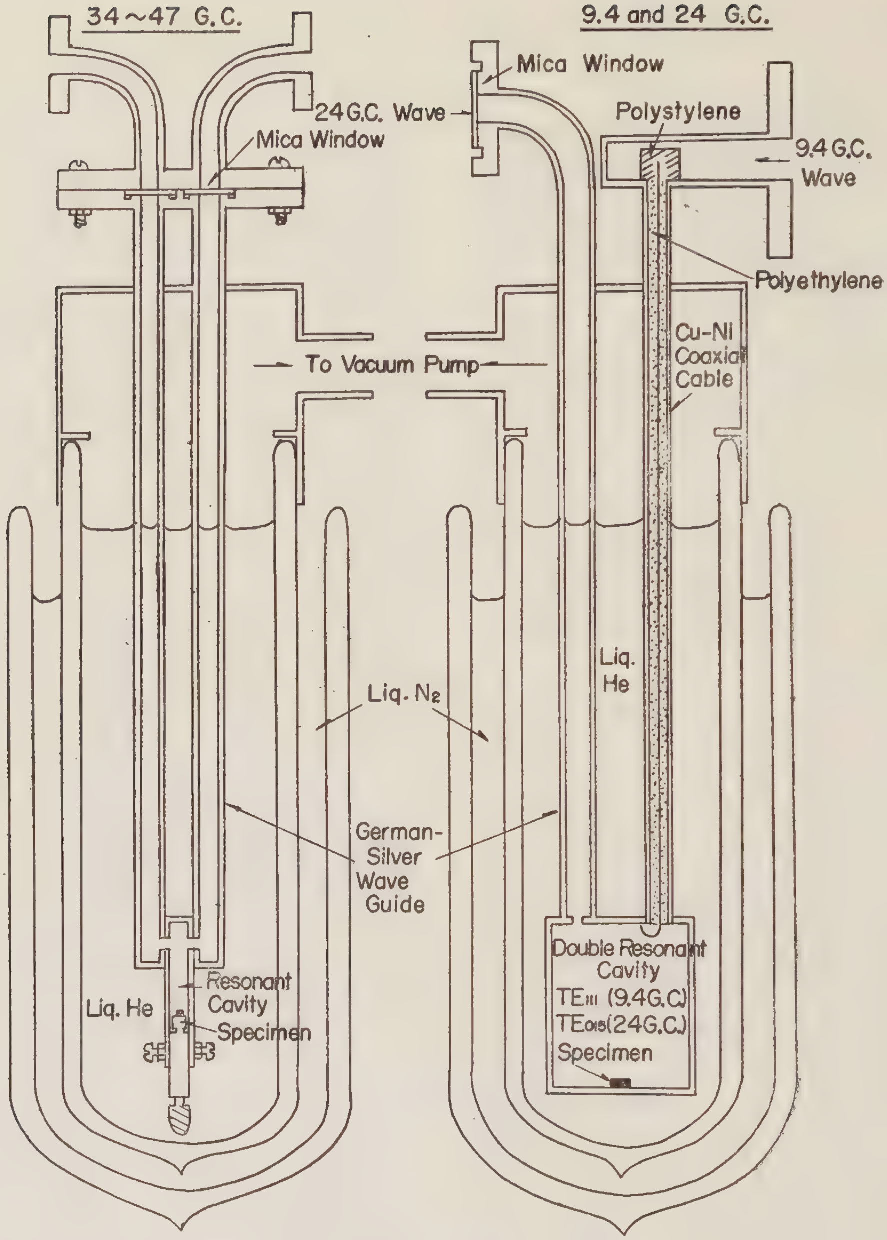


Fig. 2. Cut view of the cryostats.

of the 10, 24 and 34 kMc/sec regions. However, no resonance was observed at 10 and 24 kMc/sec. It was seen only in the 34 kMc/sec region. Even in this range, there was no resonance absorption above the liquid helium temperature and a very broad resonance line was observed at 4.2° as is shown in Fig. 3.

It is well known that the line width of paramagnetic resonance under usual condi-

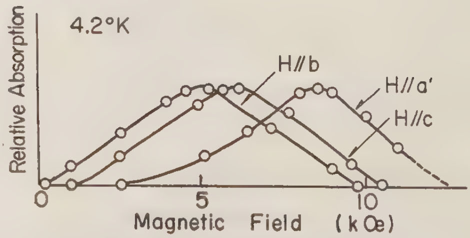

Fig. 3. Paramagnetic resonance curves of $CoCl_2 \cdot 6H_2O$ at 35.55 kMc/sec.

tions is determined by dipolar interaction and exchange effect. Usually the former causes a broadening and the latter produces a narrowing effect if the exchange interaction is isotropic. The calculated dipolar width of $CoCl_26H_2O$ along the principal axes using the theory of Van Vleck[20] are

$$\left.\begin{aligned}\Delta H_{a'}&=\ 620\text{ gauss}\,,\\ \Delta H_b&=2000\text{ gauss}\,,\\ \Delta H_c&=2200\text{ gauss}\,,\end{aligned}\right\}$$

where $\Delta H_{a'}$, ΔH_b and ΔH_c represent the full half width along the crystallographic axes.

From the above calculation, it is clear that the experimental line width can not be explained by the usual dipolar and exchange effects.

As is seen in Fig. 3, the widths are $\Delta H_{a'}\sim 4500$, $\Delta H_b\sim 5000$ and $\Delta H_c\sim 5000$ gauss respectively, whereas only $100\sim 200$ gauss can be expected on the basis of the calculated dipolar width and the exchange narrowing effect[21].

Two origins of these extremely broad paramagnetic resonance lines may be considered. One of them is a short spin-lattice relaxation time of Co^{++} ion and the other is the broadening due to an anisotropic exchange interaction. It is well known that the spin-lattice relaxation time T_1 of Co^{++} ion in paramagnetic state is very short and frequently resonance cannot be observed because of the violation of the relation: $T_1<$ Larmor precession time, under usual experimental conditions. If we assume that the line width is due to the spin-lattice relaxation time only, T_1 will be estimated to be about 4×10^{-12} sec at 4.2°K. However, anisotropic exchange interaction may also make a large contribution to the resonance line width. Because of lack of the precise treatment of the line width due to an anisotropic exchange interaction, no quantitative analysis can be performed, but we shall see in following sections that there exists a considerably large anisotropic exchange interaction among the cobaltous ions so that the extreme broadening of the resonance line can entirely due to this anisotropic exchange interaction.

The g-values are as given in Fig. 4. The principal g-values obtained in our experiment are $g_{a'}=2.9$, $g_b=5.0$ and $g_c=4.0$. It is interesting to compare our data with the results of the susceptibility measurements by Haseda[14] and by Flippen and Friedberg[15]. Haseda obtained $g_{a'}=2.7$, $g_b=4.9$ and $g_c=4.9$ in accord with Flippen and Friedberg. Their data are referred to in Fig. 4 with a dotted line.

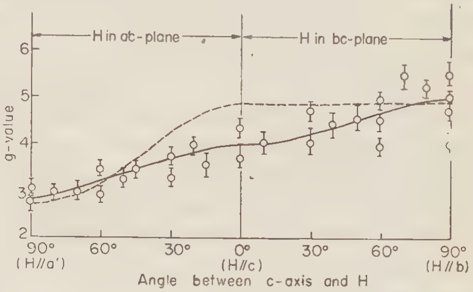

Fig. 4. Angular dependence of g-value in the range of $34\sim 37$ kMc/sec at 4.2°K. Dotted line shows the result obtained from susceptibility data.

Is must be noted that a considerable difference is present in g_c. This discrepancy could be explained as follows. From the result of our experiment, existance of a considerable amount of antiferromagnetic short range order at 4.2°K might be concluded, and this is consistent with the result of the specific heat measurement performed by Robinson and Friedberg[13]. As will be shown in the following section, there is an antiferromagnetic field higher than the paramagnetic resonance field along the c-axis below the Néel temperature, and to this the paramagnetic resonance field appears to join as temperature is decreased and passed through the Néel point. Therefore, it is possible that the observed paramagnetic resonance field is shifted to the higher side; this may probably be due to the existance of short range order. Accordingly, the resonance g-value may be considered as apparent; so we shall use the g-value obtained from the susceptibility data in analysing the results of our antiferromagnetic resonance experiment.

Now let us consider briefly the ground state of Co^{++} ion in $CoCl_26H_2O$. As is well known, the ground state of Co^{++} ion is ^4F, which splits into an orbital singlet and two orbital triplets in a crystalline field of cubic symmetry. As early as 1951, Abragam and Pryce[22] calculated the set of levels arising from ^4F for the case of trigonal and tetragonal symmetries including the effect of spin-orbit coupling. Recently, optical absorption spectra of $CoCl_26H_2O$ and $CoBr_26H_2O$ were investigated by Pappalardo[23] and the results were analysed by Koide[24] who included the higher multiplet levels neglected by Abragam and Pryce. However, no data of the crystal structure of $CoCl_26H_2O$ were available at that time so that they assumed the crystalline electric field to be cubic. Accordingly their results cannot be applied to the analysis of the present paramagnetic resonance experiment. Considering the effect of higher multiplet levels to be small, comparison between the theoretical and experimental g-value was made, and the result is shown in Fig. 5. The agreement is satisfactory.

§ 5. Antiferromagnetic Resonance

As was described in the preceding section, very broad paramagnetic resonance was observed in the 34 kMc/sec region at 4.2°K. Below 4.2°K, the resonance line becomes more broad and weak, being accompanied with a slight shift toward the antiferromagnetic resonance field observed below T_N. These effects could be due to increasing short range order with decreasing temperature. Pure antiferromagnetic resonance was observed below 2.0°K and the results are shown in Figs. 6~14. Satisfactory data of the temperature dependence could not be obtained because the Néel temperature is so low and moreover the line width was very large at intermediate temperatures. Except for this point, a satisfactory amount of experimental data was obtained. In Figs. 6 and 7, the temperature and angular dependences in the bc-

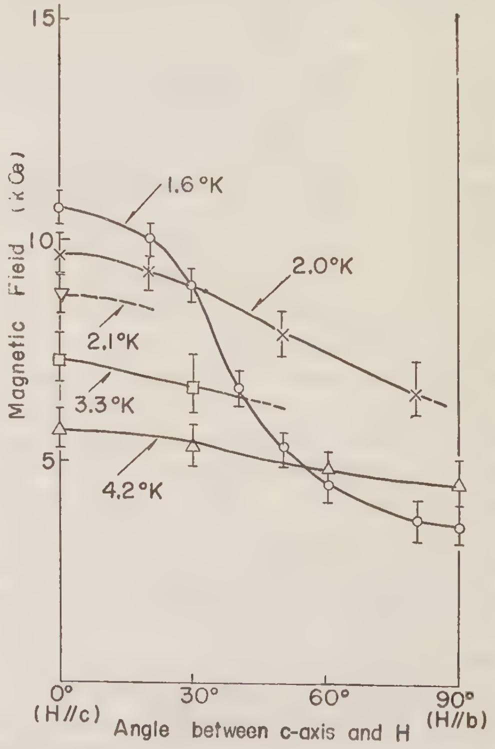

Fig. 7. Temperature and angular dependence of resonance points in bc-plane at 34.820 kMc/sec.

plane at 34 kMc/sec region are shown. With decreasing temperature, the resonance line becomes sharp and its angular dependence increases. Similar behavior of resonance line was reported in the case of $CuCl_22H_2O$. On the other hand, weak and angular independent resonance line was observed near the *c*-axis, along which the spins align at low temperatures. The resonance curves are shown in Figs. 8 and 9. This resonance cannot be seen below 35 kMc/sec and the origin of this weak absorption is not clear. Above 1.7°K, this

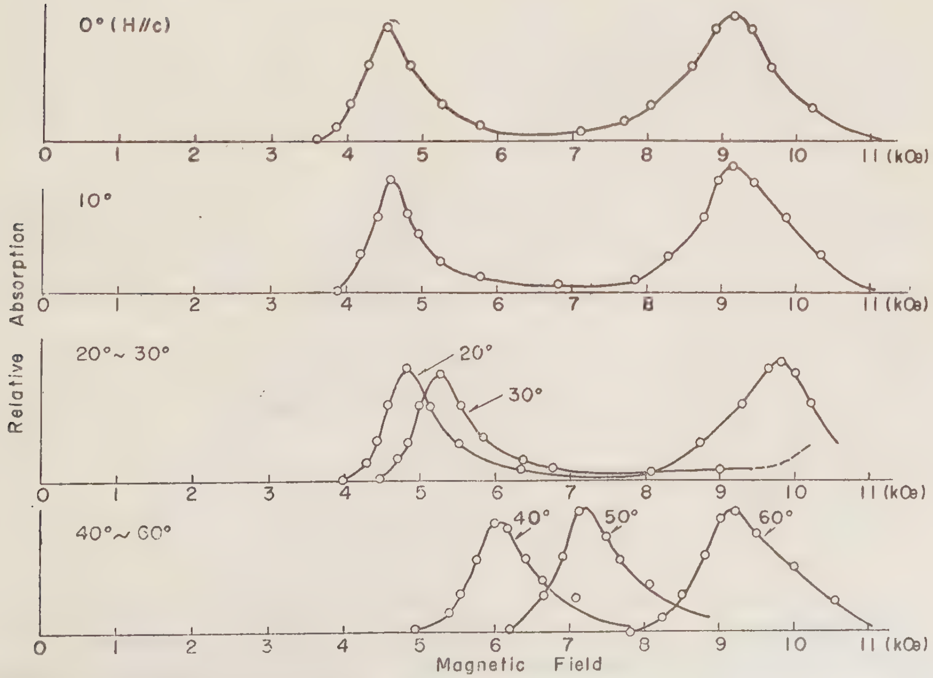

Fig. 10. Antiferromagnetic resonance lines of $CoCl_2 \cdot 6H_2O$ in *a*′*c*-plane at 23.580 kMc/sec (1.47°K)

curious resonance vanishes. The experimental results of the 24 kMc/sec region are summarized in Figs. 10∼12. In this frequency range, the results are similar to those in $CuCl_2 2H_2O$. It must be noticed that a dip of the resonance diagram of $CuCl_2 2H_2O$ in the *ab*-plane is not seen in $CoCl_2 6H_2O$ in the corresponding *cb*-plane. This fact was confirmed with 9 *k*Mc/sec, the result being shown in Figs. 13 and 14. The frequency dependences at the lowest temperature are illustrated in Fig. 15. From this figure, it is seen that the present results are analogous to those for $CuCl_2 2H_2O$, though qualitatively. However, our experimental results cannot be explained

by the theory of antiferromagnetic resonance of orthorhombic anisotropy developed by Nagamiya, Yosida and Ubbink by a mere adjustment of the parameters contained in the theory: a systematic deviation was observed between the theory and the experiment as was described in a previous short report[17]. A detailed analysis of the present results by improved theory including a large anisotropic exchange interaction will be discussed in the following section.

§ 6. Analysis of the Experimental Result

As was described in the preceding section, the qualitative aspect of antiferromagnetic resonance in $CoCl_26H_2O$ is analogous to that in $CuCl_22H_2O$. So we performed at first the analysis of the experimental results following Nagamiya and Yosida's treatment of $CuCl_2$-$2H_2O$.

First of all, the reduction of the g-tensor to a scalar g-factor must be considered. This can be easily done by introducing a modified magnetic field defined by the following relation:

$$H=(g/2)H_{\mathrm{exp}} \qquad (1)$$

where H and H_{exp} are the reduced field and experimental field, respectively. In $CoCl_2$-$6H_2O$, $H_{a'}=1.5H_{a'\mathrm{exp}}$, $H_b=2.5H_{b\,\mathrm{exp}}$ and $H_c=2.5H_{c\,\mathrm{exp}}$, using the g-values from the paramagnetic susceptibility data. Hereafter we shall use the fictitious field H in place of the real experimental field H_{exp}. Using Eq. (1), the experimental results can be adjusted so as to be compared directly with the Nagamiya-Yosida theory. The result is shown in Fig. 16. The open circles show the experimental results and the dotted line represent the results of the calculation. We assumed the temperature parameter α to be 0.83 using the susceptibility data. It will be seen that there is a considerable discrepancy between theory and experiment. Generally speaking, the experimental resonance field shifts to the higher field side with respect to the calculated one in both the c- and b-directions. Moreover, the critical field resonance to be observed at finite temperature could not be detected.

At the origin of these discrepancies, we considered several correction factors, such as the magnetization effect, demagnetization effect, higher order anisotropy energy and anisotropic exchange interaction[25]. Among these effects, however, it was found that only anisotropic exchange interaction of symmetric tensor form can explain the discrepancy. Let

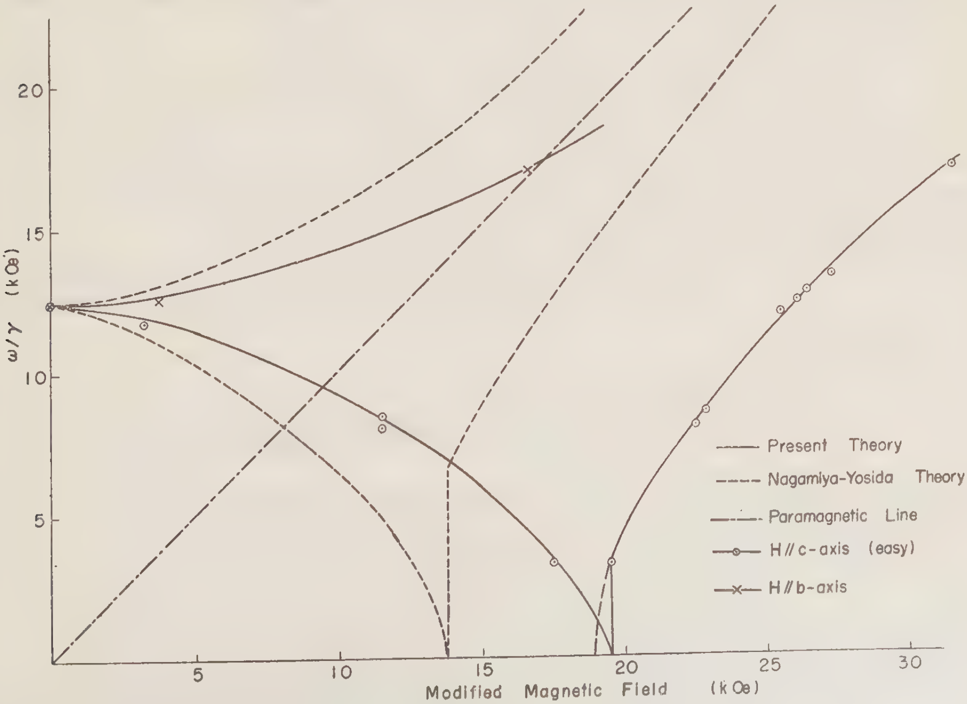

Fig. 16. Frequency-field diagram of the resonance points (1.5°K)

us consider the equation of antiferromagnetic oscillation including an anisotropic exchange interaction of symmetric tensor form. For convenience, we use Nagamiya's notation except for the anisotropic exchange interaction. The equation of motion of the two sublattice magnetizations are

$$\frac{1}{\gamma}\frac{d}{dt}M^{\pm}=M^{\pm}\times(H+H_E^{\pm})\,, \tag{2}$$

where γ is the gyromagnetic ratio, $M^{\pm}$ is the magnetization of the $+$ and $-$ sublattices, H and H_E represent the external magnetic field and the exchange field, respectively. Following Nagamiya and Yosida's procedure, we define

$$M=M^{+}+M^{-}\,,\qquad M'=M^{+}-M^{-}\,. \tag{3}$$

Now an anisotropic exchange interaction will be introduced in the following way. The exchange energy is defined by

$$E_{ex}=AM^{+}M^{-}+\frac{1}{2}\Gamma(M^{+2}+M^{-2})+M^{+}A'M^{-}+\frac{1}{2}(M^{+}\Gamma'M^{+}+M^{-}\Gamma'M^{-})\,. \tag{4}$$

The first and second terms represent the isotropic exchange interactions which are present in the Nagamiya-Yosida theory, where A and Γ are scalars. The third and 4th terms are the anisotropic part of the exchange energy having the tensor form given by

$$A'=\begin{pmatrix} A_x' & 0 & 0 \\ 0 & A_y' & 0 \\ 0 & 0 & A_z' \end{pmatrix},\qquad \Gamma'=\begin{pmatrix} \Gamma_x' & 0 & 0 \\ 0 & \Gamma_y' & 0 \\ 0 & 0 & \Gamma_z' \end{pmatrix}, \tag{5}$$

where the diagonal sum of both tensors is assumed to be zero, namely,

$$A_x'+A_y'+A_z'=0\,,\qquad \Gamma_x'+\Gamma_y'+\Gamma_z'=0\,. \tag{6}$$

It may be noted that the anisotropy energy used in the Nagamiya-Yosida theory is equivalent to the fourth term in Eq. (4), but that the third term expressed by $M^{+}A'M^{-}$ is newly introduced in the present treatment. Moreover, since we are dealing with the case of an effective spin of 1/2, any one ion type anisotropy energy does not appear.

With the use of (3), we rewrite Eq. (2) in terms of M and M'. Then adding and substructing the two equations (2), we obtain the following equations:

$$\frac{1}{\gamma}\frac{d}{dt}M=M\times H+\frac{1}{2}M\times(H_E^{+}+H_E^{-})+\frac{1}{2}M'\times(H_E^{+}-H_E^{-})\,, \tag{7}$$

$$\frac{1}{\gamma}\frac{d}{dt}M'=M'\times H+\frac{1}{2}M\times(H_E^{+}-H_E^{-})+\frac{1}{2}M'\times(H_E^{+}+H_E^{-})\,. \tag{8}$$

The exchange field H_E is now obtained from the relation

$$\delta E_{ex}=-H_E^{+}\delta M^{+}-H_E^{-}\delta M^{-}\,, \tag{9}$$

the result being

$$\begin{aligned} H_E^{\pm}&=-AM^{\mp}-\Gamma M^{\pm}-A'M^{\mp}-\Gamma'M^{\pm}\\ &=-\frac{1}{2}\{A(M\mp M')+\Gamma(M\pm M')+A'(M\mp M')+\Gamma'(M\pm M')\}\,. \end{aligned} \tag{10}$$

Using Eq. (10), the components of Eqs. (7) and (8) can be written as follows:

$$\left.\begin{aligned} \frac{1}{\gamma}\frac{d}{dt}M_x&=H_zM_y-H_yM_z+\frac{1}{2}(P_y-P_z)M_yM_z+\frac{1}{2}(Q_z-Q_y)M_y'M_z'\\ \frac{1}{\gamma}\frac{d}{dt}M_y&=H_xM_z-H_zM_x+\frac{1}{2}(P_z-P_x)M_zM_x+\frac{1}{2}(Q_x-Q_z)M_z'M_x'\\ \frac{1}{\gamma}\frac{d}{dt}M_z&=H_yM_x-H_xM_y+\frac{1}{2}(P_x-P_y)M_xM_y+\frac{1}{2}(Q_y-Q_x)M_x'M_y' \end{aligned}\right\} \tag{11}$$

$$\left.\begin{aligned}
\frac{1}{\gamma}\frac{d}{dt}M_x'&=H_zM_y'-H_yM_z'+\left\{A+\frac{1}{2}(P_y+Q_z)\right\}M_yM_z'-\left\{A+\frac{1}{2}(P_z+Q_y)\right\}M_zM_y'\\
\frac{1}{\gamma}\frac{d}{dt}M_y'&=H_xM_z'-H_zM_x'+\left\{A+\frac{1}{2}(P_z+Q_x)\right\}M_zM_x'-\left\{A+\frac{1}{2}(P_x+Q_z)\right\}M_xM_z'\\
\frac{1}{\gamma}\frac{d}{dt}M_z'&=H_yM_x'-H_xM_y'+\left\{A+\frac{1}{2}(P_x+Q_y)\right\}M_xM_y'-\left\{A+\frac{1}{2}(P_y+Q_x)\right\}M_yM_y'
\end{aligned}\right\}\tag{12}$$

where new parameters P and Q are used which are defined by

$$P=A'+\Gamma', \qquad Q=A'-\Gamma'. \tag{13}$$

Of course P and Q are tensors whose diagonal sum is equal to zero. To obtain the resonance conditions of the system represented by the equation of motion (11) and (12), we assume that the deviation of M and M' from their equilibrium values is small and retain in the equations only the first order terms. As long as the external field is small compared with the exchange field, these equation of small oscillation derived from Eqs. (11) and (12) can be simplified, and the results in several important cases are as follows.

(1) The applied field is parallel to the x-axis (c-axis).

In this case we have to distinguish between three cases, that is, $H<H_c$, $H=H_c$ and $H>H$, where H_c is the critical field at which the direction of M' turns in the xy-plane.

(a) $H<H_c$. The vectors M and M' both point to the x-direction so that (11) and (12) can be written as the variational form:

$$\left.\begin{aligned}
&\frac{1}{\gamma}\frac{d}{dt}\delta M_x=0\\
&\frac{1}{\gamma}\frac{d}{dt}\delta M_y=H\delta M_z+\frac{1}{2}(P_z-P_x)M_x\delta M_z+(Q_x-Q_z)M_0\delta M_z'\\
&\frac{1}{\gamma}\frac{d}{dt}\delta M_z=-H\delta M_y+\frac{1}{2}(P_x-P_y)M_x\delta M_y+(Q_y-Q_x)M_0\delta M_y'
\end{aligned}\right\}\tag{14}$$

$$\left.\begin{aligned}
&\frac{1}{\gamma}\frac{d}{dt}\delta M_x'=0\\
&\frac{1}{\gamma}\frac{d}{dt}\delta M_y'=H\delta M_z'+2\left\{A+\frac{1}{2}(P_z+Q_x)\right\}M_0\delta M_z-\left\{A+\frac{1}{2}(P_x+Q_z)\right\}M_x\delta M_z'\\
&\frac{1}{\gamma}\frac{d}{dt}\delta M_z'=-H\delta M_y'+\left\{A+\frac{1}{2}(P_x+Q_y)\right\}M_x\delta M_y'-2\left\{A+\frac{1}{2}(P_y+Q_x)\right\}M_0\delta M_y
\end{aligned}\right\}\tag{15}$$

where the external magnetic field H_x is written as H. Taking δM_y, δM_z, $\delta M_y'$ and $\delta M_z'$ proportional to $\exp(i\omega t)$, we obtain the determinantal equation

$$\begin{vmatrix}
\frac{-i\omega}{\gamma} & H\left\{1+\frac{1}{2}(P_z-P_x)\chi_{\parallel}\right\} & 0 & (Q_x-Q_z)M_0\\
-H\left\{1-\frac{1}{2}(P_y-P_x)\chi_{\parallel}\right\} & \frac{-i\omega}{\gamma} & (Q_y-Q_x)M_0 & 0\\
0 & 2\left\{A+\frac{1}{2}(P_z+Q_x)\right\}M_0 & \frac{-i\omega}{\gamma} & H\left[1-\left\{A+\frac{1}{2}(P_x-Q_z)\right\}\chi_{\parallel}\right]\\
-2\left\{A+\frac{1}{2}(P_y+Q_x)\right\}M_0 & 0 & -H\left[1-\left\{A+\frac{1}{2}(P_x+Q_y)\right\}\chi_{\parallel}\right] & \frac{-i\omega}{\gamma}
\end{vmatrix}=0 \tag{16}$$

Reducing the determinant, we obtain a complicated expression for the resonance condition, which, however, can be simplified when $\omega/\gamma=0$ or $H=0$ as follows:

$$\frac{\omega}{\gamma}=0:\quad H^2\left\{1-\frac{1}{2}(P_y-P_x)\chi_\parallel\right\}\left[1-\left\{A+\frac{1}{2}(P_x+Q_z)\right\}\chi_\parallel\right]$$
$$+2(Q_y-Q_x)\left\{A+\frac{1}{2}(P_y+Q_x)\right\}M_0^2=0\,, \tag{17}$$

$$H=0:\quad \left(\frac{\omega}{\gamma}\right)^2=2(Q_x-Q_y)\left\{A+\frac{1}{2}(P_z+Q_x)\right\}M_0^2\,. \tag{18}$$

(b) $H>H_c$. In this case M is parallel to the x-axis but M' is perpendicular to it and points to the y-axis (b-axis). The equations are

$$\left.\begin{aligned}\frac{1}{\gamma}\frac{d}{dt}\delta M_x&=(Q_z-Q_y)M_0\delta M_z'\\ \frac{1}{\gamma}\frac{d}{dt}\delta M_y&=H\delta M_z+\frac{1}{2}(P_z-P_x)M_x\delta M_z\\ \frac{1}{\gamma}\frac{d}{dt}\delta M_z&=-H\delta M_y+\frac{1}{2}(P_x-P_y)M_x\delta M_y+(Q_y-Q_x)M_0\delta M_x'\end{aligned}\right\} \tag{19}$$

$$\left.\begin{aligned}\frac{1}{\gamma}\frac{d}{dt}\delta M_x'&=-2\left\{A+\frac{1}{2}(P_z+Q_y)\right\}M_0\delta M_z\\ \frac{1}{\gamma}\frac{d}{dt}\delta M_y'&=H\delta M_z'-\left\{A+\frac{1}{2}(P_x+Q_z)\right\}M_x\delta M_z'\\ \frac{1}{\gamma}\frac{d}{dt}\delta M_z'&=-H\delta M_y'+\left\{A+\frac{1}{2}(P_x+Q_y)\right\}M_x\delta M_y'+2\left\{A+\frac{1}{2}(P_x+Q_y)\right\}M_0\delta M_x\end{aligned}\right\} \tag{20}$$

Solving these equations, we can obtain the resonance conditions as

$$\left(\frac{\omega}{\gamma}\right)^2=H^2\left\{1+\frac{1}{2}(P_z-P_x)\chi_\perp\right\}\left\{1+\frac{1}{2}(P_y-P_x)\chi_\perp\right\}-2(Q_x-Q_y)\left\{A+\frac{1}{2}(P_z+Q_y)\right\}M_0^2 \tag{21}$$

$$\left(\frac{\omega}{\gamma}\right)^2=2(Q_y-Q_z)\left\{A+\frac{1}{2}(P_x+Q_y)\right\}M_0^2-H^2\left\{1-\left[A+\frac{1}{2}(P_x+Q_y)\right]\chi_\perp\right\}$$
$$\times\left\{1-\left[A+\frac{1}{2}(P_x+Q_z)\right]\chi_\perp\right\} \tag{22}$$

(2) The applied field is parallel to the y-axis.

In this case the resonance equation can be solved in the same way as in the case (1) (b), and the result is

$$\left(\frac{\omega}{\gamma}\right)^2=H^2\left\{1+\frac{1}{2}(P_x-P_y)\chi_\parallel\right\}\left\{1+\frac{1}{2}(P_z-P_y)\chi_\perp\right\}+2(Q_x-Q_y)\left\{A+\frac{1}{2}(P_z+Q_x)\right\}M_0^2 \tag{23}$$

Now let us consider the experimental result shown in Fig. 16. The most precise experimental point is the resonance frequency at $H=0$. This frequency was determined to be

$$\nu=34{,}630\pm50\ \text{Mc/sec}\,. \tag{24}$$

So the resonance constants should be so adjusted that a good accord with the experimental result is obtained at $H=0$.

Then the anisotropic exchange tensors P and Q are determined in the following way. Using the experimental results, $(\omega/\gamma)^2$ of Eqs. (21) and (23) can be expressed respectively as

$$(\omega/\gamma)^2=0.45H^2-161\,, \tag{21'}$$
$$(\omega/\gamma)^2=0.50H^2-153\,. \tag{23'}$$

Comparing Eqs. (21) with (21′) and (23) with (23′), the following relations are obtained:

$$\{1+\tfrac{1}{2}(P_z-P_x)\chi_\perp\}\{1+\tfrac{1}{2}(P_y-P_x)\chi_\perp\}=0.45 \tag{25}$$
$$\{1+\tfrac{1}{2}(P_x-P_y)\chi_\perp\}\{1+\tfrac{1}{2}(P_z-P_y)\chi_\perp\}=0.50 \tag{26}$$

Strictly speaking, the susceptibilities in Eqs. (25) and (26) are not the same because $\chi_\perp$ in

(25) means the perpendicular susceptibility along the c-axis when $H>H_c$ while $\chi_\perp$ in (26) is that along the *b*-axis; if there is a large anisotropy in the *bc*-plane, they cannot be equal to each other. Namely $\chi_{\perp H /\!/ x\text{-axis}}=1/(A+\frac{1}{2}P_x)$ and $\chi_{\perp H /\!/ y\text{-axis}}=1/(A+\frac{1}{2}P_y)$ as can be calculated from the torque balance equation. However, as will be seen from Eqs. (25) and (26) P_x/P_y is nearly equal to one so that $(P_x-P_y)/A$ may be negligible in Eqs. (25) and (26). Thus, solving these equations, we get the components of the *P*-tensor as

$$\left.\begin{aligned} P_x&=(0.44\pm0.04)A\,, \\ P_y&=(0.38\pm0.04)A\,, \\ P_z&=-(0.82\pm0.04)A\,. \end{aligned}\right\} \qquad (27)$$

To determine the *Q*-tensor, we compare Eqs. (23) and (23′) and obtain the following relation:

$$2(Q_x-Q_y)\{A+\tfrac{1}{2}(P_z+Q_x)\}M_0{}^2=153\,. \qquad (28)$$

Further, we have the following ratio by comparing Eq. (16) with the corresponding experimental result:

$$(Q_x-Q_z)/(Q_x-Q_y)=3.5\,. \qquad (29)$$

Together with the relation $Q_x+Q_y+Q_z=0$, the components of the *Q*-tensor can be calculated, if we could determine *A* and M_0 in Eq. (28). *A* can be determined from susceptibility data obtained by Haseda and Friedberg et al., namely, $\chi_{\perp b}=1/(A+\frac{1}{2}P_y)=9\times10^{-4}$ /gram. M_0 can be calculated from the definition, $M_0=\frac{1}{2}Ng\mu_B\langle S\rangle$, where $\langle S\rangle$ is the thermal average of the spin. At absolute zero, M_0 can be calculated using the observed *g*-value, and at 1.5°K, i.e. the temperature of our measurements, it can be determined with reference to the proton resonance measurements performed by Sugawara. This M_0 is the magnitude of sublattice magnetizations in an external field small compared with H_c, in which case they lie along the easy axis. M_0 in Eq. (23) correspond to this M_0, whereas M_0 in Eqs. (21) and (22) is the magnitude of sublattice magnetizations when they are along the *y*-axis. These two quantities may be assumed to be equal to each other for the same reason as that mentioned in the argument concerning $\chi_{\perp H /\!/ x\text{-axis}}$ and $\chi_{\perp H /\!/ y\text{-axis}}$. Thus the Q-tenson is determined to be

$$\left.\begin{aligned} Q_x&=(0.055\pm0.002)A\,, \\ Q_y&=(0.018\pm0\text{-}002)A\,, \\ Q_z&=-(0.073\pm0.002)A\,. \end{aligned}\right\} \qquad (30)$$

It is interesting to note that the ratio P/Q is of the order of 10 which means $A'/\Gamma'\sim1$. Using Eqs. (27) and (30), A' and Γ' are calculated as

$$\left.\begin{aligned} &A_x'=0.25A\,, \quad A_y'=0.20A\,, \quad A_z'=-0.45A\,, \\ &\Gamma_x'=0.19A\,, \quad \Gamma_y'=0.18A\,, \quad \Gamma_z'=-0.37A\,. \end{aligned}\right\} \qquad (31)$$

The results calculated with these values represented by full lines in Fig. 16, which are in satisfactory agreement with the experimental points.

§ 7. Discussion of the Resonance Conditions

In the preceding section we showed that a revised resonance formula can satisfactorily explain our experimental results with the use of anisotropic exchange constants A' and Γ'. These tensors have the same symmetry with that of the *g*-tensor. Accordingly such anisotropic exchange interaction may come mainly from the isotropic exchange interactions, which become anisotropic in the effective spin hamiltonian which is obtained when the true spin is replaced by the effective spin of $\frac{1}{2}$. In $CuCl_22H_2O$, in which the anisotropy of the *g*-tensor is not so large as in $CoCl_26H_2O$, these anisotropic parts of exchange interactions are small compared with the isotropic parts, so that the old theory was satisfactorily applicable. However, there may be other causes which may produce the anisotropic exchange interaction. The magnetic dipole interaction may make a contribution to some extent. This interaction can be represented by a tensor form. Thus, A' and Γ' determined by the present study include this effect. Though we cannot evaluate its contribution quantitatively, since we do not know the spin arrangement in antiferromagnetic state, it may be relatively small and will not account for the main experimental results. The dipolar interaction was also incapable of accounting for the width of the paramagnetic resonance, as was discussed in a previous section.

As other correction factors the 4-th order anisotropy energy and demagnetization effect may be considered. The former can be introduced in the following form:

$$E=L_1\alpha^4+L_2\beta^4+L_3\gamma^4+L_4\alpha^2\beta^2 \qquad (32)$$

where L_1, L_2,, $\cdots$, L_4 are constants and α, β, γ represent the direction cosines of the spins along the x, y and z-axes, respectively. Using this energy, we can obtain the resonance formula including 4-th order anisotropy constants. However, it was found that this energy is unimportant and is whithin experimental errors.

Next, let us consider the demagnetization effect. To take this into acconnt, external field H must be reduced to

$$H-(iN_xM_x+jN_yM_y+kN_zM_z)\ . \tag{33}$$

Substituting this in the equation of motion, we can see easily that the resonance formula can be obtained with the substitution of

$$\frac{1}{2}\begin{pmatrix} P_x & 0 & 0 \\ 0 & P_y & 0 \\ 0 & 0 & P_z \end{pmatrix} \quad \text{by} \quad \begin{pmatrix} \frac{P_x}{2}+N_x-\frac{4\pi}{3} & 0 & 0 \\ 0 & \frac{P_y}{2}+N_y-\frac{4\pi}{3} & 0 \\ 0 & 0 & \frac{P_z}{2}+N_z-\frac{4\pi}{3} \end{pmatrix}, \tag{34}$$

where $4\pi/3$ comes from the Lorentz field correction. In our experiments, however, this correction is also negligible, so that the obtained anisotropic exchange interaction coefficients can be regarded as the intrinsic parameters of the antiferromagnetic $CoCl_2$-$6H_2O$.

§ 8. Line Width

Line width measurements were performed in the paramagnetic state as well as in the antiferromagnetic state of $CoCl_26H_2O$. Two examples of the angular dependence are shown in Fig. 17. One of them is the result for in the bc-plane at 34.820 kMc/sec and the other is that for in the $a'c$-plane at 23.580 kMc/sec, and the high and low field branches corresponding to those of Fig. 11. Temperature dependences of the resonance line width at various frequencies are summalized in Fig. 18. As was described in Section 4, an anomalous broadening of the paramagnetic resonance line was observed at 4.2°K, which

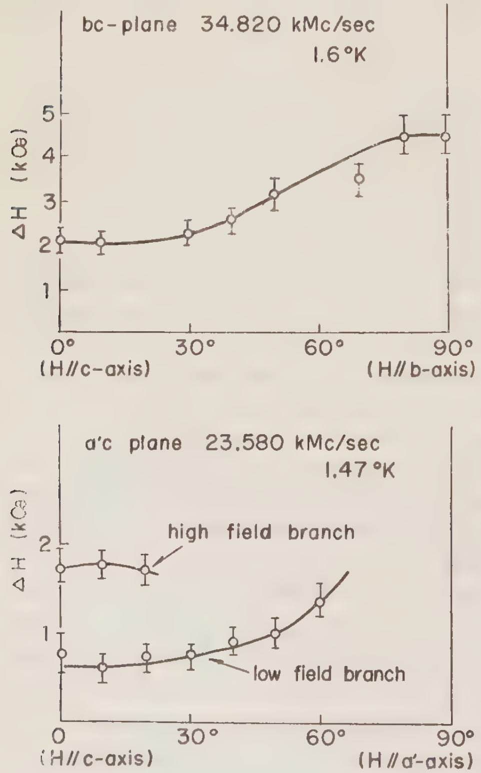

Fig. 17. Angular dependence of the line width.

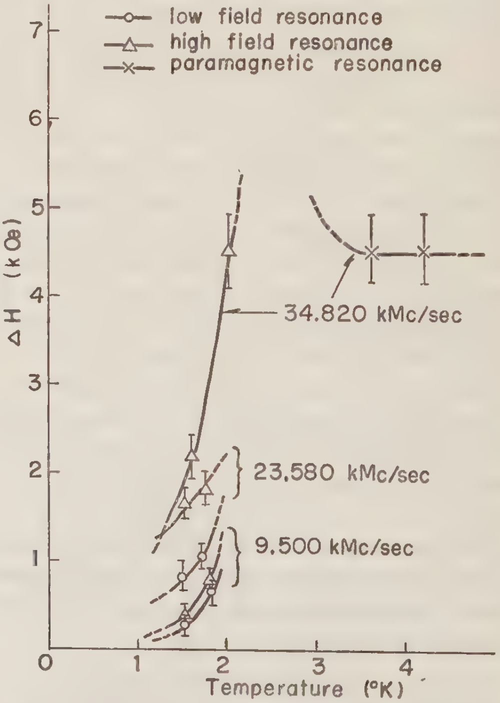

Fig. 18. Temperature dependence of the line width ($H//c$-axis).

may be due to the anisotropic exchange interaction among Co^{++} ions as was introduced in the foregoing section. Below the Néel temperature, however, a considerable narrowing effect was seen in all the crystalline directions as shown in Fig. 18. An interesting result was obtained in the measurement of the frequency dependence, namely, the fact that the line width increases with increasing resonance frequency. This fact cannot be explained by a simple theory of antiferromagnetic resonance line width discussed by Townes, Johnson and Nethercot[4]. Imperfections of the crystal, such as antiferromagnetic domain boundaries, dislocations, or the presence of chemical impurities, may not be responsible for the main origin of the line width, because the extrapolated value of the width to 0°K is estimated to be zero in almost all cases.

In must be added that there was no trace of side peaks which were frequently observed in $CuCl_22H_2O$, $CuBr_22H_2O$ and MnF_2.

Acknowledgement

The present work was initiated at the low temperature division, Institute for Iron, Steel and Other Metals, Tohoku University, and was completed in the low temperature laboratory of Osaka University. The author wishes to express his thanks to Prof. Fukuroi at Tohoku University for offering the facility of making this low temperature experiment and to Prof. Itoh, Prof. Nagamiya and Dr. Kanamori for valuable discussions and suggestions on the present problem.

Thermal Properties of $NaNO_2$

By Shoichiro NOMURA

Physics Department, Tokyo Institute of Technology
Oh-okayama, Meguro, Tokyo

(Received April 1, 1961)

Specific heat and thermal expansion coefficients of $NaNO_2$ crystal were measured from room temperature to 210°C. A conduction-type calorimeter was adopted for the measurement of the specific heat and a differential-type dilatometer for the measurement of the thermal dilatation. A λ-type anomaly in specific heat was observed near the transition temperature, the transition heat being calculated as *ca* 285 cal/mol. The crystal expands in the *a* and *b* direction, while it contracts in the *c* direction with increasing the temperature, and further the transition is accompanied by abrupt changes in the cell dimensions. Our results on thermal dilatation were compared with the ones obtained from the x-ray data. Ferroelectricity in $NaNO_2$ was discussed in connection with our results on thermal properties.

§ 1. Introduction

Ferroelectricity in $NaNO_2$ has first been revealed by the measurements of the dielectric properties[1] and further ascertained by the observations of the domain structure[2]*. The ferroelectric axis of $NaNO_2$ crystal lies in the *b* direction of the orthorhombic structure, the space group of which is C_{2v}^{20} (I_{m2m})[4,5,6]. (The crystallographic *a*, *b*, and *c* axes adopted by Ziegler[4] will be used throughout the present paper.) The crystal undergoes a phase transition at the Curie temperature near 160°C, from the state of lower symmetry to the state of higher symmetry. The space group of higher symmetry is D_{2h}^{25} (I_{mmm})[7,8,9], which corresponds to the paraelectric phase. The unit cell has two molecular units, both above and below the Curie point.

Before the ferroelectricity in $NaNO_2$ has been found, several investigations were made concerning this phase transformation. Jaffray[10] studied the transition by means of differential thermal analysis and found out an abrupt anomaly in specific heat at 160~162°C. Analysing the x-ray data, Strijk and MacGillavry[7,8] reported that $NaNO_2$, which is orthorhombic hemihedral at ordinary temperature, shows an abrupt change in the temperature coefficients of the all dimensions at about 158°C and the original strong piezoelectric effect disappears above this temperature. He pointed out further that the change is probably caused by the occurrence of two symmetrical sets of atomic positions in an average structure.

Since the occurrence of ferroelectricity in $NaNO_2$ became clear, it has been necessary to measure the various properties in detail near the transition temperature, for developing a thorough discussion about the ferroelectricity in $NaNO_2$. For this purpose, we have measured the thermal properties of $NaNO_2$: specific heat and thermal dilatation, in the temperature range from ordinary temperature to 210°C and tried to make their characters clear. (The specific heat is the one at constant pressure.) In this paper, these experimental results are described and some discussions on the ferroelectricity in $NaNO_2$ are presented.

§ 2. Experimentals

a) *Specific heat*

The adopted method was of the conduction-type, in which the thermo-electromotive force of the differential thermo-couple was recorded when the temperature of the furnance was varied in a definite manner. But the detailed descriptions on the apparatus and the measuring method are omitted here, since they have been described in the other paper[11,12].

Before the beginning of the measurement, a powder sample of $NaNO_2$ of 16 grs was dried at about 100°C during 12 hrs. in the container of the calorimeter. The measurement was done under the pressure of 10^{-2} mm Hg, and the rate of heating of the sample was kept nearly constant about 1°C/min, by a controll of the furnace input voltage. The calibration curve of the calorimeter was taken by using both Al_2O_3 and SiO_2 powders and nearly same curves were obtained in the two cases.

---

* Recently, Dr. Shibuya have carried out x-ray studies of the phase transition in $NaNO_2$, using the Bragg reflections, and the critical scatterings[3].

b) *Thermal dilatation*

The magnitude of the linear thermal expansion coefficients of $NaNO_2$ crystal being of the order of 10^{-4}°C^{-1}, the measurement of the thermal dilatation was easily done by using an usual dilatometer of differential type, in which an optical lever combined with a fine roller was adopted, a fused silica rod being used for comparison. The diameter r of the roller and the distance D between the mirror and the scale were 0.24 cm and 148.2 cm respectively, so the dilatation of the sample, enlarged $2D/r=1235$ times, was observed on the scale. The calibration of the dilatometer was done by using a copper rod. The rate of the temperature increase of the sample in the measurement was 1°C/min in avarage, but in the vicinity of the transition temperature, it was slowed down less than 0.1°C/min.

Samples of rod shape were cut out from the crystals prepared by the fusion method, of which description was given in our previous paper[2]. The lengths of the a, b, and c crystal rods were 0.848 cm, 0.997 cm, and 1.040 cm respectively.

§ 3. Results and Discussions

a) *Specific heat*

The specific heat of $NaNO_2$ in the temperature range from 50°C to 220°C is shown in Fig. 1. A large anomaly of λ-type is observed near the transition temperature. The anomaly appears from near 110°C, in the temperature region far below the transition temperature and reaches to a peak at 161°C. It is noticiable that the anomaly remains in the paraelectric region upto about 170°C, though its magnitude decreases rapidly with increasing the temperature. The transition heat was estimated as 285 cal/mol, the magnitude of which depends upon to some extent the situation of the curve of the normal specific heat shown by a dashed line in the figure, and the transition entropy was calculated as 0.7 cal/°C mol.

Our result on specific heat coincides with Jaffray's work[10], that the transition is not accompanied by a latent heat, but an abrupt anomaly in specific heat. This seems to be favorable to the view that the transition is of the second kind. At the present step, however, we had better refrain from judging the kind of the transition in $NaNO_2$, because a detection of a small amount of latent heat is beyond the ability of our calorimater.

b) *Thermal dilatation*

The temperature dependences of the thermal dilatation in each direction of the crystal

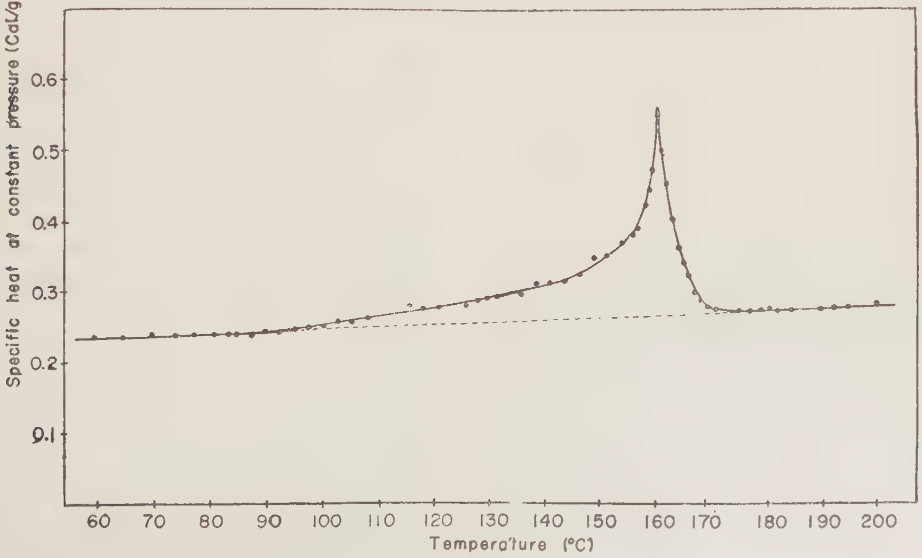

Fig. 1. The specific heat of $NaNO_2$.

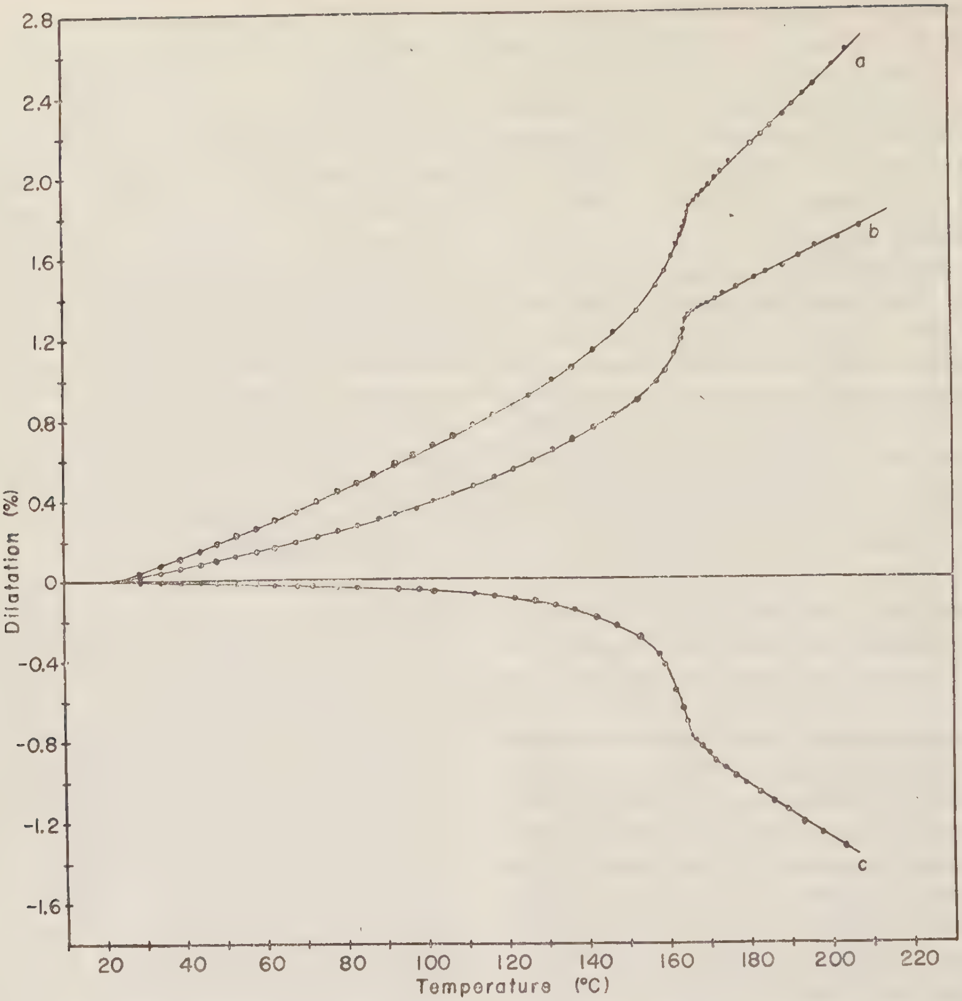

Fig. 2. The thermal dilatation of $NaNO_2$ crystal. The relative change of the length, taken as zero at 20°C, is expressed in each direction of the crystal axes.

axes of the orthorhombic structure are illustrated in Fig. 2, where the changes in length of the crystal rods are plotted in percents, the lengths at 20°C being taken as the original ones in all directions. It is quite obvious that the crystal expands in the *a* and *b* direction, while it contracts in the *c* direction with increasing the temperature. The linear thermal expansion coefficients obtained from the curves of the dilatation are shown in Fig. 3. Sharp peaks are observed in all directions at 164°C and anomalies can be observed also far below the transition temperature, as in the case of the specific heat. The coefficient of the *a* direction is larger than that of the *b* direction, though the peak value at the transition is superior in the later. Above 168°C, the coefficients take nearly constant values, excepting for in the *c* direction, in which a minor anomaly is noticed near 170°C*.

To show how the cell dimensions vary at the transition temperature, the dilatation curve in the *b* direction in the vicinity of the transition temperature is enlarged in Fig. 4. Judging from this curve, we may say that the transition is not accompanied by a discontinuous change in the cell dimensions but rather a continuous one, though its variation is steep, and if some amounts of the discontinuity occurred at the transition temperature, it should be smaller than $4\times10^{-2}\%$

---

* Dr. Hoshino and Shibuya have reported that the minor anomaly of this kind was observed not only in the *c* direction but also in the *a* and *b* direction by his x-ray analysis. (J. Phys. Soc. Japan **16** (1961) 1254.)

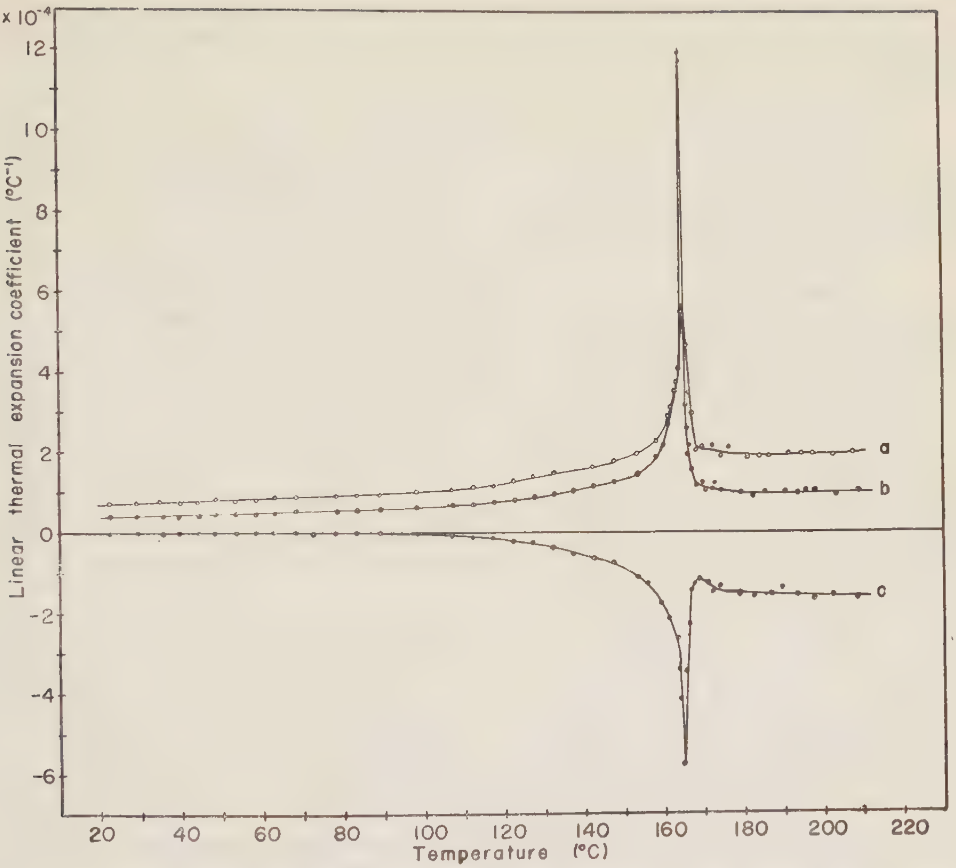

Fig. 3. The linear thermal expansion coefficients in the directions of the crystal axes of NaNO$_2$.

in its magnitude in the b direction.

Our results on the thermal dilatation show the same characteristic as the ones obtained from the x-ray data$^{7),8)}$, but quantitatively some discrepancies exist between them. The situations are illustrated in Table I, where the percentages of the changes in the cell dimensions caused by rising the temperature of the crystal from room temperature to 205°C, are given in both cases. The values obtained by the dilatometric method are smaller than the ones by the x-ray method in all directions. It may be natural that they should show some differences in their magnitude, because one of them is due to the macroscopic measurement, while the other is the microscopic one. The existence of the domain boundaries and some kinds of crystal imperfections may be considered to be the causes for the discrepancies. As the discrepancy is remarkable in the a direction, it may be related with the fact that the domain boundaries lie parallel to the bc plane$^{2)}$. In high temperature, moreover, a plastic flow might be slightly induced by a mechanical stress owing to the metal springs, holding the sample in the dilatometer. This flow effect seems to be supported by our recent experiments on the deformation of the crystal with a two dimensional stress*.

Table I. The comparion of the magnitudes of the dilatation. The values of the cell dimensions are quoted from "Crystal Structures Vol. Ⅲ (1951) (by R. W. Wyckoff)".

	cell dimension (Å)		dilatation (%)	
	26°C	205°C	x-ray	dilatometer
a	3.570	3.69	3.3	2.6
b	5.578	5.68	1.8	1.7
c	5.390	5.33	−1.1	−1.3

c) *Relations with the ferroelectricity*

The spontaneous polarization P_s of a ferroelectric crystal intimately relates with the

---

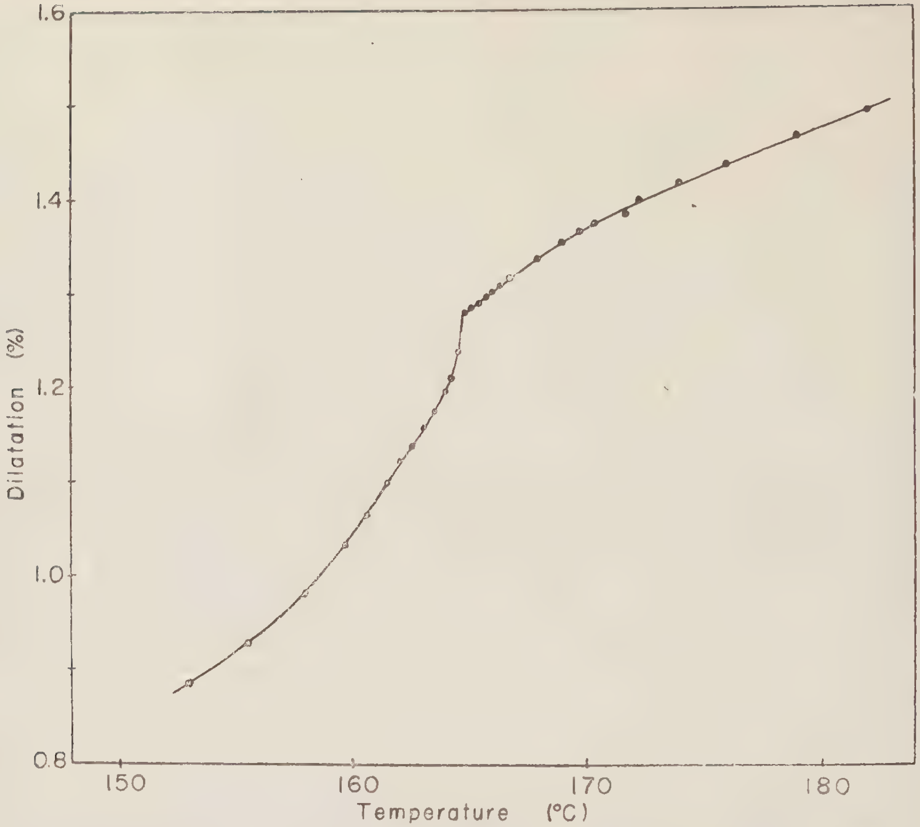

Fig. 4. The dilatation curve in the b direction in the vicinity of the transition temperature.

transition heat Q from the ferroelectric state to the para electric state. We have the well-known formula[13].

$$Q \simeq 2\pi \cdot \frac{T_0}{C} \cdot P_s^2 , \qquad (1)$$

which holds experimentaly to a good approximation in many kinds of ferroelectrics, where T_0 is the transition temperature and C is the Curie-Weiss constant. Putting the numerical values on T_0, C, and P_s as follows,

$$T_0 = 437°\text{K}$$
$$C = 5000°\text{K}$$
$$P_s = 8.6\mu\text{C/cm}^2*$$

we obtain the value of Q as 279 cal/mol. The agreement with experiment is satisfactory when the experimental difficulties are considered that are encountered in the measurement of the transition heat and the spontaneous polarization.

Ferroelectricty in $NaNO_2$ is probably due to the alignment of NO_2^- radicals along the b direction, and the disordering of their sense is realized above the Curie temperature. The order of the alignment of NO_2^- radicals ought to be estimated from the magnitude of the transition heat and also the transition entropy.

Since a strict calculation of the transition entropy of $NaNO_2$ seems to be complicated, we give here a rough estimation on it. Supposing that a NO_2^- radical has two equilibrium positions in its surrounding, being of opposite sense along the b direction and the transformation is accompanied by the order-disorder arrangement of NO_2^- radicals between them. If the parameter of the long range order is denoted by s, the entropy of the system S will be represented by a simple calculation, neglecting the effect due to the short range interaction, as follows,

$$S = -kN\left\{\frac{1+s}{2}\ln\left(\frac{1+s}{2}\right) + \frac{1-s}{2}\ln\left(\frac{1-s}{2}\right)\right\}, \qquad (2)$$

where N is the total number of the radicals and k is the Boltzman's canstant[14]. In the case of $s=0$, which corresponds to the completely disordered state, S becomes 1.38 cal/°C·mol. Subtracting the transition entropy of 0.7 cal/°C·mol from it, we get 0.68 cal/°C·mol, which may be considered as the value of S at ordinary temperature. Therefore the parameter s at ordinary temperature is calculated as 0.78 from Eq. (2). Thus *ca* 89% of NO_2^- radicals are expected to arrange in one sense and the others in the opposite. Perhaps this may be true, though the numerical value of s might differ somewhat from our estimation. Considering the effects of Na^+ ions, which give a restriction for the disordering behaviors of NO_2^- radicals, we ought to give a smaller value than 1.38 cal/°C·mol as the entropy of the system in the disordered state. Then the ordering parameter s at ordinary temperature will more approach to 1 than the value estimated above.

---

* This is the value at room temperature obtained from the pyroelectric measurement.

It seems to be sure that the anomalies in the specific heat and dilatation observed above the transition temperature, including the minor anomaly in the dilatation, should be due to the short range interactions between the constituent ions. From the consideration on the interatomic distances of the constituents and the behavior of the domain boundary in the crystal$^{2)}$, we may imagine that the disordering arrangement of NO_2^- radicals is easily realized in the direction perpendicular to the b axis, keeping their alignments along the b direction, and even in the paraelectric phase the alignment is held in short range. The recent x-ray study by Tanizaki$^{15)}$ is considered to show an evidence of the remaining of the short range order above the Curie temperature. These problems will be discussed further in our subsequent paper.

Notes on the Lustre of Moiré Patterns

By Jien NISHIWAKI

Department of Physics, Faculty of Science, Tokyo Metropolitan University
Setagaya, Tokyo, Japan

(Received March 4, 1961)

Moiré patterns produced by passing diffuse light from uniformly illuminated background through two net or gauze screens of suitable mesh size, set face-parallel, one behind the other with a space in between, are tinged with some lustre which is more or less vitreous or slightly metallic. A number of results obtained by visual observation and photographing show that this is a typical case in which the so-called false stereoscopic effect gives rise to the impression of gloss.

§ 1. Introduction

There are a number of cases in which one perceives lustre on a surface that is not specularly reflective[1]. One of the most well-known is the case of binocular lustre shown by Dove[1] and Kiesow[1]. For example, when two figures of the type shown in Fig. 1 are stereoscopically brought together, lustre appears on the sectors which are not lustrous when viewed separately. It should be noted that, of the corresponding two sectors which are to be brought together, one is white and the other is black.

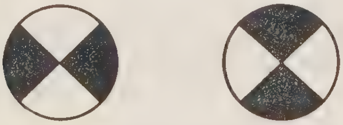

Fig. 1. A pair of drawings for stereoscope to demonstrate binocular lustre.

It is also known that, even in ordinary binocular vision, a similar, but false, stereoscopic effect may often give rise to the impression of gloss when the two eyes do not receive the same images[1]. The following sections give some of the evidence showing that the case of Moiré patterns is a typical one of such cases which has not been so far wellknown.

§ 2. Appearance of Moiré Patterns

Moiré patterns produced by passing diffuse light from uniformly illuminated background—for instance, a sheet of white mat paper of ample size—through two pieces of net or gauze, set face-parallel, one behind the other with a space in between, are tinged with some lustre. It is rather difficult to describe it precisely in words: roughly speaking, it is vitreous in general appearance, slightly metallic in some cases, varies with the conditions of illumination and other factors.

Fig. 2 shows photographs of Moiré Patterns obtained on five specimens prepared with wire gauze of mesh 50 and wire diameter of 0.15 mm. For the spacing, d, between the front and back gauze screens, 0, 5, 10, 15 and 20 mm were used. The effective diameter for all was 6 cm. The specimens were so constructed that all the patterns gave roughly equall perception with respect to their shapes or distributions. By hand, it was difficult to obtain the same pattern from all the specimens, because of inhomogeneities in mesh.

In actual observation, the specimens were set against a large ground glass window pane illuminated from behind by daylight at about 3000 lux. The specimen on the extreme left ($d=0$) had the lowest lustre while that on the extreme right ($d=20$) the highest when viewed from 4 to 5 meters. The lustre decreased with the increasing distance between the observer and specimens, thus, as the observer backed away step by step from the specimens, the lustre of the second ($d=5$) and the rest specimens became in turn equal to the first. The distances at which the lustre of the last four specimens became equal to that of the first were estimated by two observers B and C. Plots of mean values of the estimation repeated six times for every specimen are shown in Fig. 3, the disagreement between the two being attributable to personal error.

On the other hand, the pattern shifted on the plane of the gauze and changed its shape when the position of the eye was changed sidewards. Hence the pattern that appeared to the right eye would not have been identical to that appeared to the left eye. From this and from a more remarkable fact that the

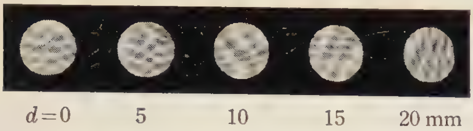

Fig. 2. Patterns obtained on five specimens constructed with ♯50 wire gauze: d is the spacing between front and back gauze screens.

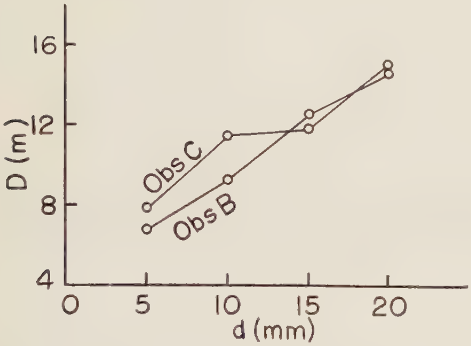

Fig. 3. Distance D between the observer and specimens at which the lustre of the last four specimens became equal to that of the first ($d=0$).

lustre on the pattern almost disappeared from all the specimens when viewed with one eye even from the distance 4 meters with which the above experiment started, it was presumed that the perceived lustre in this case was attributed to the false stereoscopic effect mentioned in the preceding section. As is readily expected, the difference between the patterns appearing to the right and left eyes will increase with the spacing between the two gauze screens and decrease with the distance between the observer and specimen under such viewing conditions as used in obtaining the results shown in Fig. 3. Hence, those obtained results themselves justify the above presumption. Another evidence will follow next.

§ 3. Best Conditions for the Lustre

By taking the false stereoscopic effect into account, one can easily calculate the best conditions for obtaining the lustre. In Fig. 4, E_r and E_l represent the observer's eyes, the interspacing of which is denoted by Δ. The distance between the observer and the front screen is denoted by D and the spacing between the front and back screens by d. Under actual conditions of observation D is large compared to d. When the observer fixes his eyes to a point, P, on the plane of the front screen the following conditions are required. For his right eye E_r wires of the back screen come between those of the front screen obstructing the light from background,

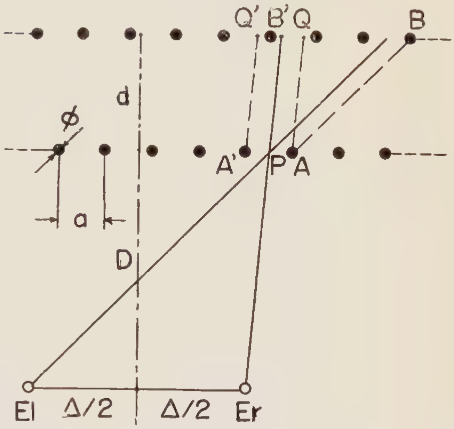

Fig. 4. Schematic illustration of the best conditions for obtaining the lustre.

hence this part appears dark. But, for his left eye E_l, the former are shadowed by the latter, hence this appears bright. The relative positions of the wires A, A' and B', and of A and B settle these particular conditions which are easily found to be expressed by

$$BQ+\phi<BB'<BQ+QQ'-\phi\ ,$$

where ϕ is the diameter of the wire. BQ is given by $\Delta d/D$. Putting $QQ'=AA'=a$ and $BB'=na$, we obtain

$$\frac{\Delta}{D}d+<na<\frac{\Delta}{D}d+a-\phi\ ,$$

or

$$\frac{\Delta}{na-\phi}d<D<\frac{\Delta}{(n-1)a+\phi}d\ , \qquad (1)$$

where a is the spacing of wires and n an positive integer. In the case of $n=1$, Eq. (1) is reduced to

$$\frac{\Delta}{a-\phi}d<D<\frac{\Delta}{\phi}d\ . \qquad (2)$$

To compare the result of this simple calculation with what is to be obtained by visual observation, a pair of wire screens of $\phi=0.84$ mm and $a=2.5$ mm were used. For the specimens used in the preceding section, such comparison was difficult owing to the slow change of the lustre with the distance D. Substituting the above values into Eq. (2) and assuming $\varDelta$ to be 70 mm, we obtain $42d<D<83d$. In Fig. 5, the upper and lower lines represent the cases of $D=83d$ and $D=42d$. The lustre will be most apparent in the region between the two lines.

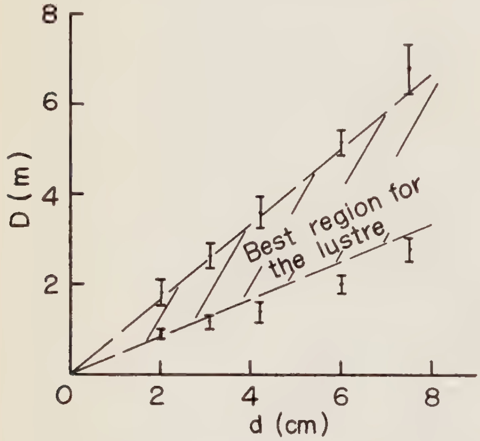

Fig. 5. Calculated range for good lustre and visual estimates of margins of the range.

In visual observation, margins of the range between which the lustre was most apparent were determined for each of five given spacings $d=2.0$, 3.1, 4.2, 6.0 and 7.5 cm. The mean and standard deviation of estimates—repeated twelve times for every margin—given by three observers are also plotted in Fig. 5. The correlation of the observed values with the calculated ones is satisfactorily well.

These results were obtained for the specimen prepared in the following way. Of the two wire net screens that were used, the first one was set parallel to and close to a ground glass window pane illuminated from behind by daylight at about 3000 lux, and the second screen was leant against the first. The second screen was masked with a sheet of black paper which had equally spaced four rows of horizontal slit, 20 cm long and 1.6 cm wide, through which the observations were made. By varying the slope of the second screen, and also shifting the mask over the screen, the observer could use the spacing between the screens along the centre lines of the slits as desired. The margins were estimated by the observer fixing his eyes at the centre of the slit under observation and, step by step, approaching to or backing away from the slit.

Fig. 6 shows as an example a stereo-photograph of a pattern taken at the distance of 175 cm from the slit with the spacing of 4.2 cm between the front and back screens. As regards the distance D and the spacing d, this setting falls almost on the lower border line of calculated range given in Fig. 5 for effective lustre to appear. The right and left halves of the photograph are what come into view to the observer's right and left eyes respectively, and the bright and dark portions on the right half are almost reversed on the left half; this is why the pattern appears to have lustre when viewed with both eyes.

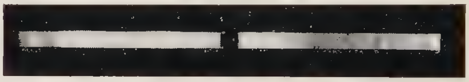

Fig. 6. Stereo-photograph of a pattern taken at 175 cm from the slit, the spacing between screens being 4.2 cm.

For the ranges of clearly perceived lustre given by Eq. (1) (the case of $n>1$), observation was to be made very close to the present specimen which was not practicable because the wires of the screens were seen quite distinctly.

§ 4. Conclusion

Every day, numbers of examples of the lustre due to the false stereoscopic effect are around us. The effect occurs when the two eyes receive different images with respect to the same part on a surface. Once one is aware of it, he can frequently see the examples, in general, on the high glossy surfaces which are lustrous too when viewed with one eye. In the case of Moiré patterns as produced in this work, lustre appears only when viewed with both eyes and was found to be due purely to the false stereoscopic effect.

The author expresses his sincere thanks to Professor E. Fukushima for his suggestion and intimate advice.

Effect of Incoherent Waves on the Electron Microscopic Images of Crystals

By Yoshihiro KAMIYA and Ryozi UYEDA

Physical Institute, Nagoya University, Nagoya, Japan

(Received, April 7, 1961)

The electron micrographs of crystalline specimens are taken by placing the aperture of the objective lens at various positions. Extinction contours, equal-thickness fringes and dislocation images are observed under a condition that none of the coherent waves—the transmitted and diffracted waves—enters the aperture. This implies that the above contrast effects are formed by incoherent waves which are neglected in current theories of diffraction contrast.

§ 1. Introduction

In the electron microscopic images of crystals, various kinds of contrast are observed: extinction contours, equal-thickness fringes[1], dislocation images[2] etc. These contrast effects are closely related to the Bragg reflection and can be interpreted by diffraction theories[3]. It is generally believed that the most reliable interpretation is given by the dynamical theory taking into account the effect of absorption[4]. However, the incoherent waves are perfectly neglected in the current theories of contrast.

In the present experiment, electron micrographs of crystalline specimens were taken by placing the aperture of the objective lens at various positions. One of the remarkable results is that equal-thickness fringes are observed on dark field images even under the condition that no diffracted beam enters the aperture. The aim of the present paper is to point out the effect of incoherent waves on the formation of contrast.

§ 2. Experiments

The electron microscope used in the present experiment was Hitachi HU-10. The accelerating voltage was 75 kV. The diameter of the objective aperture was about 10 μ, namely 1.3×10^{-3} rad. in scattering angle. Specimens used were molybdenite films and magnesium oxide crystallites.

Electron micrographs were taken by placing the aperture of the objective lens at the following (Figs 2 and 4).

(a) Bright field: The transmitted beam enters the objective aperture.

(b) Usual dark field: The transmitted beam does not enter the objective aperture while one diffracted beam does.

(c) Special dark field: None of the transmitted and diffracted beams enters the objective aperture. Only the background scattering does. In (b) and (c), adjectives *usual* and *special* are used because (b) is adopted usually in routine experiments and (c) is adopted specially in the present experiment.

It should be noted here that as shown in Fig. 7 c the incident spot and the strong diffraction spots are not sharp on diffraction patterns. Examining carefully, however, it is found that the diffuse background due to incoherent waves is considerably strong around each sharp spot due to the coherent wave—the transmitted or diffracted wave. In the above classification, the transmitted and diffracted beams mean only the sharp beams corresponding to coherent waves.

§ 3. Results

(i) *Extinction contours*

Fig. 1 reproduces the images of molybdenite film taken by placing the objective aperture at various positions: Figs. 1 a, b, c and d correspond, respectively, to aperture positions a, b, c and d indicated in Fig. 2. The molybdenite film was placed directly on a specimen grid without any supporting film. Thus the part of field which is free of the film is perfectly dark in dark field images (Figs. 1 b, c and d). Although extinction contours which appear on bright field and usual dark field images are well-known, those on special dark field images have not yet been studied. Comparing Figs. 1 a with c, the following conclusion may be obltained: The contrast of

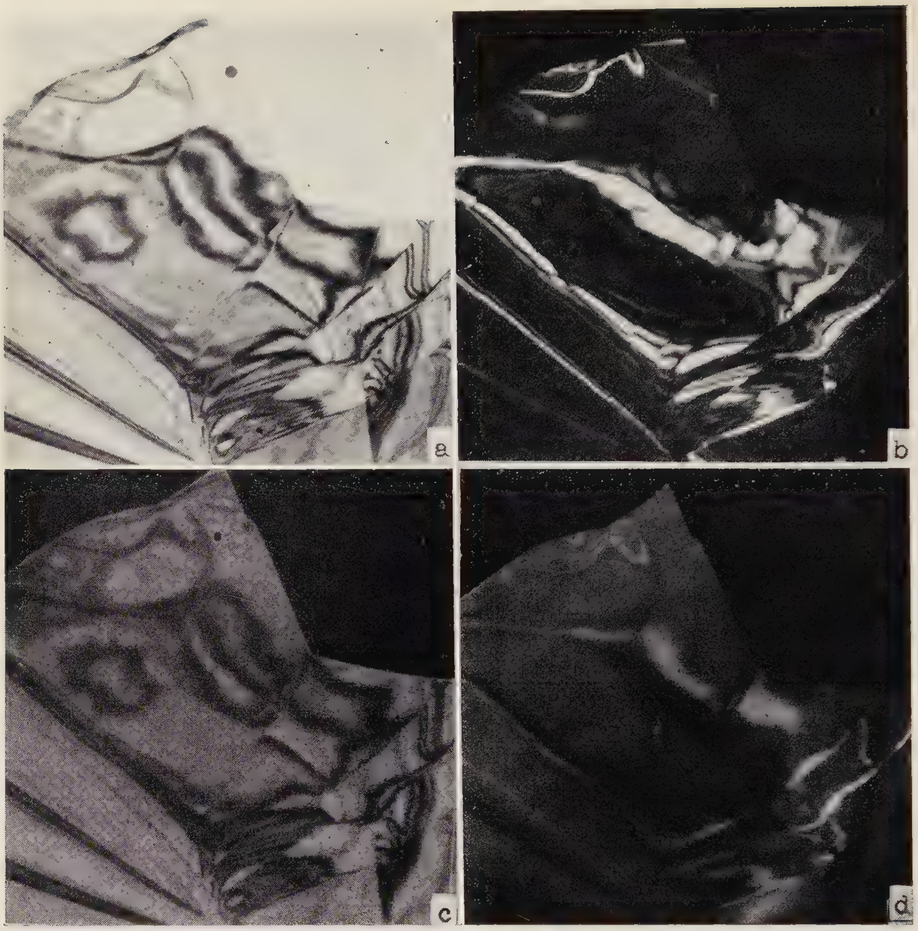

Fig. 1. Extinction contours of a molybdenite film. ×9,000.
a) Bright field. b) Usual dark field. c) Special dark field at a small angle.
d) Special dark field at a large angle. (Aperture positions indicated in Fig. 2).

special dark field image is similar to that of bright field image, provided that the former is taken by placing the objective aperture close to the incident spot. A similar conclusion is obtained when the objective aperture is placed close to a Bragg spot: the special dark field image is similar to the usual dark field image corresponding to the Bragg spot (Fig. 1 d).

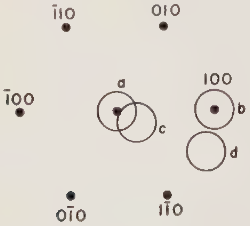

Fig. 2. Indicating size and positions of the objective aperture for Fig. 1. Positions a, b, c, and d correspond respectivety to Figs. 1 a, b, c, and d.

(ii) *Equal-thickness fringes*

Fig. 3 reproduces images of magnesium oxide crystallites. The aperture position corresponding to each micrograph is shown in Fig. 4. Again, nothing new is observed in the equal-thickness fringes on bright field and

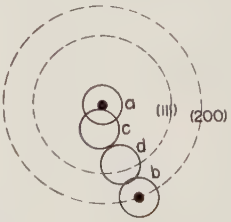

Fig. 4. Indicating size and positions of objective aperture for Fig. 3. Positions a, b, c, and d correspond respectively to Figs. 3 a, b, and d.

usual dark field images** but those on special dark field images are interesting. By comparing Figs. 3 a and c, the same conclusion as that described in the previous subsection on extinction contours is obtained. The contrast of fringes on a special dark field image becomes quickly low when the objective aperture is shifted to large scattering angles. No fringe is observed in Fig. 3 d which is taken at a large angle. Fig. 5 reproduces another example showing equal-thickness fringes on a bright field image and those of a special dark field image.

---

* Faces indicated by arrows are remarkably bright. This may be caused by the specular reflection of the incident wave[10].

** The difference of spacings observed in Figs. 3 a and b is due to the change of crystal orientation.

In this case one might suspect that the equal-thickness fringes in Fig. 3 c and Fig. 5 b might have been produced by coherent waves which are deviated slightly due to double refraction effects[5]. As illustrated in Fig. 6, the coherent wave penetrating a crystal produces two pairs of spots P and P' and Q and Q'. It is possible that one of the pairs, say P and P', passes through the objective

aperture even when the central spot 0 is stopped. In such a case, the image of the face CD is expected to appear much brighter than the face AB. Since no such effect is observed in Fig. 5 b, the suspicion is cleared.

(iii) *Images of dislocations*

Figs. 7 and 8 reproduce the images of dislocations in molybdenite films⁶⁾. In each figure, (a) is a bright field image and (b) is a special dark field image. The latter are taken by placing the objective aperture close to the incident spot. Figs. 7 and 8 are from a thin specimen (~200Å) and a thick specimen (>1,000Å), respectively. The approximate thickness was inferred from diffraction patterns (Figs. 7 c and 8 c). Comparing (a) and (b) of both figures, the same conclusion as described in the previous subsection is obtained also for dislocation images. In thick specimens, a bright field image is only a little sharper than the corresponding special dark field image. In thin specimens, the difference in sharpness is a little more conspicuous compared with thick specimens. Sometimes, details of contrast are different as indicated by arrows in Figs. 7 a and b. In Fig. 7 b the upper side of the indicated dislocation line is always dark while the lower side is slightly light. On the other hand, in Fig. 7 a the corresponding line has a complicated structure.

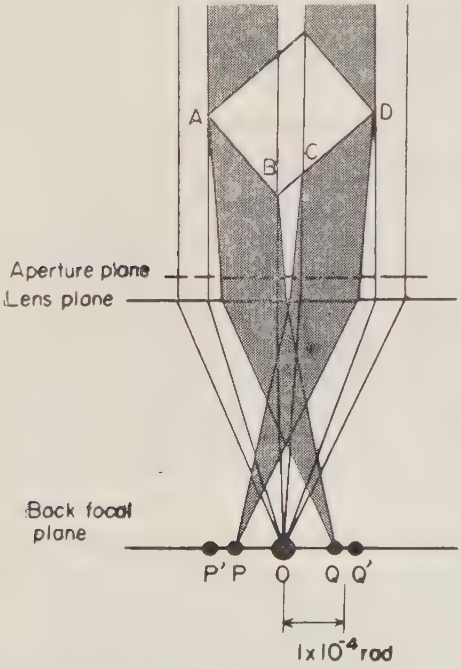

Fig. 6. Illustration of refraction effect.

§ 4. Discussion

In cases of the bright field and the usual dark field, coherent waves enter the objective aperture. Since incoherent waves also enter the objective aperture with coherent waves, a bright field image or a usual dark field image is a superposition of a partial image formed by coherent waves and that by incoherent waves. This fact has been pointed out by one of the present authors (R.U.) and the different natures of partial images have been explained in the previous paper⁷⁾. Therefore, the explanation is not repeated here.

The intensities of partial images in a bright field image can be estimated from the ratio of exposure times for the bright field and special dark field images. The ratio is small when the crystal is thin. For example, it is 1:15 in Fig. 7. This implies that in Fig. 7 a the part due to coherent waves is much stronger than that due to incoherent waves. On the other hand, the ratio is comparable with unity when the crystal is thick. For example, it is 1:2 in Fig. 8. Taking into account that the intensity of incoherent waves decreases rapidly with the scattering angle, ratio 1:2 implies that in Fig. 8 a the part due to incoherent waves prevails over that due to coherent waves.

It is concluded in Sec. 3 that the contrast of special dark field images is similar to that of bright field images, provided that the former is taken by placing the objective aperture close to the incident spot. This is possible only when the contrast of the transmitted wave and that of the accompanying incoherent waves vary in a similar manner. For example, if the contrast of the transmitted wave oscillates according to Pendellösung, that of the accompanying incoherent waves must have a similar oscillation. To understand such a behavior of incoherent waves, the dynamical theory must be generalized to include incoherent waves. Although such a theory is most difficult, the theory of Kikuchi pattern by Kainuma⁸⁾ may be the first step to the generalization.

Recently, the behaviors of stacking fault, extinction contour and dislocation images in the case of thick crystals were explained by a dynamical theory, taking into account the effect of absorption4),9). However, the agreement may be fortuitous because the theory neglects the part due to incoherent waves. In the case of thick crystals, the neglected part prevails over the calculated part, according to the present result. If correct figures of the absorption coefficient were available and they were adopted in the calculation, the result would explain only the part due to coherent waves. Agreement between the theory and experiment is possible so far as the contrast due to the coherent waves and that due to accompanying incoherent waves are similar. It is not known to what extent the similarity holds. The difference of contrast observed in Figs. 7a and b may be an example where the similarity breaks.

We thank Professor N. Kato and Professor Y. Kainuma for their helpful discussions.

Flow Birefringence of Polymer Solutions

By Ryuzo Koyama

Electrical Communication Laboratory, Musashino, Tokyo

(Received January 27, 1961)

By making use of a gaussian chain model for a polymer molecule, a theoretical calculation on the flow birefringence of polymer solution is carried out, in which the optical internal field in the polymer molecule in solvent is taken into account.

The obtained expression for the intrinsic birefringence contains a quadratic form of the refractive index of solvent, and this can account for several experimental results. The expression for the intrinsic extinction angle also has a certain optical factor, and thus it predicts that the extinction angle depends on the refractive index of the solvent.

Assuming that there is no hydrodynamic interaction between molecular segments, we carried out some numerical calculations to the optical factors. The result can well reproduce the recent experimental values of the polystyrene molecules, and of the polymethylmethacrylate molecules.

§ 1. Introduction

The recent studies on polymer solution show that the observed value of the flow birefringence of polymer solution depends on the refractive index of solvent, and this fact is explained by introducing the effect of the optical internal field in polymer solution into the theoretical considerations. This problem was first discussed by Sadron, Peterlin and Stuart, and Cerf1) by means of models such as a rigid ellipsoid and a deformable elastic sphere. Lately Tsvetkov2) and Copic3) also treated it with more detailed models. Thus, these theories can well explain the observed reslt through the form anisotropy of polymer molecule and the optical internal field.

We can consider a similar problem in the case of the extinction angle of the birefringence, though such an effect has not been observed in experiments. The expressions for the extinction angle which have been obtained heretofore do not contain any optical parameters, and hence the extinction angle has been considered to be determined from the purely mechanical condition of that polymer solution as in the case, for example, of the viscosity of the solution. However, the recent detailed theoretical treatment by Copic[3] which is based on a dumbbell model throws doubt upon the above statement. According to his calculations, in case of the rigid polymer molecule with infinite internal viscosity the expression of the intrinsic orientation number* has a certain optical factor which depends on the optical constants of the polymer solution, whereas in case of the soft polymer molecule with negligible internal viscosity such an optical factor again does not appear in his expression.

In the following discussion the calculations are based on a gaussian chain model recently used by several authors[4],[5] in which the method of determining the molecular configuration is more direct than those of the earlier works, and the optical factors for both birefringence and extinction angle are examined.

§ 2. Average Polarizability of a Polymer Molecule and Flow Birefringence of the Polymer Solution

In the following calculation, the solute polymer molecule is assumed to be a gaussian chain formed by a large number of the identical segments in linear connection. The connecting point of the segments is represented by a bead and is subjected to the viscous resistance from the solvent. The polymer molecule is also supposed to have an internal viscosity accompanied by its internal deformation, which can be treated by the method given by Cerf[5] on this model.

It is assumed that the segment has no permanent dipole, but may have an induced dipole in the presence of an applied electric field. The segment is supposed to be axially symmetric about the axis joining its two ends, and its dielectric property is represented by two components of polarizability, one of which is parallel to the axis, and the other is perpendicular to this axis. Also, the polymer molecule is assumed to be sufficiently small compared with the wave length of the light, so that the phase of incident ray is put to be the same everywhere in a polymer molecule at any time, and the method of quasi-static treatment can be applied.

When the electric field is applied to a polymer molecule, it induces an electric dipole in each segment, and this dipole produces the secondary electric field in the same molecule. In such a case the total electric field E_i acting on a segment i can be written in a form of superposition as follows

$$E_i=E+\sum_{k(\neq i)} T_{ik}p_k\,, \tag{1}$$

where the term $T_{ik}p_k$ represents the induced field from the dipole p_k on the segment k. The summation over k is taken over all the segments other than i of the same molecule, because in our case the polymer solution is so diluted that the interactions between different molecules can be neglected by virtue of their very large distances. The interaction tensor T_{ik} is a function of the relative coordinates r_{ik} of two segments i and k, and is given in the diadic notation by

$$T_{ik}=n_0^{-2}r_{ik}^{-3}(3r_{ik}r_{ik}/r_{ik}^2-1)\,, \tag{2}$$

where n_0 represents the index of refraction of the solvent.

On the other hand the electric polarizability tensor α_i of a segment i is given by the relation:

$$p_i=\alpha_i E_i\,, \tag{3}$$

and also for the given external electric field E we can define the total electric polarizability tensor A of a whole polymer molecule by the following relation,

$$\sum_i p_i=AE\,. \tag{4}$$

Therefore, from these relations the average polarizability of a polymer molecule $\langle A\rangle$ can

---

* The intrinsic orientation number $[\omega]$ is defined as

$$[\omega]=\lim_{\substack{G\to 0\\ c\to 0}}(\pi/4-\chi)/G\eta_0$$

and this is different from the intrinsic extinction angle defined by Eq. (31) by the factor η_0.

be written in the following form:

$$\langle A\rangle=\langle A_1\rangle+\langle A_2\rangle\,, \tag{5}$$

$$\langle A_1\rangle=\sum_i\langle\alpha_i\rangle\,, \tag{5$'$}$$

$$E\langle A_2\rangle=\sum_i\sum_{k(\neq i)}\langle\alpha_i T_{ik}p_k\rangle\,. \tag{5$''$}$$

The notation $\langle\ \rangle$ means the average over all the possible internal configurations of a polymer molecule for the given external condition of the solution. In order to calculate such an average value we can employ the distribution function of polymer molecule if it is known, or in some cases we may use the differential equation satisfied by the distribution function.

At the present discussion we are treating a polymer molecule which is immersed in a solvent, and E_i ($i=1, 2, \cdots, N$) should be the internal electric field acting on the segment i in the solvent. For this purpose we shall substitute for α_i of Eqs. (5), (5′) and (5′′) the effective polarizability α_i' given by

$$\alpha_i'=\alpha_i-P_0\,, \tag{6}$$

where P_0 corresponds to the polarizability of a mass of solvent which is excluded by one segment in the solution. In the subsequent calculation we shall assume that every segment has an equal spherical form in solution, and the velocity gradient does not affect the molecular construction of solvent, so that P_0 is a constant scalar quantity. In this way the effect of the internal field in the solvent can be taken into account in our theoretical calculations.

We can use for α_i the expression of the polarizability tensor obtained by Kuhn and Grün[6] for the statistical chain segment. By using their result the component of polarizability α_i' parallel to the axis of the segment, γ_1, and that perpendicular to the same axis, γ_2, are written respectively as

$$\begin{aligned}\gamma_1&=P-P_0+2Ql^2\,,\\ \gamma_2&=P-P_0-Ql^2\,,\end{aligned} \tag{7}$$

where P and Q are constants depending upon the constitution of the segment, and l denotes the end-to-end length of the segment. From the above expressions the polarizability α_i' can be written in tensor form as follows;

$$\alpha_i'=3Q\cdot\begin{pmatrix} x_{ii-1}^2+\beta & x_{ii-1}y_{ii-1} & x_{ii-1}z_{ii-1}\\ y_{ii-1}x_{ii-1} & y_{ii-1}^2+\beta & y_{ii-1}z_{ii-1}\\ z_{ii-1}x_{ii-1} & z_{ii-1}y_{ii-1} & z_{ii-1}^2+\beta \end{pmatrix}, \tag{8}$$

$$\begin{aligned} x_{ii-1}&=x_i-x_{i-1}\,,\\ y_{ii-1}&=y_i-y_{i-1}\,,\\ z_{ii-1}&=z_i-z_{i-1}\,,\\ \beta&=(P-P_0-Ql^2)/3Q\,, \end{aligned}$$

where $r_i(x_i, y_i, z_i)$ represents the cartesian coordinates of the i-th linking point of segment in the polymer chain.

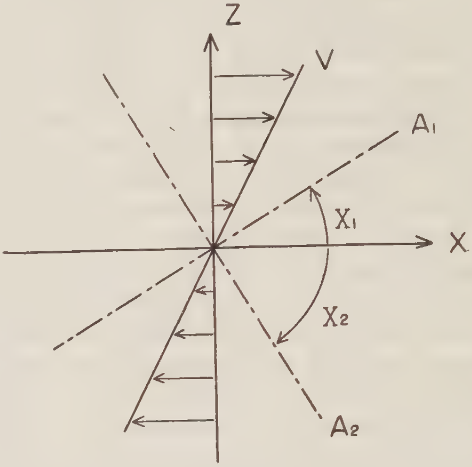

Fig. 1. Physical conditions and cartesian coordinate axes.

For simplicity, we assume a laminar flow in the polymer solution, and we choose the directions of the cartesian coordinate axes so that the macroscopic flow of the solution $v(v_x, v_y, v_z)$ can be represented by the following expressions:

$$\begin{aligned} v_x&=G\cdot z\,,\\ v_y&=0\,,\\ v_z&=0\,, \end{aligned} \tag{9}$$

where G denotes the magnitude of the velocity gradient.

In order to discuss the flow birefringence by an incident light propagating in the y-direction under this condition we have to know only two expressions for the matrix elements $\langle A_{xx}-A_{zz}\rangle$ and $\langle A_{xz}\rangle$ of the polarizability tensor of Eq. (5). The corresponding expressions for the first term $\langle A_1\rangle$ in Eq. (5) can be obtained by using Eq. (8), and they can be reduced into the following forms, as have been already done by Zimm[4] and by Cerf[5],

$$\langle A_{1xx}-A_{1zz}\rangle=(3/2)\cdot QD\delta^{-3}\cdot\sum_{p=1}^{N}\lambda_p{}^{-2}g_p\cdot G\,, \tag{10}$$

$$\langle A_{1xz}\rangle=(3/2)\cdot QD\delta^{-2}\cdot\sum_{p=1}^{N}\lambda_p{}^{-1}\cdot G\,, \tag{11}$$

where the constants D and δ are represented by the frictional constant ζ of a bead in the solvent, the absolute temperature T, the Boltzmann's constant k and by the mean square length of a segment at equilibrium state l_0^2, as follows,

$$\begin{aligned} D&=kT\cdot\zeta^{-1}\,, \\ \delta&=3kT\cdot l_0^{-2}\zeta^{-1}\,, \end{aligned} \tag{12}$$

N is the total number of segments in the molecule, λ_p is given by the relation:

$$\lambda_p=\nu_p\mu_p\,, \tag{13}$$

where μ_p and ν_p are the p-th eigenvalues of two matrices $\mathbf{A}$ and $\mathbf{H}$ respectively, whose elements are defined as follows,

$$\mathbf{A}=\begin{pmatrix} 1 & -1 & 0 & 0 & \cdots & \cdots & 0 \\ -1 & 2 & -1 & 0 & & & \cdot \\ 0 & -1 & 2 & -1 & & & \vdots \\ 0 & 0 & -1 & 2 & & & \vdots \\ \vdots & & & & \ddots & & 0 \\ \vdots & & & & -1 & 2 & -1 \\ 0 & \cdots & \cdots & \cdots & 0 & -1 & 1 \end{pmatrix}, \tag{14}$$

$$\begin{aligned} &H_{ii}=1\,, \\ &H_{ij}=(6\pi^3)^{-1/2}\zeta\eta_0^{-1}l_0^{-1}\cdot|i-j|^{-1/2}\,,\quad i\neq j\,, \\ &\qquad\qquad (i,\,j=0,1,2,\cdots,N)\,, \end{aligned} \tag{15}$$

in which η_0 represents the viscosity of the solvent. In a special case where the hydrodynamic interaction between the beads in polymer molecule is neglected, the matrix $\mathbf{H}$ is a unit matrix, so that

$$\begin{aligned} &\nu_p=1\,, \\ &\lambda_p=\mu_p\,,\qquad (p=1,2,\cdots,N)\,, \end{aligned} \tag{16}$$

Further, g_p in Eq. (10) is given by

$$g_p=1+\rho_p\nu_p \tag{17}$$

for the polymer molecule having very small internal viscosity, or

$$g_p=2+\lambda_p\cdot\sum_q\lambda_q^{-1} \tag{18}$$

for the polymer molecule having infinite internal viscosity. ρ_p in Eq. (17) is given by the element of the internal viscosity matrix, φ_p, which is referred to the p-th normal coordinates of the molecule, as follows, (cf. reference 5),

$$\rho_p=\zeta^{-1}\varphi_p\,. \tag{19}$$

Next, we proceed to the calculation of the second term $\langle A_2\rangle$ in Eq. (5). We substitute the interaction tensor T_{ik} by its average value $\langle T_{ik}\rangle$, as is often done in case of the hydrodynamic interaction tensor in viscosity theories[4),5)], and thus we have an approximate expression:

$$\langle A_2\rangle=\sum_i\sum_{k(\neq i)}\langle\alpha_i'\langle T_{ik}\rangle p_k\rangle/E\,. \tag{20}$$

Thus by using Eq. (3), this can be developed as

$$\langle A_2\rangle=\sum_i\sum_{k(\neq i)}\langle\alpha_i'\langle T_{ik}\rangle\alpha_k'\rangle+\sum_i\sum_{k(\neq i)}\sum_{l(\neq k)}\langle\alpha_i'\langle T_{ik}\rangle\alpha_k'\langle T_{kl}\rangle\alpha_l'\rangle+\cdots\,. \tag{21}$$

For small velocity gradient G we assume a following approximate pair distribution function $f_{ik}(r)$ of two beads i and k,

$$\begin{aligned} &f_{ik}(r)=f_{ik}^{(0)}(r)[1+G\cdot\delta_{ik}xz+G^2\cdot(\vartheta_{ik}^2a_{ik}^2+\alpha_{ik}^2x^2+\beta_{ik}^2y^2+\gamma_{ik}^2z^2)]\,, \\ &f_{ik}^{(0)}(r)=\left(\frac{1}{2\pi a_{ik}^2}\right)^{3/2}\cdot\exp\left\{-\frac{r^2}{2a_{ik}^2}\right\}\,, \end{aligned} \tag{22}$$

where the constants a_{ik}, δ_{ik}, ϑ_{ik}, α_{ik}, β_{ik} and γ_{ik} are determined by the relations:

$$\begin{aligned} \langle(x_k-x_i)^2\rangle&=\int f_{ik}(r)x^2\,dr\,, \\ \langle(y_k-y_i)^2\rangle&=\int f_{ik}(r)y^2\,dr\,, \\ \langle(z_k-z_i)^2\rangle&=\int f_{ik}(r)z^2\,dr\,, \\ \langle(x_k-x_i)(z_k-z_i)\rangle&=\int f_{ik}(r)xz\,dr\,. \end{aligned} \tag{23}$$

Applying the above distribution function to Eq. (21) we arrive at the following results:

$$\langle A_{2xx}-A_{2zz}\rangle=(9/5)(3/2\pi)^{1/2}\cdot(P-P_0)^2 n_0^{-2} l_0^{-5} D\delta^{-3}\cdot\sum_{p=1}^{N} f_p \mu_p^{-1}\lambda_p^{-2} g_p\cdot G \tag{24}$$

$$\langle A_{2xz}\rangle=(9/5)(3/2\pi)^{1/2}\cdot(P-P_0)^2 n_0^{-2} l_0^{-5} D\delta^{-2}\cdot\sum_{p=1}^{N} f_p \mu_p^{-1}\lambda_p^{-1}\cdot G \tag{25}$$

where f_p is given by

$$f_p=\sum_{i}\sum_{k(\neq i)}(Q_{kp}-Q_{ip})^2\cdot|k-i|^{-5/2}\ , \tag{26}$$

and Q_{ip} represents the element of a matrix **Q** which transforms the normal coordinates $\rho(u, v, w)$ into the cartesian coordinates $r(x, y, z)$ of the molecule in the following manner

$$\begin{aligned} x_i&=\sum_{p=0}^{N} Q_{ip}u_p\ ,\\ y_i&=\sum_{p=0}^{N} Q_{ip}v_p\ ,\\ z_i&=\sum_{p=0}^{N} Q_{ip}w_p\ . \end{aligned} \tag{27}$$

In the above calculation the terms of higher power of velocity gradient G are neglected.

In the experimental study of the flow birefringence one observes usually the magnitude of birefringence and the direction of the optical axes. As is shown in Fig. 1, under the condition of Eq. (9) the polymer solution has ordinarily two optical axes in the xz-plane, one of which A_1 lies in the first and the third quadrants, and the other A_2 lies in the second and the fourth quadrants. We denote the principal refractive indices of the polymer solution in the directions of the axes A_1 and A_2 as n_1 and n_2 respectively, also denote the acute angle between the A_1 axis and x axis as χ_1. Then we define the magnitude of birefringence $\varDelta n$ and the extinction angle χ by the following relations,

$$\begin{aligned} \varDelta n&=n_1-n_2\ ,\\ \chi&=\chi_1\ . \end{aligned} \tag{28}$$

For the comparison with the experimental results, we also define two quantities, the intrinsic birefringence $[\varDelta n]$ and the intrinsic extinction angle $\tan\alpha$ as follows,

$$\begin{aligned} [\varDelta n]&=\lim_{\substack{c\to 0\\ G\to 0}}(\varDelta n/Gc)\ ,\\ \tan\alpha&=\lim_{\substack{c\to 0\\ G\to 0}}(\pi/4-\chi)/G\ , \end{aligned} \tag{29}$$

where c denotes the weight concentration of the polymer in the solution. The value of $\tan\alpha$ represents the initial gradient of the curve $-\chi_1$ vs. G at the infinitely dilute solution.

On the other hand, the quantities $[\varDelta n]$ and $\tan\alpha$ are represented, in terms of the polarizability tensor $\langle A\rangle$, as follows,

$$[\varDelta n]=4/9\cdot\pi N_a M^{-1}(n_0^2+2)^2 n_0^{-1}\cdot\lim_{G\to 0}\langle A_{xz}\rangle/G \tag{30-1}$$

$$\tan\alpha=1/4\cdot\lim_{G\to 0}\langle A_{xx}-A_{zz}\rangle/\langle A_{xz}\rangle G\ , \tag{30-2}$$

where N_a is the Avogadro's number, and M is the molecular weight of the polymer. Now, we put:

$$\lim_{G\to 0}\frac{\langle A_{2xx}-A_{2zz}\rangle}{\langle A_{1xx}-A_{1zz}\rangle}=a_0\Theta\ , \tag{31}$$

$$\lim_{G\to 0}\frac{\langle A_{2xz}\rangle}{\langle A_{1xz}\rangle}=b_0\Theta\ , \tag{32}$$

$$\Theta=32\cdot5^{-1}\cdot3^{1/2}\cdot\pi^{-2}(P-P_0)^2N^{1/2}Q^{-1}(n_0{}^2+2)n_0{}^{-2}l_0{}^{-5}\,, \tag{33}$$

where it is assumed that the limiting values are finite and definite. Then $[\varDelta n]$ and $\tan\alpha$ are rewritten as

$$[\varDelta n]=[\varDelta n]_0(1+b_0\Theta)\,, \tag{34}$$

$$\tan\alpha=\tan\alpha_0\cdot\frac{1+a_0\Theta}{1+b_0\Theta}\,, \tag{35}$$

where $[\varDelta n]_0$ and $\tan\alpha_0$ represent the respective quantities when the optical interaction between segments is neglected. a_0 and b_0 are numerical constants, and by introducing the results of Eqs. (10), (11), (24) and (25) into Eqs. (31) and (32), they can be written as follows,

$$a_0=8^{-1}(\pi/2)^{3/2}N^{1/2}\cdot\sum_{p=1}^{N}f_p\mu_p{}^{-1}\lambda_p{}^{-2}g_p\bigg/\sum_{p=1}^{N}\lambda_p{}^{-2}g_p\,, \tag{36}$$

$$b_0=8^{-1}(\pi/2)^{3/2}N^{1/2}\cdot\sum_{p=0}^{N}f_p\mu_p{}^{-1}\lambda_p{}^{-1}\bigg/\sum_{p=0}^{N}\lambda_p{}^{-1}\,. \tag{37}$$

Kuhn and Grün[6] obtained the following formulas for a random chain segment constitued of ν monomer units

$$\begin{aligned}P&=(\alpha_1+2\alpha_2)/3\,,\\ Q&=(\alpha_1-\alpha_2)/5\nu a^2\,,\end{aligned} \tag{38}$$

where a represents the effective bond length of a monomer unit, and α_1 and α_2 denote the components of polarizability of the monomer unit, which are parallel and perpendicular to the monomer bond respectively.

Also, from the Clausius-Mrssotti's equation we can derive a relation:

$$\begin{aligned}(P-P_0)^2n_0{}^{-2}&=\left(\frac{9}{2\pi N_s}\right)^2\frac{n_p{}^2}{(n_p{}^2+2)^4}\left(\frac{\varDelta n_0}{n_0}\right)^2,\\ \varDelta n_0&=n_0-n_p\,,\end{aligned} \tag{39}$$

where n_p is the refractive index of the pure polymer, and N_s is the number density of segment in this polymer.

Substituting Eqs. (38) and (39) into Eq. (33), we can obtain another expression of Θ as follows,

$$\Theta=2\cdot3^{1/2}\left(\frac{18}{\pi^2}\right)^2\cdot\frac{n_p{}^2(n^2+2)}{(n_p{}^2+2)^4(\alpha_1-\alpha_2)}\cdot\left(\frac{\varDelta n_0}{n_0}\right)^2\cdot\left(\frac{N_m}{N_0}\right)^2\langle L^2\rangle^{-3/2}\,, \tag{40}$$

where $N_m=N\nu$ is the total number of monomer unit in one polymer molecule, $N_0=\nu N_s$ is the number density of solvent molecule in the pure solvent, and

$$\langle L^2\rangle=Nl_0{}^2 \tag{41}$$

is the mean square length of a polymer molecule in the solution.

§ 3. Calculation for Free Draining Molecule

As is seen in the previous theories[4),5)] it is possible to perform some analytical calculations, when the hydrodynamic interaction between the beads is neglected.

In this case the matrix element Q_{ip}, and λ_p and μ_p can be calculated as follows:

$$Q_{ip}=\left(\frac{2}{N+1}\right)^{1/2}\cdot\cos\left(\frac{i+1/2}{N+1}\cdot p\pi\right), \tag{42}$$

$$\mu_p=\lambda_p=4\cdot\sin\left(\frac{1/2}{N+1}\cdot p\pi\right). \tag{43}$$

Inserting these into Eq. (17), and transforming the summation over suffices i and k into the double integral, we can obtain the formulas:

$$f_p=16(2\pi)^{1/2}(N+1)^{-3/2}\cdot\sigma_p\,, \tag{44}$$

$$\sigma_p=p^{1/2}\int_0^{(\pi/2)p}\sin^2y\,dy\int_0^y\sin^2x/x^5\cdot dx\,. \tag{45}$$

The values of the integrals σ_p were evaluated by numerical calculations from $p=1$ to $p=20$. Employing these results in Eq. (44), and substituting Eqs. (43), (44), into Eqs. (36) and (37), we calculated the constants a_0 and b_0. The results are:

$$\begin{aligned} &a_0=1.53 \quad \text{for} \quad \rho_1=0\,, && a_0/b_0=1.20=6/5\,,\\ &a_0=1.51 \quad \text{for} \quad \rho_1=1/4\,, && a_0/b_0=1.18\,,\\ &a_0=1.39 \quad \text{for} \quad \rho_1=\infty\,, && a_0/b_0=1.09=13/12\,,\\ &b_0=1.28\,. \end{aligned} \tag{46}$$

Now referring to Eqs. (34) and (35), we have the formulas on the flow birefringence in the free draining polymer molecule.

The expression of Θ, i.e. Eq. (40), has a factor $(n_0-n_p)^2$, so that our result for $[\Delta n]$ predicts that when the refractive indices of solvents used in an experiment are sufficiently close to that of the polymer, the observed values of flow birefringence depend upon the refractive index of solvent in a form of parabolic relation. This is in agreement with several experimental results. For the comparison with experimental results we adopted the recent experimental data of Tsvetkov[2], and Tsvetkov and Petrova[7] of polystyrene and polymethylmethacrylate in several solvents.

In Fig. 2 and Fig. 3 the experimental data[2] for polystyrene of molecular weight $M_1=0.57\times10^6$ and $M_2=1.29\times10^6$ are plotted against the refractive indices of solvents. The curves 1 and 1′ show the calculated values of $[\Delta n]$, where the values of the parameters are respectively chosen as follows:

$$\begin{aligned} &[\Delta n]_0=-2.90\,,\\ &b_0\Theta/(n_0-n_p)^2=-46.55\,,\\ &n_p=1.6 \qquad \text{for curve 1}\,, \end{aligned} \tag{47-1}$$

and

$$\begin{aligned} &[\Delta n]_0=-4.50\,,\\ &b_0\Theta/(n_0-n_p)^2=-55.56\,,\\ &n_p=1.6 \qquad \text{for curve 1}'\,, \end{aligned} \tag{47-1′}$$

Thus our calculation are found to reproduce the experimental values quite well.

The figures also show the theoretical values of $\tan\alpha/\tan\alpha_0$ by the curves 2, 3, 2′ and 3′ which are respectively calculated from the same values of the parameters. The curves 2 and 2′ represent the case of zero internal viscosity, in which the value $a_0/b_0=1.20$ is used in the calculation. The curves 3 and 3′

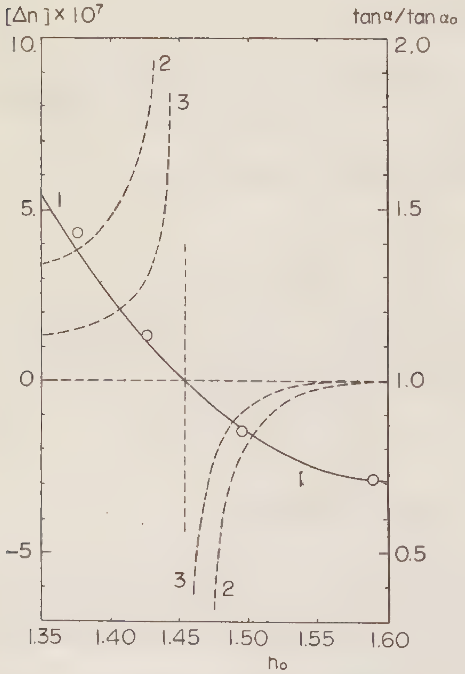

Fig. 2. Comparison of calculation with experimental values for polystyrene molecules ($M=0.57\times10^6$).

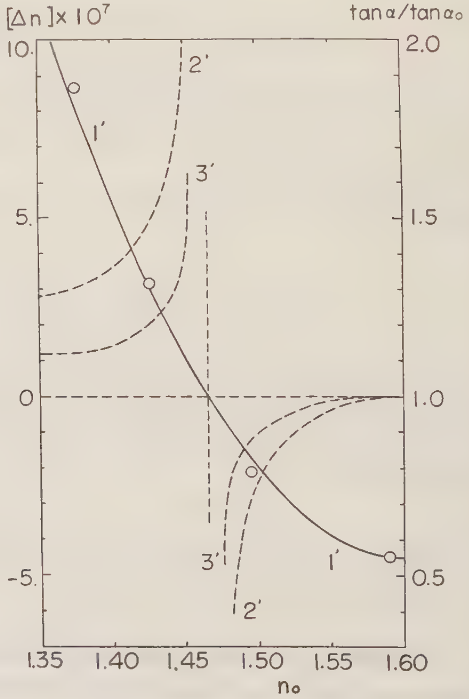

Fig. 3. Comparison of calculation with experimental values for polystyrene molecules ($M=1.29\times10^6$).

represent the case of infinite internal viscosity, in which the value $a_0/b_0=1.09$ is used.

As for the dependence of the extinction angle upon the refractive index of solvent the experimental result is not yet reported.

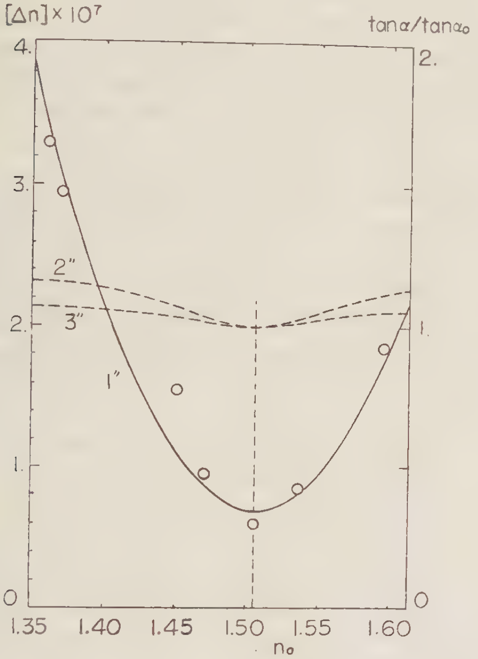

Fig. 4. Comparison of calculation with experimental values for polymethylmethacrylate molecules.

In Fig. 4 the experimental values[7] of birefringence for the polymethylmethacrylate molecules of the molecular weight $M=4.5\times 10^5$ are plotted against the refractive indices of the solvents. The curve 1'' shows the calculated value of $[\Delta n]$, where the values of the parameters are chosen as follows:

$$[\Delta n]_0=7.0\times10^{-8}\ ,\quad b_0\Theta/(n_0-n_p)^2=186\ ,\quad n_p=1.505\ . \tag{47-1''}$$

The curves 2'' and 3'' show the theoretical values of $\tan\alpha/\tan\alpha_0$ calculated from the same values of parameters. The curve 2'' corresponds to the case of zero internal viscosity in which $a_0/b_0=1.20$; and the curve 3'' to the case of infinite internal viscosity in which $a_0/b_0=1.09$.

§ 4. Summary and Discussions

Our result shows that the observed values of the birefringence and of the extinction angle depend on the refractive index of the solvent, and the numerical calculation for $[\Delta n]$ can well reproduce the experimental values of the polystyrene molecules and of the polymethylmethacrylate molecules.

Our theory is a generalization of that of Cerf[5] who neglected the optical interaction between the molecular segments. When this interaction is neglected in our calculation, the expressions of $[\Delta n]$ and of $\tan\alpha$ must therefore coincide with those of Cerf for small internal viscosity as well as for infinite internal viscosity. Indeed, in the case of negligible optical interaction we obtain

$$[\Delta n]_0=\frac{4}{45}\pi\frac{(n_0{}^2+2)}{n_0}(\alpha_1-\alpha_2)\frac{\eta_0[\eta]}{kT}\ , \tag{48}$$

and

$$\tan\alpha_0=C_1\cdot\frac{M\eta_0[\eta]}{RT}+C_2\cdot\frac{\mathscr{F}\langle L^2\rangle}{kT} \tag{49-1}$$

for small internal viscosity, and

$$\tan\alpha_0=C_1{}'\cdot\frac{M\eta_0[\eta]}{RT} \tag{49-2}$$

for infinite internal viscosity, where $\mathscr{F}=\varphi_1 N$ gives the magnitude of internal viscosity, and constants C_1, C_2 and $C_1{}'$ depend on the hydrodynamic interaction between molecular segments. When the hydrodynamic interaction is small, they take the values:

$$C_1=0.2\ ,\quad C_2=0.0062\ ,\quad C_1{}'=0.9\ , \tag{50-1}$$

and when the hydrodynamic interaction is large they take the values:

$$C_1=0.1\ ,\quad C_2=0.0045\ ,\quad C_1{}'=0.705\ , \tag{50-2}$$

Introduction of Eqs. (48), (49-1) and (49-2) into Eqs. (34) and (35) yields

$$[\Delta n]=\frac{4}{45}\pi\cdot\frac{(n_0{}^2+2)^2}{n_0}\cdot\frac{\eta_0[\eta]}{kT}(\Theta_i+b_0\Theta_f)\ , \tag{51}$$

$$\tan\alpha=\left(C_1\cdot\frac{M\eta_0[\eta]}{RT}+C_2\cdot\frac{\mathscr{F}\langle L^2\rangle}{kT}\right)\cdot\frac{\Theta_i+a_0\Theta_f}{\Theta_i+b_0\Theta_f} \tag{52-1}$$

(for small internal viscosity) and

$$\tan\alpha=C_1{}'\cdot\frac{M\eta_0[\eta]}{RT}\cdot\frac{\Theta_i+a_0\Theta_f}{\Theta_i+b_0\Theta_f} \tag{52-2}$$

(for infinite internal viscosity), where Θ_i and Θ_f are defined by

$$\begin{aligned}\Theta_i&=\alpha_1-\alpha_2\ ,\\ \Theta_f&=(\alpha_1-\alpha_2)\Theta\\ &=2.3^{1/2}\left(\frac{18}{\pi}\right)^2\cdot\frac{n_p{}^2(n^2+2)}{(n_p{}^2+2)^4}\cdot\left(\frac{\Delta n_0}{n_0}\right)^2\\ &\quad\cdot\left(\frac{N_m}{N_0}\right)^2\cdot\langle L^2\rangle^{-3/2}\ ,\end{aligned}\tag{54}$$

In the above expressions the optical factor Θ_f takes always the positive value, and it contains a factor $(\Delta n_0)^2=(n_0-n_p)^2$, therefore in the neighbourhood of $n_0=n_p$ the curve $[\Delta n]$ vs. n_0 is approximately expressed by a parabola which is concave upwards and has a minimum point at $n_0=n_p$, as is seen in Figs. 2 and 3. On the other hand the factor Θ_i can take either the positive or the negative value according as $\alpha_1>\alpha_2$ or $\alpha_1<\alpha_2$. From these properties the results can be classified into several cases in which the curve $[\Delta n]$ vs. n_0 and the curve $\tan\alpha$ vs. n_0 have different figures (Figs. 5, 6 and 7).

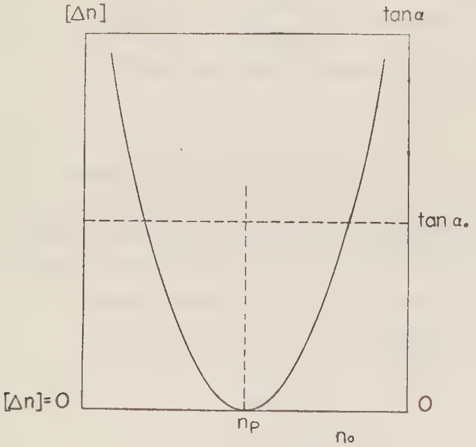

Fig. 6. Curves of $[\Delta n]$ vs. n_0, and of $\tan\alpha$ vs n_0 for $\alpha_1=\alpha_2$.

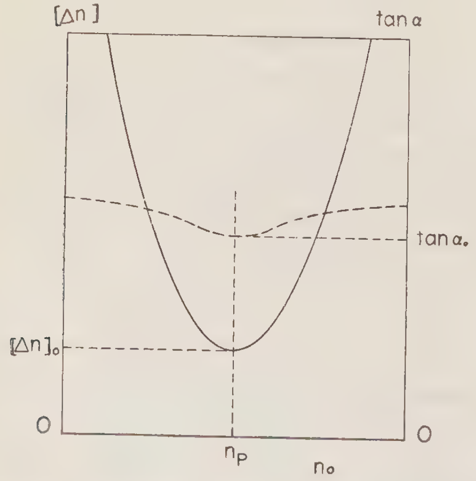

Fig. 5. Curves of $[\Delta n]$ vs. n_0, and of $\tan\alpha$ vs. n_0 for $\alpha_1>\alpha_2$

(i) $\alpha_1>\alpha_2$, $\Theta_i>0$ (Fig. 5)

In this case both $[\Delta n]$ and $\tan\alpha$ take always the positive value. The curve $[\Delta n]$ vs. n_0 and that $\tan\alpha$ vs. n_0 have their minimum points at $n_0=n_p$. The curves are shown in Fig. 5, and this case corresponds to that of Fig. 4.

(ii) $\alpha_1=\alpha_2$, $\Theta_i=0$ (Fig. 6)

In this special case $[\Delta n]$ also takes the positive value except at the minimum point where it becomes to zero. The optical factor in the expression of $\tan\alpha$ vanishes, so that $\tan\alpha$ does not depend on the refractive index of solvent. The curves are shown in Fig. 6.

(iii) $\alpha_1<\alpha_2$, $\Theta_i<0$ (Fig. 7)

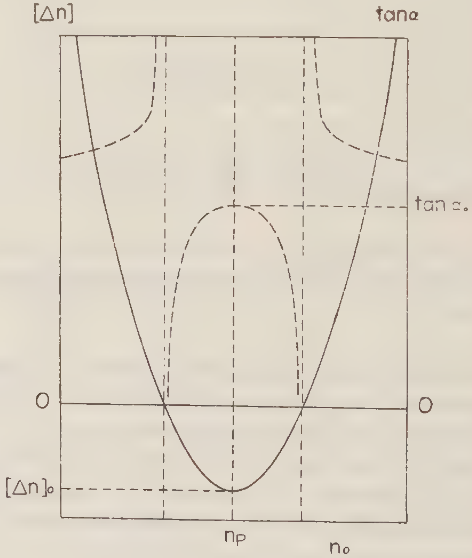

Fig. 7. Curves of $[\Delta n]$ vs. n_0, and of $\tan\alpha$ vs. n_0 for $\alpha_1<\alpha_2$.

In this case $[\Delta n]$ takes negative value when $|\Delta n_0|=|n_0-n_p|$ is small, but it takes the positive value when $|\Delta n_0|$ is large. The behavior of $\tan\alpha$ is quite different from that of the other two cases. The curve $\tan\alpha$ vs. n_0 has a maximum point at $n_0=n_p$, where $[\Delta n]$ takes a minimum value. At the special point at which $[\Delta n]$ vanishes, that is, where the equation:

$$\Theta_i+b_0\Theta_f=0 \tag{55}$$

is satisfied, the curve $\tan\alpha$ vs. n_0 is discontinuous. The pattern of these curves are shown in Fig. 7, and this case corresponds to that of Fig. 2 and Fig. 3.

As we can see in Eqs. (51), (52-1) and (52-2), the optical factors of $[\Delta n]$ and $\tan\alpha$ consist of two factors Θ_i and Θ_f. The former Θ_i represents simply the intrinsic optical anisotropy of a monomer unit of the polymer $\alpha_1-\alpha_2$, and so this is independent of the optical interaction. The latter Θ_f comes from the optical interaction between molecular segments in the solvent, and it depends on the refractive index of solvent. So our result shows that when the optical interaction between segments does not exist, or when it is negligible, the observed values of $[\Delta n]$ and of $\tan\alpha$ do not depend on the refractive index of the solvent. Also it is shown that when the observed values of $[\Delta n]$ and $\tan\alpha$ do not depend on the refractive index of solvent, then the effect of the optical interaction is negligible in such a system.

However we can see that in a certain case, as is shown in Fig. 6 of the case (ii), where the optical anisotropy of the monomer unit is very small, or when $|\alpha_1-\alpha_2|$ has very small value, the value of $\tan\alpha$ becomes almost independent of the refractive index of the solvent, even though the optical interaction between segments is very large.

It is generally recognized that when the absolute value of the ratio of the two optical factors $\Theta=\Theta_f/\Theta_i$ is sufficiently smaller than unity, the effect of the optical interaction on the observed results is negligible as compared with that of the intrinsic optical anisotropy. So, when we choose an appropriate small number, ε, we can determine a domain of the refractive index of solvent, in which the effect of optical interaction is negligible, by a following definition:

$$-\varepsilon<\Theta<\varepsilon\,, \qquad 0<\varepsilon\ll 1\,. \tag{56}$$

Then from Eq. (40) the magnitude δn_0 for this domain:

$$n_p-\delta n_0<n_0<n_p+\delta n_0$$

can be expressed by the following equation:

$$\begin{aligned}\delta n_0&=\sqrt{\varepsilon/|\Theta_0|}\,,\\ \Theta_0&=\Theta/(\Delta n_0)^2\,.\end{aligned} \tag{57}$$

According to this definition the magnitude δn_0 is proportional to $\sqrt{|\alpha_1-\alpha_2|}$, therefore this domain is enlarged as the optical anisotropy of monomer unit becomes large. Also the magnitude of δn_0 is independent of the sign of $\alpha_1-\alpha_2$.

The results in Eqs. (51), (52-1) and (52-2) can be compared with those of the theory of Copic[3] (C-theory), which is based on the dumbbell model. The expressions of C-theory are given by

$$[\Delta n]=\frac{4}{27}\pi\cdot\frac{(n_0{}^2+2)^2}{n_0}\cdot\frac{\eta_0[\eta]}{RT}\cdot(\theta_i+\theta_f)\,, \tag{58}$$

and

$$\tan\alpha=\frac{1}{2}\cdot\frac{\eta_0[\eta]}{RT} \tag{59-1}$$

for negligible internal viscosity, and

$$\tan\alpha=\frac{7}{6}\cdot\frac{\eta_0[\eta]}{RT}\cdot\frac{\vartheta_i+6/7\cdot\theta_f}{\vartheta_i+\vartheta_f} \tag{59-2}$$

for infinite internal viscosity, where ϑ_i and θ_f are parameters depending upon the optical constants of the polymer solution, which are given by

$$\vartheta_i=\frac{3}{5}(\alpha_1-\alpha_2)\,, \tag{60}$$

$$\vartheta_f=\frac{16}{15}\cdot\left(\frac{3}{2\pi}\right)^{1/2}\left(\frac{9M}{4\pi\rho N}\right)^2\langle L^2\rangle^{-3/2}\cdot\frac{n_0{}^2(n_p{}^2-n_0{}^2)^2}{(n_p{}^2+2n_0{}^2)^2}\,. \tag{61}$$

As we can see in the above results, both theories give the similar form of equation for $[\Delta n]$ and $\tan\alpha$, except $\tan\alpha$ for negligible internal viscosity, where the expression of C-theory has no optical parameter. Our result shows that the observed value of $\tan\alpha$ depends on the refractive index of solvant because of an optical factor $\Theta_i+a_0\Theta_f/\Theta_i+b_0\Theta_f$ as in case of $[\Delta n]$. So when $[\Delta n]$ vanishes at a certain value of the refractive index of solvent, which is given by the equation:

$$\Theta_i+b_0\Theta_f=0 \tag{55}$$

the value of $\tan\alpha$ is discontinuous at this point, as is seen in Figs. 2 and 3.

In case of the polymer molecule with infinite internal viscosity our numerical calculation gives a value $a_0/b_0=13/12$, and this value should correspond to the value 6/7 in C-theory, which is the coefficient of ϑ_f in Eq. (59-2). Probably such a difference of the values comes from the differences in the theoretical models and in the mathematical approximations used in the two theories.

The constants a_0 and b_0 are at first defined by Eqs. (31) and (32) in terms of the elements of polarizability tensor, $\langle A_1\rangle$ and $\langle A_2\rangle$ only. But our calculations of such quantities were performed through some mathematical approximations, such as $T_{ik}=\langle T_{ik}\rangle$ as is done in Eq. (20). One can still imagine that another more rigourous theory would give a relation:

$$a_0=b_0 \quad \text{or} \quad a_0/b_0=1\,, \tag{62}$$

and as the result the optical factor of tan α in Eq. (52) or (35) will disappear, and such a calculation will predict non-dependence of tan α upon the refractive index of the solvent.

The equation: $a_0=b_0$, that is $a_0/b_0=1$ requires the relation:

$$\lim_{G\to 0}\frac{\langle A_{2xx}-A_{2zz}\rangle}{\langle A_{1xx}-A_{1zz}\rangle}=\lim_{G\to 0}\frac{\langle A_{2xz}\rangle}{\langle A_{1xz}\rangle}\,. \tag{63}$$

The experimental varification of this relation will be considerably difficult, because the calculation shows that the birefringence $[\Delta n]$ vanishes at the critical point where tan α is discontinuous, so the absolute value of Δn becomes very small in the neighbourhood of this point.

Finally it is to be noted that there is another difference of the results of tan α between C-theory and our theory. As we can see in the above result, the calculated values of the constant a_0/b_0 are larger than unity for both small and infinite internal viscosities of the molecules. But on the other hand C-theory gives values not larger than unity, i.e., unity and 6/7 for small and infinite internal viscosities respectively. This result yields a remarkable difference between the patterns of the curves: tan α vs. n_0 in two theories. That is, if the value of a_0/b_0 is smaller than unity as in the case of C-theory, the curve comes just into the position of its reflected image on the other side of the straight line:

$$\tan\alpha=constant=\tan\alpha_0$$

which is parallel to the abscissa, and so in the neighbourhood of the critical point tan α takes the different sign. Such a difference of the two theories might originate in the theoretical models and in the mathematical approximations used in them.

The author is very grateful to Professor Ch. Sardon and to Professor R. Cerf of the "Centre de Recherches sur les Macromolécules", who gave him facilities and invaluable suggestions for this work during his stay in Strasbourg.

An Expression for Orientation in Cellulose Fibres

By V. D. GUPTA*

Textile Research Institute, Princeton, New Jersey, U. S. A.

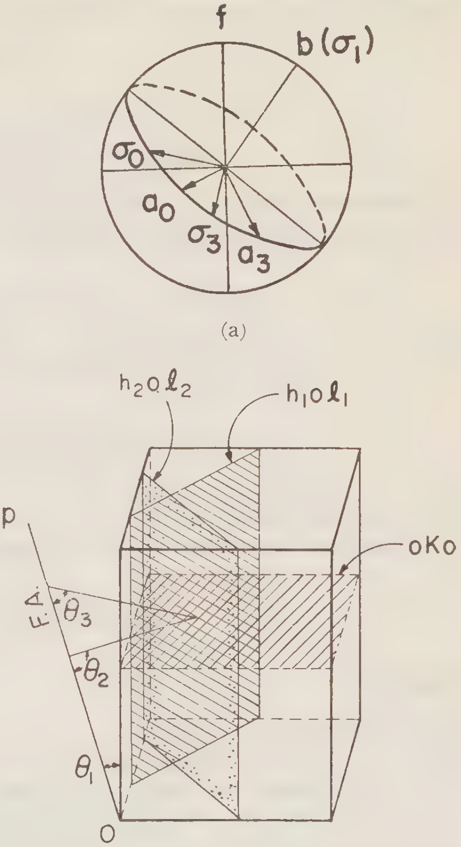
(Received January 31, 1961)

Hermans' orientation factor can be evaluated only when the diatropic and paratropic interferences arise from planes which form an orthogonal set. This is only approximately satisfied in case of both Cellulose I and Cellulose II. In the present communication an exact expression has been derived which can be evaluated from x-ray measurements, angle between face normals of paratropic interferences and the optical constants.

The problem of crystallite orientation in natural and synthetic fibres has been solved by many workers[1-4]. It has been studied both from x-ray and optical methods. The x-ray method is more useful because optical methods furnish informations merely as to the average orientation of the entire fibrous substance whereas the x-ray method gives orientation of only the crystallite components. Hermans and others[5] have worked out an expression for a quantitative evaluation of the crystallite orientation in cellulose. This is, however, applicable only when the diatropic and paratropic interferences arise from an orthogonal set of planes and it is only approximately satisfied in case of both Cellulose I and Cellulose II. In the present paper an exact expression has been derived.

Section I

In Fig. 1a let one of the axes of the polarisation ellipsoid coincide with the crystallographic b axis which represents the direction along the cellulose chains and σ_1, σ_0, σ_3 the three polarisabilities. Further let b denote the normal to the diatropic planes $0k0$ and a_0, a_3 those to h_10l_1 and h_20l_2 respectively. The pricipal axis σ_1 of the polarisation ellipsoid coincides with b and σ_0, σ_3 lie in the plane a_0a_3. If δ is the angle $\widehat{\sigma_0a_0}$, θ_1 is $\widehat{bf}$, ψ_0 is $\widehat{\sigma_0f}$ and ψ_3 is $\widehat{\sigma_3f}$, the polarisability in the direction of the fibre axis resulting from unit electric field in the direction of the fibre axis is



(a)

(b)

Fig. 1.

$$\sigma_{\|}=\sigma_1\cos^2\theta_1+\sigma_0\cos^2\psi_0+\sigma_3\cos^2\psi_3\,, \tag{1}$$

and averaging over all positions of the crystal

$$\sigma_{\|}=\sigma_1\overline{\cos^2\theta_1}+\sigma_0\overline{\cos^2\psi_0}+\sigma_3\overline{\cos^2\psi_3}\,.$$

---

* On leave from the Physics Department, University of Allahabad, India.

It is obvious that

$$\cos\psi_0 = \operatorname{cosec}\alpha\{\sin(\alpha+\delta)\sin\theta_2 - \sin\delta\sin\theta_3\}$$
$$\cos\psi_3 = \operatorname{cosec}\alpha\{-\cos(\alpha+\delta)\sin\theta_2 + \cos\delta\sin\theta_3\}\ ,$$

where α is the anngle $\widehat{a_0 a_3}$.

Also

$$\overline{\cos^2\theta_1} = 1 - \operatorname{cosec}^2\alpha(\overline{\sin^2\theta_2} + \overline{\sin^2\theta_3})\ ,$$

(see Section II) where θ_2, θ_3 are the angles which the normals to the two paratropic planes make with the fibre axis and are measured from the equator in the x-ray photograph when this relation is satisfied. Making these substitutions in I we have,

$$\sigma_{\parallel} = \sigma_1 - \operatorname{cosec}^2\alpha[\sigma_1 - \sigma_0\sin^2(\alpha+\delta) - \sigma_3\cos^2(\alpha+\delta)]\,\overline{\sin^2\theta_2}$$
$$-\operatorname{cosec}^2\alpha[\sigma_1 - \sigma_0\sin^2\delta - \sigma_3\cos^2\delta]\,\overline{\sin^2\theta_3}\ ,$$

remembering that $\overline{\sin\theta_2\sin\theta_3} = 0$.

Polarisability perpendicular to the fibre

$$\sigma_{\perp} = \tfrac{1}{2}(\sigma_1 + \sigma_0 + \sigma_3 - \sigma_{\parallel})\ ,$$
$$\sigma_{\perp} = \tfrac{1}{2}[\sigma_0 + \sigma_3 + \operatorname{cosec}^2\alpha\{\sigma_1 - \sigma_0\sin^2(\alpha+\delta) - \sigma_3\cos^2(\alpha+\delta)\}\overline{\sin^2\theta_2}$$
$$+\operatorname{cosec}^2\alpha(\sigma_1 - \sigma_0\sin^2\delta - \sigma_3\cos^2\delta)\,\overline{\sin^2\theta_3}]\ .$$

The orientation factor f is defined as the ratio between the actual double refraction of the crystalline material and that at complete orientation. Hence

$$f = \frac{\sigma_{\parallel} - \sigma_{\perp}}{(\sigma_{\parallel} - \sigma_{\perp})_c}\ ,$$
$$f = 1 - \frac{3}{2}\left[\frac{\operatorname{cosec}^2\alpha\{\sigma_1 - \sigma_0\sin^2(\alpha+\delta) - \sigma_3\cos^2(\alpha+\delta)\}}{\sigma_1 - \frac{1}{2}(\sigma_0 + \sigma_3)}\right]\overline{\sin^2\theta_2}$$
$$-\frac{3}{2}\left[\frac{\operatorname{cosec}^2\alpha(\sigma_1 - \sigma_0\sin^2\delta - \sigma_3\cos^2\delta)}{\sigma_1 - \frac{1}{2}(\sigma_0 + \sigma_3)}\right]\overline{\sin^2\theta_3}\ ,$$

which is the general equation.

If we assume $\sigma_0 = \sigma_3$ as is true for most of the cellulose fibres,

$$f = 1 - \frac{3}{2}\operatorname{cosec}^2\alpha\,(\overline{\sin^2\theta_2} + \overline{\sin^2\theta_3})\ .$$

Section II

Relation between θ_1, θ_2 and θ_3:

Let the normals to three planes $0k0$, $h_1 0 l_1$ and $h_2 0 l_2$ represent the three axes fixed in space and $0P$ the direction of the fibre axis. The angles θ_1, θ_2 and θ_3 are then as shown in the figure. If l be a vector along the fibre axis and a_1, a_2 and a_3 its components, we can write,

$$l = a_1 i + a_2 j + a_3 k\ ,$$

where i, j, k, l are unit vectors. Or

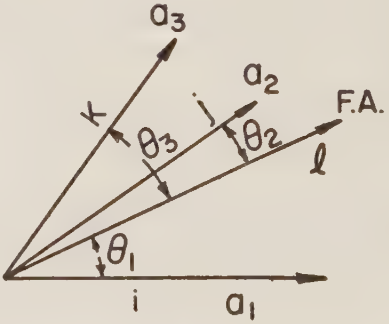


Fig. 2.

$$l.l = a_1^2 + a_2^2 + a_3^2 + 2a_1a_2 i.j + 2a_2a_3 j.k + 2a_1a_3 i.k = 1\ . \qquad \text{(a)}$$

Again we have,

$$\cos\theta_1=a_1+a_2 i.j+a_3 i.k\ ,$$
$$\cos\theta_2=a_1 j.i+a_2+a_3 j.k\ ,$$
$$\cos\theta_3=a_1 k.i+a_2 k.j+a_3\ .$$

Solving these equations for a_1, a_2 and a_3 we get

$$a_1=\begin{vmatrix}\cos\theta_1 & i.j & i.k\\ \cos\theta_2 & 1 & j.k\\ \cos\theta_3 & k.j & 1\end{vmatrix}\div\begin{vmatrix}1 & i.j & i.k\\ j.i & 1 & j.k\\ k.i & k.j & 1\end{vmatrix},$$

and two similar determinants for a_2, a_2 and a_3.

In a monoclinic system $0k0$ is orthogonal to $h_1 0 l_1$ and $h_2 0 l_2$ and therefore,

$$i.j=0\ ,$$
$$i.k=0\ ,$$
$$j.k=\cos\alpha\ \text{(say)}\ .$$

On simplification of these determinants we have

$$a_1=\cos\theta_1\ ,$$
$$a_2=(\cos\theta_2-\cos\alpha\cos\theta_3)/\sin^2\alpha\ ,$$
$$a_3=(\cos\theta_3-\cos\alpha\cos\theta_2)/\sin^2\alpha\ .$$

Substituting these values in (a) we get,

$$\sin^2\theta_1=\operatorname{cosec}^2\alpha(\cos^2\theta_2+\cos^2\theta_3)-2\operatorname{cosec}\alpha\cot\alpha\cos\theta_2\cos\theta_3\ .$$

If, however, the angles θ_2 and θ_3 are measured from the equator and an average value of the angles is taken,

$$\overline{\sin^2\theta_1}=\operatorname{cosec}^2\alpha(\overline{\sin^2\theta_2}+\overline{\sin^2\theta_3})\ ,$$

The values of $\overline{\sin^2\theta_2}$ and $\overline{\sin^2\theta_3}$ can be evaluated from the x-ray photographs in the usual manner. The author has also derived a general expression for the angle between face normals in a crystallographic system⁶⁾. This is given by,

$$\cos^{-1}\frac{T(x,y)}{\sqrt{T(x,x)T(y,y)}}\ .$$

Where $T(x, y)$ is

$$\frac{\sin^2\alpha}{x_1y_1}+\frac{\sin^2\beta}{x_2y_2}+\frac{\sin^2\gamma}{x_3y_3}+(\cos\gamma\cos\beta-\cos\alpha)\left(\frac{1}{x_3y_2}+\frac{1}{x_2y_3}\right)$$
$$+(\cos\gamma\cos\alpha-\cos\beta)\left(\frac{1}{x_3y_1}+\frac{1}{x_1y_3}\right)+(\cos\alpha\cos\beta-\cos\gamma)\left(\frac{1}{x_1y_2}+\frac{1}{x_2y_1}\right),$$

where x_1, x_2, x_3 and y_1, y_2, y_3 are the intercepts along three axes and α, β, γ are the axial angles. For a monoclinic system (to which cellulose belongs) the angle between the paratropic planes in terms of Miller indices and axial lengths is given by:

$$\cos^{-1}\frac{h_1h_2\dfrac{bc}{a}+l_1l_2\dfrac{ab}{c}-b\cos\beta\,(l_1h_2+h_1l_2)}{\sqrt{\left(\dfrac{h_1^2}{a^2}+\dfrac{l_1^2}{c^2}-\dfrac{2l_1h_1}{ac}\cos\beta\right)\left(\dfrac{h_2^2}{a^2}+\dfrac{l_2^2}{c_2}-\dfrac{2h_2l_2}{ac}\cos\beta\right)}}\ .$$

Here a is the monoclinic angle. Thus the orientation factor can be completely evaluated.

An experimental determination of this is being carried out and will be shortly reported elsewhere.

The Confinement of Plasma by the Heliotron Magnetic Field

By Kōji Uo

Electrical Engineering Institute, Faculty of Engineering,
Kyōto University, Kyōto

(Received February 1, 1961)

A magnetic field named the Heliotron field is produced by the electric current in a series of pair coils wound around the discharge tube with regular intervals. The electric current in each coil of the pair differs both in intensity and direction. The lines of force in this field undulate near the tube axis without cutting the wall, while these near the tube wall cross the wall. Thus the high temperature plasma can be produced by ohmic heating in the central region of this field being prevented from touching the wall. This field is found to satisfy the necessary condition for the equilibrium. The interchange instability of the plasma confined in this field is discussed. A general expression is given for the magnetic field, and it is shown that the Heliotron B magnetic field, the cylindrical cusp field, the helical winding field of the Stellarater and the Picket-Fence field are derived as special cases of this general formula.

§1. Introduction

There are two different types in the confinement of high temperature plasma by a magnetic field. The magnetic pressure is comparable with the plasma pressure in one type, and in the other the magnetic pressure is much larger than the plasma pressure. For example, the pinch type machine belongs to the first type and the mirror type machine and the Stellarator to the second.

Recently two machines of the second type have been constructed successively in Kyoto University and named the Heliotron A and the Heliotron B[1]. The Heliotron* magnetic field uses series of pair colis which are wound around the discharge tube of toroidal shape with regular intervals. In general, the electric current in each coil of a pair is different in both intensity and direction. The magnetic field produced by these currents are composed of two different regions. In the region near the tube axis the magnetic lines of force undulate along the axis without cutting the wall, whereas those near the tube wall cross the boundary making short arcs inside the wall. Therefore, the high-temperature plasma can be produced by ohmic heating only in the central region of the magnetic field, since particles near the wall cannot be accelerated sufficiently by the applied axial electric field.

Thus it may be said that the machine has the effect of preventing the hot plasma from directly touching the wall, and it does not need such an apparatus as the aperture limiter which was used in the Stellarater in order to limit the radius of the plasma column.

---

* The basic plan of the Heliotron field was first presented at the meeting of Thermonuclear Conference of Japan (May 5, 1958), and was published in Kakuyūgō Kenkyū, **1**, (1958) 20.

The Heliotron A of toroidal shape was constructed first. Its discharge tube was made of Zircon ceramic with the torus radius of 30 cm, the inner radius of the tube of 8 cm, and the thickness of the tube wall of 1 cm. It had six apertures for observation. Unfortunately the Heliotron A was damaged presumably due to the residual stress in the ceramic and the mechanical stress caused by the field coils which were wound around the torus tube.

Next, the Heliotron B has been constructed. Its discharge tube has the shape of the race-track, and is made of strainless steel. Its curved part has nearly same size as the Heliotron A, and the length of its straight part is 50 cm, the inner radius of the tube 8.4 cm, and the wall thickness 0.2 cm. It has nine apertures for observation. The field intensity is about 20,000 gausses. Now, various experiments are being carried on with the Heliotron B.

In this paper, we describe first the configuration of the Heliotron magnetic field and discuss the condition for the confinement of high temperature plasma in this field. Secondly, it will be shown that this field satisfies the necessary condition for the equilibrium within the framework of the magnetohydrodynamic approximation. Lastly, we will discuss the interchange instability of plasma in this field.

§ 2. General Configuration of the Heliotron Magnetic Field

Let us consider a magnetic field produced by the electric current in the coils, which are wound, as shown in Fig. 2.1, around a torus tube with regular intervals. The outline of the magnetic field in a cylindrical section involving the tube axis is shown graphically in Fig. 2.2.

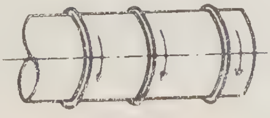

Fig. 2.1.

It is assumed that the charged particles in slightly ionized gas in the tube move along the lines of force being accelerated by an electric field, and that the plasma is so dilute and the magnetic field is so strong that the magnetic pressure p_{mag} is much larger than the plasma pressure p_{gas}. In this case charged particles inside the curve AB of Fig. 2.2 are accelerated over a long distance and obtain high energy. On the other hand, particles outside AB run along the lines of force which are interupted by the tube wall and therefore they cannot obtain high energy. Thus it may be expected that we can generate the discharge only in the region inside the curve because the electric conductivity along the direction becomes so poor near the wall that the high temperature plasma in

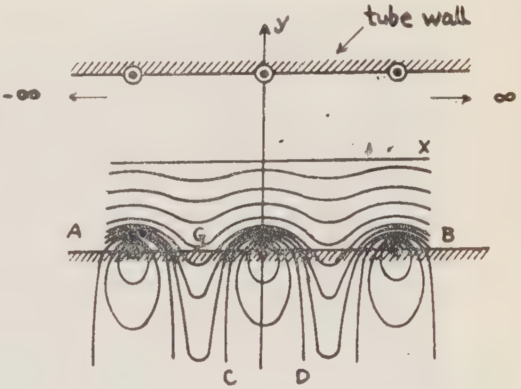

Fig. 2.2. The lines of force inside the curve AB undulate along the axis without cutting the wall whereas those outside the curve AB cross the wall and those outside CD are the leakage flux.

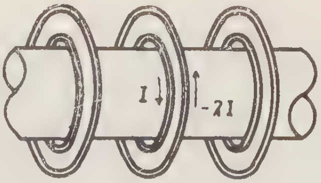

Fig. 2.3.

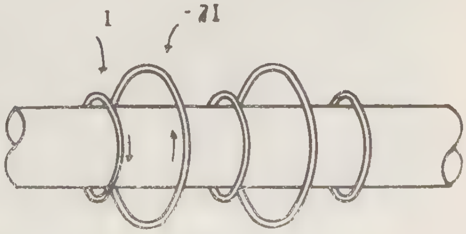

Fig. 2.4.

inner region is prevented to reach the wall except at the point G (see Fig. 2.2.)

This field appears to be effective for protecting the wall against the hot plasma and for decreasing the influx of impurity from the wall. At point G however, the high temperature plasma touches the wall. In order save this defect double rows of coils as shown in Figs. 2.3 and 2.4 are introduced. The direction of electric current in outer coils is opposite to inner one. The magnetic lines of force in these fields are roughly skeched in Fig. 2.5 and 2.6.

In these fields the magnetic lines of force inside AMB do not touch the wall, whereas all lines outside AMB cross the wall leaving short arcs inside the wall. The lines of force near the axis are completely separated from those near the wall, and therefore the high temperature plasma confined by the lines of force inside AMB do not touch the wall at all. Therefore, these fields are evidently more advantageous for confining hot plasma than the field shown in Fig. 2.2.

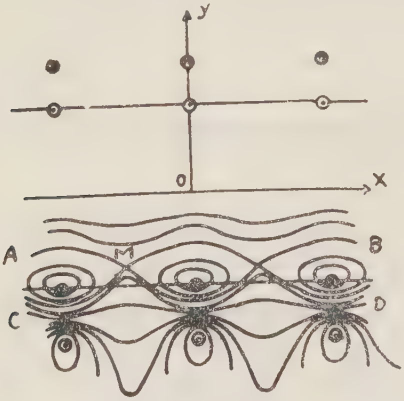

Fig. 2.5.

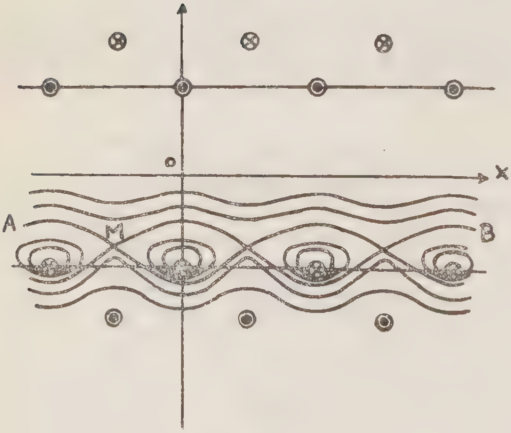

Fig. 2.6.

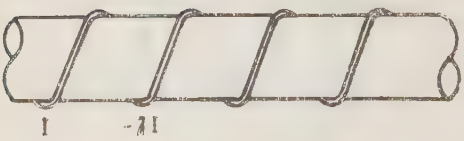

Fig. 2.7.

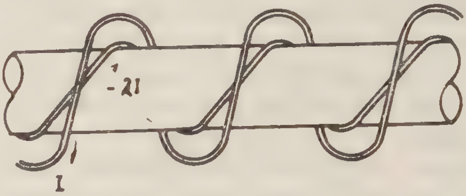

Fig. 2.8.

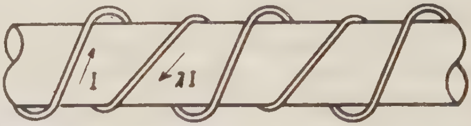

Fig. 2.9.

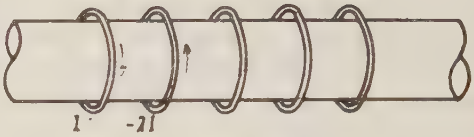

Fig. 2.10.

The rows of coils in Fig. 2.4 may be modified as shown in Fig. 2.7, or coils may be wound helically around the tube as shown in Figs. 2.8~2.10. In the latter case the lines of force also become helical, and this field may be called the Heliotgon H field.

The magnetic fields generated by these double rows of coils are named the Heliotron magnetic field. Let us denote the ratio of electric currents in two coils of a pair by λ. If we put $\lambda=1$ in the windings of Figs. 2.7 and 2.10, they reduce to the Picket Fence field and to the field produced by the helical windings of the Stellarator respectively.

It is one of the merits of the Heliotron field that we can bore apertures for observation without introducing correction coils, which are usually necessary for eliminating the field distortion caused by the irregularity of the coils near the apertures.

The patterns of the magnetic fields produced by the windings are observed experimentally by the iron sand method, and their pictures are shown in Figs. 2.11, 2.12 and 2.13.

§ 3. Basic Equations of the Cylindrical Magnetic Field

If we assume that a cylindrical magnetic field is generated by the coils wound around a cylindrical tube and no current exists inside of it, we have

$$\mathrm{rot}\,\boldsymbol{B}=0\ . \tag{3.1}$$

Then the magnetic flux density $\boldsymbol{B}$ is given by

$$\boldsymbol{B}=\mathrm{grad}\,\phi\ , \tag{3.2}$$

where ϕ is a scalar function. From Eqs. (3.1) and (3.2) we have

$$\nabla^2\phi=0\ , \tag{3.3}$$

and if we solve this Laplace equation we obtain $\boldsymbol{B}$ from Eq. (3.2). Equation (3.3) may be expressed in the cylindrical coordinates (ρ, θ, z) as

$$\frac{\partial^2\phi}{\partial\rho^2}+\frac{1}{\rho}\frac{\partial\phi}{\partial\rho}+\frac{1}{\rho^2}\frac{\partial^2\phi}{\partial\theta^2}+\frac{\partial^2\phi}{\partial z^2}=0\ . \tag{3.4}$$

Let us assume ϕ in the following form:

$$\phi=F(\rho)G(\theta)S(z)\ , \tag{3.5}$$

where $S(z)$ and $G(\theta)$ are periodic functions of z and θ respectively. Substituting (3.5) into Eq. (3.4) and solving the resultant ordinary differential equations we have the following solution (see Appendix II):

$$\begin{aligned}\phi&=e_1\log\rho+e_2\theta+e_3z\\&+\sum_{\nu=1}^{\infty}\sum_{n=0}^{\infty}\{c_\nu\cos(\nu\kappa z)+d_\nu\sin(\nu\kappa z)\}(P_n\cos n\theta+Q_n\sin n\theta)\\&\times\{A_nI_n(\nu\kappa\rho)+B_nK_n(\nu\kappa\rho)\}\end{aligned} \tag{3.6}$$

where $e_1\log\rho$, $e_2\theta$ and e_3z are particular solutions of Eq. (3.4), and κ, c_ν, d_ν, P_n, Q_n, A_n and B_n are numerical constants. If we impose the bundary conditions

$$\begin{aligned}|\boldsymbol{B}|&\neq\infty &&\text{for}\quad \rho=0\\ B_\rho&=0 &&\text{for}\quad n\theta+\nu\kappa z=m\pi\ , \qquad m=0,1,2,\cdots\end{aligned} \tag{3.7}$$

to (3.6), ϕ becomes

$$\phi=e_3z+\sum_{\nu=1}^{\infty}\sum_{n=0}^{\infty}A_{n\nu}I_n(\nu\kappa\rho)\sin(n\theta+\nu\kappa z)\ . \tag{3.8}$$

Substituting (3.8) into Eq. (3.2) we have

$$B_\rho=\kappa\sum_{\nu=1}^{\infty}\sum_{n=0}^{\infty}\nu A_{n\nu}I_n'(\nu\kappa\rho)\sin(n\theta+\nu\kappa z)\ , \tag{3.9}$$

$$B_\theta=\frac{1}{\rho}\sum_{\nu=1}^{\infty}\sum_{n=0}^{\infty}nA_{n\nu}I_n(\nu\kappa\rho)\cos(n\theta+\nu\kappa z)\ , \tag{3.10}$$

$$B_z=e+\kappa\sum_{\nu=1}^{\infty}\sum_{n=0}^{\infty}\nu A_{n\nu}I_n(\nu\kappa\rho)\cos(n\theta+\nu\kappa z)\ , \tag{3.11}$$

and the magnetic lines of force are obtained by solving the following differential equation:

$$\frac{d\rho}{B_\rho}=\frac{\rho d\theta}{B_\theta}=\frac{dz}{B_z}\ , \tag{3.12}$$

§ 4. Equations for the Heliotron B Magnetic Field

Putting

$$n=0\,, \tag{4.1}$$

in (3.9)~(3.11), we have the expression for the axisymmetrical magnetic field of the Heliotron B type as follows:

$$\left.\begin{aligned} B_\rho&=\kappa\sum_{\nu=1}^{\infty}\nu A_{0\nu}I_1(\nu\kappa\rho)\sin(\nu\kappa z)\,,\\ B_\theta&=0\,,\\ B_z&=e_3+\kappa\sum_{\nu=1}^{\infty}\nu A_{0\nu}I_0(\nu\kappa\rho)\cos(\nu\kappa z)\,, \end{aligned}\right\} \tag{4.2}$$

The magnetic field given by (4.2) approximately expresses the situation in the region inside the curve AMB of Fig. 2.5. Putting, as a simplest case,

$$\nu=1 \tag{4.3}$$

in (4.2), we have

$$\left.\begin{aligned} B_\rho&=\kappa A_{01}I_1(\kappa\rho)\sin\kappa z\,,\\ B_z&=e_3+\kappa A_{01}I_0(\kappa\rho)\cos\kappa z\,. \end{aligned}\right\} \tag{4.4}$$

Expression (4.4) can also be derived from the vector potential given by Lüst and Schlüter²⁾.

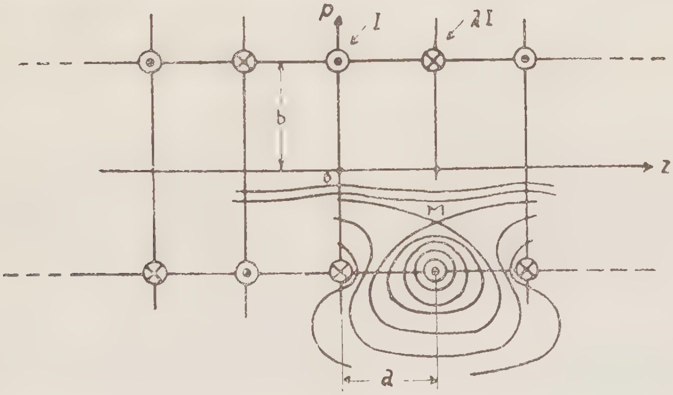

Fig. 4.1.

Now we take (4.4) as an approximate expression of the Heliotron B magnetic field. First we have to determine the integration constants κ, e_3, A_{01}. The assumption that the field is periodic in the z direction gives (see Fig. 4.1)

$$\kappa=\pi/a\,. \tag{4.5}$$

Putting

$$\alpha=(\pi/a)z\,,\qquad \beta=(\pi/a)\rho\,, \tag{4.6}$$

(4.4) becomes

$$\left.\begin{aligned} B_\rho&=\kappa A_{01}I_1(\beta)\sin\alpha\,,\\ B_z&=e_3+\kappa A_{01}I_0(\beta)\cos\alpha\,. \end{aligned}\right\} \tag{4.7}$$

In order to determine constants A_{01} and e_3, we have to calculate the intensity of the magnetic field along the axis of the colis as shown in Fig. 4.1. Coils have the radius b in common and their centres are located on the z axis with equal interval a. The electric currents in these coils are I and $-\lambda I$ alternately.

The magnetic flux density along the axis due to a single coil placed at the origin is

$$B_{0z}=(\mu_0 b^2 I/2)(b^2+z^2)^{3/2}\ .$$

Therefore the flux density along the axis due to all coils is given by

$$B_{0z}=\frac{\mu_0 b^2 I}{2}\sum_{\nu=-\infty}^{\infty}[\{b^2+(z-2\nu a)^2\}^{-3/2}-\lambda\{b^2+(z-\overline{2\nu+1}\,a)^2\}^{-3/2}]\ . \tag{4.8}$$

Let the flux density at the origin (0, 0) and the point (0, a), B_{00} and B_{0z} respectively, they are given by

$$\left.\begin{aligned} B_{00}&=\{\mu_0 b^2 I/(2a^3)\}(S_1-\lambda S_2)\ ,\\ B_{0}&=\{\mu_0 b^2 I/(2a^3)\}(S_2-\lambda S_1)\ , \end{aligned}\right\} \tag{4.9}$$

where

$$\left.\begin{aligned} S_1&=\frac{a^3}{b^3}\left\{1+\frac{b^3}{4a^3}\frac{1}{\sqrt{(1+b^2/4a^2)^3}}+\frac{b^3}{a^3}\left(0.0505-0.0035\frac{b^2}{a^2}+\cdots\right)\right\}\ ,\\ S_2&=\frac{2}{\sqrt{(1+b^2/a^2)^3}}+\left(0.1036-0.0107\frac{b^2}{a^2}+\cdots\right)\ . \end{aligned}\right\} \tag{4.10}$$

B_{00} and B_{0a} are determined by (4.9) and (4.10) if the aspect ratio of the coils a/b and the current ratio λ are given. From (4.7) we have

$$e_3=\frac{1}{2}(B_{00}+B_{0a})=\frac{\mu_0 b^2 I}{4a^3}(S_1+S_2)(1-\lambda)\ , \tag{4.11}$$

$$B_e=\kappa A_{01}=\frac{1}{2}(B_{00}-B_{0a})=\frac{\mu_0 b^2 I}{4a^3}(S_1-S_2)(1+\lambda)\ . \tag{4.12}$$

Denoting the coordinates of the equilibrium point M by $[\rho_e, (2n+1)a]$ in the (ρ, z) coordinate or $[\beta_e, (2n+1)\pi]$ in the (β, α) coordinate, we have, from (4.7),

$$e_0=I_0(\beta_e)=\frac{e_3}{\kappa A_{01}}=\frac{1-\lambda}{1+\lambda}\frac{S_1+S_2}{S_1-S_2}\ . \tag{4.13}$$

The position of the equilibrium point is also dependent upon a/b and λ. Substituting (4.12) and (4.13) into (4.7) we have

$$\left.\begin{aligned} B_\rho&=B_e I_1(\beta)\sin\alpha\ ,\\ B_z&=B_e\{I_0(\beta_e)+I_0(\beta)\cos\alpha\}\ . \end{aligned}\right\} \tag{4.14}$$

Again substituting (4.14) into Eq. (3.12), we obtain

$$\frac{d\rho}{dz}=\frac{d\beta}{d\alpha}=\frac{I_1(\beta)\sin\alpha}{I_0(\beta_e)+I_0(\beta)\cos\alpha}\ . \tag{4.15}$$

Integrating (4.15), we obtain the following equation for the line of force:

$$\cos\alpha=\frac{I_0(\beta_e)}{2I_1(\beta)}\beta\left(\frac{\beta_0^2}{\beta^2}-1\right)\ , \tag{4.16}$$

where β_0 is the parameter which designates the line of force. For the lines of force inside the equilibrium point M, β_0 of a line of force equal to the value of β on the lines of force at $\alpha=\pi/2$. The field represented by (4.14) and (4.16) is shown graphically in Fig. 4.2. But the solution given by (4.16) does not represent the true situation near the coil. In order to obtain better approximation we must compute the line of force using the complete expression (4.2). If λ tends to S_2/S_1 it may be seen from (4.13) that β_e becomes 0, that is, the equilibrium points come to the axis as shown in Fig. 4.3. Further increasing the value of λ we find that there appear two equilibrium points on the axis in one period (see Fig. 4.4). Finally for $\lambda=1$ the equilibrium points coinside with the points $[0, (n+1/2)\pi]$ on the axis (Fig. 4.5), and the magnetic field becomes the Picket Fence field. Figs. 4.3∼4.5 have been drawn using (A.4).

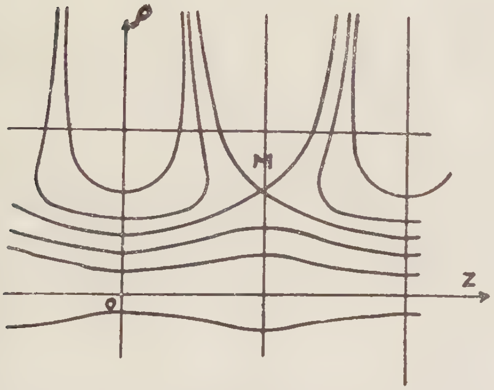

Fig. 4.2.

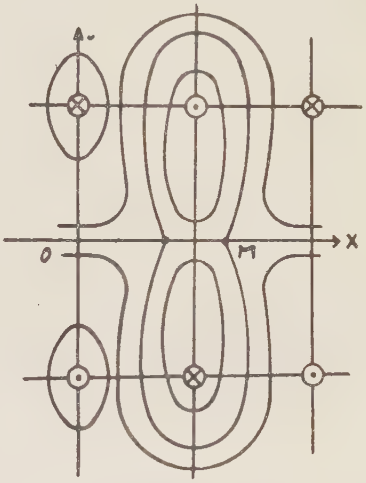

Fig. 4.4.

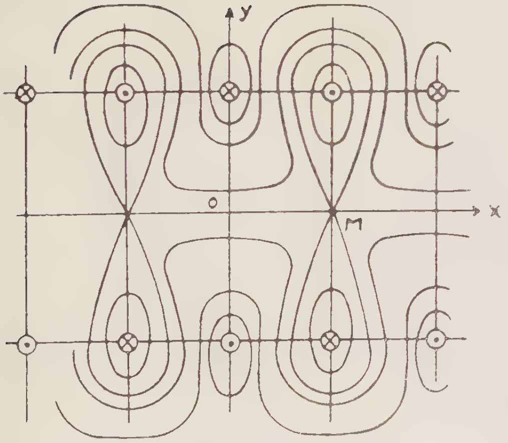

Fig. 4.3.

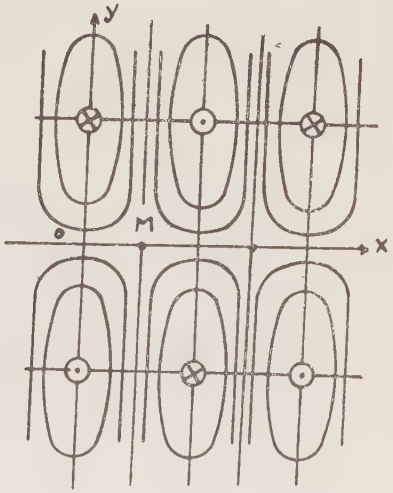

Fig. 4.5.

§ 5. Cylindrical Cusp Field

The magnetic fields given by (3.9)∼(3.11) include the cylindrical cusp fields as a special case. If we put, in (3.9)∼(3.11),

$$\left.\begin{array}{l}\nu=1\,,\\ \kappa z\to 0\,,\end{array}\right\} \qquad (5.1)$$

and expand the modified Bessel functions, we have the following expression:

$$\left.\begin{aligned} B_\rho &= \sum_{n=1}^{\infty} \frac{\kappa^n A_{n1}}{2^n(n-1)!}\rho^{n-1}\sin n\theta\,, \\ B_\theta &= \sum_{n=1}^{\infty} \frac{\kappa^n A_{n1}}{2^n(n-1)!}\rho^{n-1}\cos n\theta\,, \\ B_z &= e_3 + \sum_{n=1}^{\infty} \kappa\rho \frac{\kappa^n A_{n1}}{2^n(n-1)!}\rho^{n-1}\cos n\theta\,. \end{aligned}\right\} \tag{5.2}$$

The limit $\kappa z \to 0$ means that the period of the field in the z direction tends to infinite and in this case $\kappa\rho \to 0$. We have to ignore the term $n=0$, since this gives $B_\theta = B_\rho = 0$. For simplicity, let us take the term $n=m$ alone:

$$\left.\begin{aligned} B_\rho &= c_m \rho^{m-1}\sin m\theta\,, \\ B_\theta &= c_m \rho^{m-1}\cos m\theta\,, \\ B_z &= e_3\,, \end{aligned}\right\} \tag{5.3}$$

where

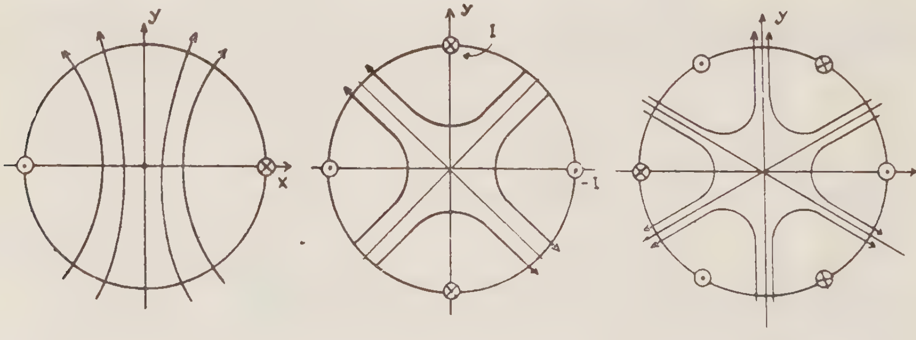
$$c_m = \kappa^m A_{m1}/\{2^m(m-1)!\}\,. \tag{5.4}$$

In (5.3) we neglected the second term of B_z as $\kappa\rho$ is assumed to be small. From (3.12) it will be seen that the projection of the line of force (5.3) to a plane perpendicular to the tube axis is represented by

$$\rho^m = \rho_0{}^m \left| \frac{1}{\cos m\theta} \right|, \tag{5.5}$$

where ρ_0 is the value of ρ at $\theta=0$.

Fig. 5.1 shows the magnetic fields in the neighbourhood of the tube axis, which are given by putting $m=1$, $m=2$ and $m=3$ in (5.3) and (5.5). The magnetic fields given by (5.3) are made by superposing a constant magnetic field in the z direction upon the field which is produced by the linear currents put on the tube wall parallel to the tube axis. The flux density of the fields takes the minimum value e_3 on the axis.



$m=1$
(a)

$m=2$
(b)

$m=3$
(c)

Fig. 5.1.

Further it may be noted that the intensity of the magnetic field decreases towards the axis and thus this part of the field appears to be a sort of magnetic bottle. However Fig. 5.1 shows that the lines of force of the field cross the tube wall, and therefore the dilute plasma, in which particles move along the lines of force, cannot be confined within this bottle. Only exceptional case $e_3=0$ may be the one in which case the dense plasma can be confined in this bottle.

§ 6. The Heliotron H Magnetic Field (Helical Heliotron)

For $n \neq 0$, (3.9)~(3.11) give the magnetic field produced by making the coils of the Heliotron

B (Fig. 2.4) helically around the tube as shown in Fig. 6.1. This field gives a transitional type from the Heliotron B field to the cylindrical cusp field, and it may be hoped to have the merits of both types of the field. Putting $\nu=1$ and $n=m$ in (3.9)~(3.11), we have

$$\left.\begin{aligned} B_\rho&=\kappa A_{m1} I_m'(\beta)\sin u\,,\\ B_\theta&=\kappa A_{m1}\frac{m}{\beta}\,I_m(\beta)\cos u\,,\\ B_z&=e_3+\kappa A_{m1} I_m(\beta)\cos u\,,\end{aligned}\right\}\tag{6.1}$$

where

$$u=n\theta+\alpha\,.\tag{6.2}$$

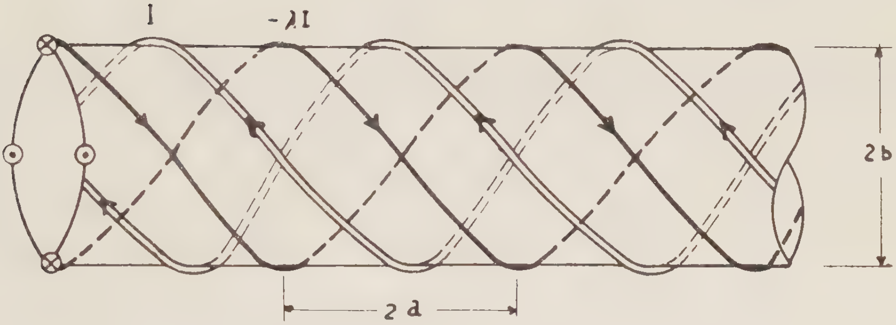


Fig. 6.1.

Assuming that

$$\left.\begin{aligned} &B_z=0 \quad \text{for}\quad \beta=\beta_e \text{ and } u=\pi,\\ &B_z=B_0 \quad \text{for}\quad u=\pi/2,\end{aligned}\right\}\tag{6.3}$$

we have

$$e_3=B_0\,,\qquad \kappa A_{m1}=B_0/\{I_m(\beta_e)\}\,.\tag{6.4}$$

Substituting (6.4) into (6.1) we obtain

$$\left.\begin{aligned} B_\rho&=B_0\{I_m'(\beta)/I_m(\beta_e)\}\sin u\,,\\ B_\theta&=(m/\beta)\{I_m(\beta)/I_m(\beta_e)\}\cos u\,,\\ B_z&=B_0\left\{1+\frac{I_m(\beta)}{I_m(\beta_e)}\cos u\right\}.\end{aligned}\right\}\tag{6.5}$$

The field given by (6.5) is produced by m pairs helical winding. From (3.12) we have

$$\frac{d\beta}{du}=\frac{\beta B_\rho}{mB_\theta+\beta B_z}\,.\tag{6.6}$$

Substituting (6.5) into (6.6) we obtain

$$\left\{\beta+\left(\frac{m^2}{\beta}+\beta\right)\frac{I_m(\beta)}{I_m(\beta_e)}\cos u\right\}d\beta-\beta\,\frac{I_m'(\beta)}{I_m(\beta)}\sin u du=0\,.\tag{6.7}$$

Equation (6.7) becomes a total differential equation by multiplying an integrating factor, and its solution is given by

$$\frac{\beta^2}{2}+\beta\frac{I_m'(\beta)}{I_m(\beta_e)}\cos u=c'\,,\tag{6.8}$$

where c' is a constant. If we assume that, along the line of force,

$$\beta=\beta_0 \qquad \text{for} \quad u=\pi/2\,, \tag{6.9}$$

we obtain the expression for the magnetic line of force

$$\cos u=\frac{I_m(\beta_e)}{2I_m'(\beta)}\beta\left(\frac{\beta_0{}^2}{\beta^2}-1\right). \tag{6.10}$$

From (6.10) we can see that β is a function of $\cos u$ alone. This means that the lines of force inside the point $[\beta=\beta_e,\ u=\pi]$ undulate in the band

$$\beta_{\min}\leq\beta\leq\beta_{\max}\,. \tag{6.11}$$

Therefore, if we take the field which satisfies the condition

$$\beta_e<(\pi/a)\times(\text{inner tube radius})\,, \tag{6.12}$$

the lines of force inside the equilibrium point do not cross the tube wall. An exact expression for the field produced by m pairs helical winding is given by

$$\left.\begin{aligned} B_\rho&=\kappa\sum_{s=1}^{\infty}c_nI_n'(\beta)\sin u_n\,,\\ B_\theta&=\frac{\kappa}{\beta}\sum_{s=1}^{\infty}nc_nI_n(\beta)\cos u_n\,,\\ B_z&=e_3+\kappa\sum_{s=1}^{\infty}c_nI_n(\beta)\cos u_n\,,\end{aligned}\right\} \tag{6.13}$$

where

$$n=ms\,, \qquad u_n=ms\theta+\alpha\,. \tag{6.14}$$

If we put $m=0$ in (6.10) it reduces to (4.16).

§ 7. Equilibrium of the Plasma in the Heriotron Field

Under the magnetohydrodynamical approximation the equilibrium condition of the plasma is given by

$$\nabla p=\boldsymbol{j}\times\boldsymbol{B}\,, \tag{7.1}$$

where the gravitational force is neglected. Equation (7.1) shows that the isobaric surfaces

$$p=\text{const}\,, \tag{7.2}$$

are weaved by the lines of current and magnetic lines of force. We define a function U by the integral along the line of force

$$U=-\int\frac{dl}{B}\,, \tag{7.3}$$

where integration is carried out over one period of the line of force. We see that the isobaric surfaces coinside with the surfaces of constant U. However, assuming ϕ to be constant we have the relation

$$-U=\int\frac{dl}{B}=\frac{1}{\phi}\int dSdl=\frac{1}{\phi}V\,, \tag{7.4}$$

where dS is the sectional area of the infinitesimal flux tube and V is its volume involved in one period. Thus $-U$ is found to be proportional to the volume of the flux tube, and we can conclude that the isobaric surfaces coincide with the magnetic surfaces weaved by the lines of force along which the volume of the flux tube is constant[3].

Besides, in order to make the magnetic surfaces coinside with the equilibrium surfaces so as to confine the plasma, it is required that the isobaric surfaces be toroidal and, for practical use, be inside the toroidal discharge tube and not cross the tube wall. For example, in the case of the field produced by coils wound uniformly around a circular toroidal tube such as Zeta, the magnetic flux density B is inversely proportional to R, the distance of the line of force from the toroidal center. Then the constant U surfaces are given by

$$R=\text{const.} \tag{7.5}$$

The surfaces are coaxial cylinders with the axis which coinside with the toroidal axis, and they are not toroidal. Therefore, these surfaces cannot be the equilibrium surfaces. Physically, in this case, the plasma current flows in the direction of the troidal axis and produces the charge separation which destroys the plasma confinement.

On the other hand, in the case of the undulated field, U takes different values at different distances from the tube axis. When the tube is a straight cylinder, the constant U surfaces become coaxial cylinders whose axis coincides with the tube axis. In the case of the troidal undulated field, the surfaces become toroidal and their axes are different from the tube axis as shown in Fig. 7.1(a). In this case, the cross-sectional area of the constant U surfaces, which do not cross the troidal tube wall, becomes very small unless one makes the the troidal radius sufficiently large compared with the tube radius or the amplitude of the undulation of the line of force sufficiently large.

The Heliotron B field, has the equilibrium points distributed periodically inside the wall. Since the flux density B becomes 0 at these points we can make U as large as we wish in the vicinity of the points. In Fig. 7.1(b), the thick solid line represent the boundary of the cross section of the magnetic surface weaved by the constant U lines of force passing through the equilibrium points. In the Heliotron B field therefore, all the constant U surfaces are located inside the solid line and make toroidal surfaces. Since it is easy to have the equilibrium points inside the tube wall, it may be said that the Heliotron field essentially satisfies the necessary condition for the equilibrium.

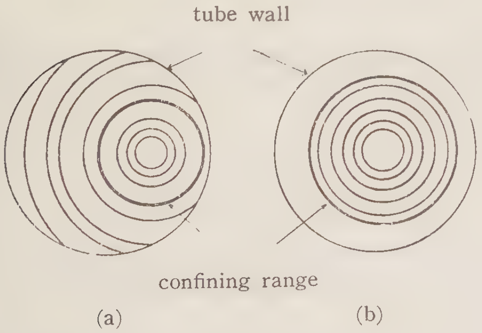

Fig. 7.1.

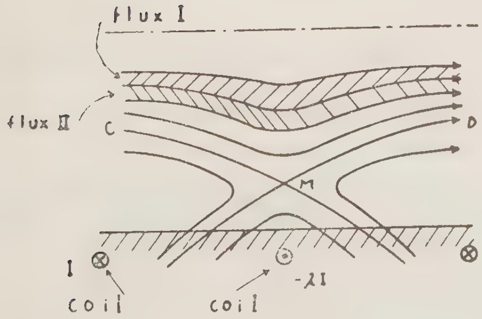

Fig. 8.1.

§ 8. Interchange Instability of the Plasma in the Heliotron B Field

Let us consider the interchange instability[4)] of the plasma confined in the Heliotron B field shown in Fig. 8.1 from the particle-dynamical point of view. In Fig. 8.1 M is an equilibrium point of the magnetic field. The change in plasma energy $\varDelta E_p$, which is caused by the interchange of the plasma contained in flux tube I with that in II of equal magnetic flux, is given by

$$\varDelta E_p = -\delta N_0 \delta w_0 , \tag{8.1}$$

with

$$\delta N_0 = N_{02} - N_{01} , \tag{8.2}$$

$$\delta w_0 = \iint \delta w(\mu, w) f(\mu, w)\, d\mu dw , \tag{8.3}$$

where N_{01} and N_{02} are number of particles contained in flux tube I and II respectively, $\delta w(\mu, w)$ is the change in energy of a single particle which has magnetic moment μ and total energy w, and $f(\mu, w)$ is the distribution function. The condition for stability is expressed by $\varDelta E_p > 0$. If $\delta w_0 > 0$ the plasma is stable for interchange instability from the orbit theory[4)], and we discuss the case $\delta w_0 < 0$. In this case plasma cannot be stable except for the case $\delta N_0 > 0$. Now,

$$N_0 = n_0 V = n_0 k_0 \int \frac{dl}{B} , \tag{8.4}$$

where n_0 denotes the average density of the plasma in the flux tube of volume V, and k_0 is a positive constant. The condition $\delta N_0 > 0$ is reduced to

$$\delta \int \frac{dl}{B} \Big/ \int \frac{dl}{B} > -\delta n_0 / n_0 . \tag{8.5}$$

The average density n_0 must be zero on the line of force CMD which forms the plasma boundary, and $\delta \int \frac{dl}{B}$ is positive inside CMD in the Heliotron B field. In order to examine the condition (8.5), we expand (4.14) and (4.16) putting

$$\left.\begin{aligned}\alpha&=\pi+\xi\,, && (\xi/\pi)^2\ll 1,\\ \beta&=\beta_e-\eta\,, && (\eta/\beta_e)^2\ll 1,\end{aligned}\right\} \tag{8.6}$$

and we have

$$B_z=a_0(e_0+e_1\sqrt{\xi^2+u^2}+e_2\xi^2)\,, \tag{8.7}$$

where a_0 is a constant and e_0, e_1, e_2 and u are functions of β_0. We put

$$Q=\int\frac{dl}{B}=k\int_0^{\pi}\frac{d\alpha}{B_z}=Q_0+Q_1\,, \tag{8.8}$$

where

$$Q_0=k\int_0^{\tau}\frac{d\xi}{B_z}\,,\qquad Q_1=k\int_0^{\pi-\tau}\frac{d\alpha}{B_z}\,, \tag{8.9}$$

and τ is a small positive constant which satisfies $(\tau/\pi)^2\ll 0$. In the vicinity of CMD we find that Q_0 is very large and Q_1 a constant value Q_{10}. Denote the value of β_0 on the line CMD by β_{0e}, then if β_0 approaches to β_{0e} we find that (see Appendix III)

$$Q\approx Q_c+\log\frac{1}{\sqrt{\beta_{0e}^2-\beta_0^2}}\,,\qquad Q_c=\text{const} \tag{8.10}$$

and that the condition (8.5) is reduced to

$$\frac{1}{n_0}\frac{\partial n_0}{\partial\beta_0}>-\frac{\beta_0}{\beta_{0e}^2-\beta_0^2}\Big/\left\{Q_c+\log\frac{1}{\sqrt{\beta_{0e}^2-\beta_0^2}}\right\}. \tag{8.11}$$

If n_0 is expressed by

$$n_0=n_{01}=k_0\Big/\left\{Q_c+\log\frac{1}{\sqrt{\beta_{0e}^2-\beta_0^2}}\right\}^m,\qquad k_0>0 \tag{8.12}$$

The stability condition becomes

$$1>m>0\,. \tag{8.13}$$

If the average density distribution satisfies the condition (8.11) the plasma is stable for interchange instability. But if the effect of diffusion gives finite gradient of n_0 in the vicinity of CMD, the stability condition will not be satisfied and the interchange instability will occur. When the plasma temperature becomes sufficiently high the effect of diffusion becomes weaker, and we may expect that the rate of growth of instability is also very small. These questions must be clarified through the future experiments by the Heliotron B.

The author wishes to acknowledge to Professor S. Hayashi for his continual encouragement and to Professor C. Hayashi for his helpful advices. He is also grateful to Professor T. Kihara, Mr. Y. Terashima and Mr. S. Hamada for their valuable discussions.

Appendix I

In order to investigate the qualitative feature of the axisynmmetric Heliotron field, first we approximate a part of the torus tube by a straight tube and then replace the magnetic field in the straight tube produced by the series of coil pairs (see Fig. 2.1) by the field produced by infinite rows of straight currents (see Fig. A.1). The vector potential of the magnetic field produced by these currents is given by

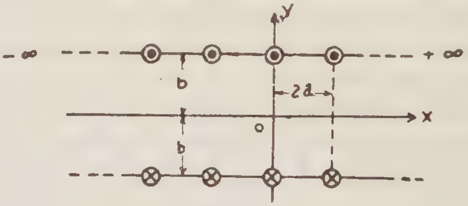

Fig. A.1.

$$\left.\begin{aligned}A_{x0}&=A_{y0}=0\,,\\ A_{z0}&=\frac{\mu_0 I}{4\pi}\sum_{\nu=-\infty}^{\infty}\log\frac{(x+2\nu a)^2+(y+b)^2}{(x+2\nu a)^2+(y-b)^2}\\ &=\frac{\mu_0 I}{4\pi}\log\frac{\cosh(\pi/a)(y+b)-\cos(\pi/a)x}{\cosh(\pi/a)(y-b)-\cos(\pi/a)x}.\end{aligned}\right\} \tag{A.1}$$

The equation of line of force is expressed by

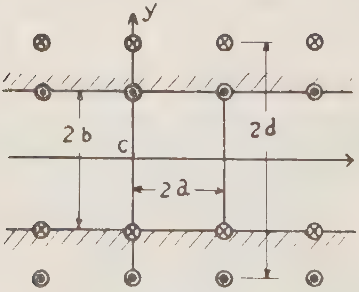

Fig. A.2.

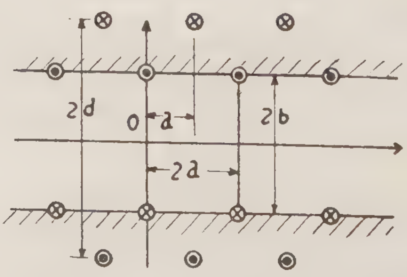

Fig. A.3.

$$\cos\frac{\pi}{a}=\cosh\frac{\pi}{a}b\cosh\frac{\pi}{a}y-\coth\zeta\sinh\frac{\pi}{a}b\sinh\frac{\pi}{a}y\,, \tag{A.2}$$

where ζ is a parameter which designates the line of force. Using Eq. (A.2) we can draw Fig. 2.2 as the qualitative skech of the magnetic field made by the double coil series as shown in Fig. 2.1. In similar way we can calculate the vector potential of the double current rows as shown in Figs. A.2 and A.3 respectively:

$$A_x=A_y=0\,,\quad A_z=\frac{\mu_0 I}{4\pi}\log\frac{\{\cosh(\pi/a)(y+b)-\cos(\pi/a)x\}\{\cosh(\pi/a)(y-d)-\cos(\pi/a)x\}^{\lambda}}{\{\cosh(\pi/a)(y-b)-\cos(\pi/a)x\}\{\cosh(\pi/a)(y+d)-\cos(\pi/a)x\}^{\lambda}}\,, \tag{A.3}$$

$$A_x=A_y=0\,,\quad A_z=\frac{\mu_0 I}{4\pi}\log\frac{\{\cosh(\pi/a)(y+b)-\cos(\pi/a)x\}\{\cosh(\pi/a)(y-d)+\cos(\pi/a)x\}^{\lambda}}{\{\cosh(\pi/a)(y-b)-\cos(\pi/a)x\}\{\cosh(\pi/a)(y+d)+\cos(\pi/a)x\}^{\lambda}}\,, \tag{A.4}$$

These magnetic fields are shown graphically in Figs. 2.5 and 2.6.

Appendix II

Since $S(z)$ in (3.5) is a periodic function of z, we have

$$S(z)=\sum_{\nu=1}^{\infty}S_\nu=\sum_{\nu=1}^{\infty}\{c_\nu\cos(\nu\kappa z)+d_\nu\sin(\nu\kappa z)\}\,, \tag{A.5}$$

where κ, c_ν, d_ν are constants. Substituting (3.5) and (A.5) into (3.4) we have

$$\sum_{\nu=1}^{\infty}\left\{G\cdot S_\nu\left(\frac{\partial^2 F}{\partial\rho^2}+\frac{1}{\rho}\frac{\partial F}{\partial\rho}-\nu^2\kappa^2 F\right)+\frac{F\cdot S_\nu}{\rho^2}\frac{\partial^2 G}{\partial\theta^2}\right\}=0\,. \tag{A.6}$$

Since the above equation must be satisfied for arbitrary values of z, we have the following relation

$$\frac{\rho^2}{F}\left(\frac{\partial^2 F}{\partial\rho^2}+\frac{1}{\rho}\frac{\partial F}{\partial\rho^2}-\nu\kappa^2 F\right)=-\frac{1}{G}\frac{\partial^2 G}{\partial\theta^2}\,, \tag{A.7}$$

The left-hand side of the above equation is a function of ρ alone and the right-hand side θ alone, and therefore both sides must be a constant, n^2 say. Thus we obtain the following two equations:

$$\frac{\partial^2 F}{\partial\rho^2}+\frac{1}{\rho}\frac{\partial F}{\partial\rho}-\left(\frac{n^2}{\rho^2}+\nu^2\kappa^2\right)F=0\,, \tag{A.8}$$

$$\frac{\partial^2 G}{\partial\theta^2}+n^2 G=0\,. \tag{A.9}$$

In n is a positive integer, the general solution of Eq. (A.8) is expressed by

$$F(\rho)=\sum_{n=0}^{\infty}\{A_n I_n(\nu\kappa\rho)+B_n K_n(\nu\kappa\rho)\}\,, \tag{A.10}$$

and that of Eq. (A.9) is given by

$$G(\theta)=\sum_{n=0}^{\infty}(P_n\cos n\theta+Q_n\sin n\theta)\,. \tag{A.11}$$

Substituting (A.5), (A.10) and (A.11) into (3.5) and adding simple particular solutions of Eq. (3.4), we obtain the solution (3.6).

Appendix III

Substituting (8.6) into (4.14) and expanding it we obtain

$$B_2=a_0\left(a_1\eta-a_2\eta^2+\frac{1}{2}\xi^2+\cdots\right) \tag{A.12}$$

where

$$\left.\begin{array}{l} a_0=B_eI_0(\beta_e)\ , \qquad a_1=I_1(\beta_e)/I_0(\beta_e)\ , \\ a_2=(1/2)(1-a_1/\beta_e)\ . \end{array}\right\} \tag{A.13}$$

As the same way, from Eq. (4.16) we have

$$\frac{\xi^2}{u^2}-\frac{(\eta-p)^2}{v^2}=-1\ , \tag{A.14}$$

where

$$\left.\begin{array}{l} p=g_1\zeta/(1-g_2\zeta)\ , \\ u^2=2g_0\zeta\left\{1+\dfrac{g_1{}^2}{2g_0(1-g_2\zeta)}\zeta+\dfrac{g_1{}^2}{2(1-g_2\zeta)}\zeta^2\right\}, \\ v^2=u^2/\{(1-g_2\zeta)(1+g_0\zeta)\}\ , \end{array}\right\} \tag{A.15}$$

$$\left.\begin{array}{l} g_0=1/(2a_1\beta_e)\ , \\ g_1=1\Big/\left\{(2a_1{}^2\beta_e)\left(1+\dfrac{1}{2a_1\beta_e}\zeta\right)\right\}, \\ g_2=\left(1-\dfrac{a_1}{2\beta_e}\right)\Big/\left\{a_1{}^3\beta_e\left(1+\dfrac{1}{2a_1\beta_e}\zeta\right)\right\}, \end{array}\right\} \tag{A.16}$$

and

$$\zeta=\beta_{0e}^2-\beta_0{}^2\ . \tag{A.17}$$

β_{0e} is the value of β_0 of the line of force passing through the equilibrium point. Eliminating η in (A.12) by using (A.14), we have (8.7), and where

$$\left.\begin{array}{l} e_0=p(a_1-a_2p)-a_2v^2\ , \\ e_1=(v/u)(a_1-2a_2p)\ , \\ e_2=(1/2)-a_2v^2/u^2\ . \end{array}\right\} \tag{A.18}$$

Putting in (8.9)

$$x=\sqrt{\xi^2+u^2}\ , \qquad u_0=\sqrt{u^2+\tau^2}\ , \tag{A.19}$$

reduces to

$$Q_0=\frac{2}{a_0e_2\kappa}\int_0^{u_0}\frac{dx}{x^2+(e_1/e_2)x+(e_0/e_2-u^2)}\,\frac{1}{\sqrt{x^2-u^2}}dx\ . \tag{A.20}$$

Q_0 is expressed by

$$\left.\begin{array}{l} Q_0=\dfrac{2}{a_0e_2\kappa}\,\dfrac{1}{x_1-x_2}\,(Q_{01}-Q_{02})\ , \\ Q_{01}=\dfrac{x_1}{\sqrt{u^2-x_1{}^2}}\left\{\dfrac{\pi}{2}+\tan^{-1}\dfrac{x_1u_0-u^2}{\sqrt{(u^2-x_1{}^2)\tau^2}}\right\}, \\ Q_{02}=\dfrac{x_2}{\sqrt{x_2{}^2-u^2}}\log\left[\dfrac{(u-x_2)\{(x_2u_0-u^2)-\sqrt{(x_2{}^2-u^2)(u_0{}^2-u^2)}}{(u_0-x_2)(x_2-u)u}\right], \end{array}\right\} \tag{A.21}$$

where x_1 and x_2 are the roots of the following equation:

$$x^2+(e_1/e_2)x+(e_0/e_2-u^2)=0\ . \tag{A.22}$$

When ζ becomes very small, Q_0 is approximately expressed by (8.10).

Microwave Study of Non-ionizing Shock Waves

By Susumu TAKEDA
Nagoya University, Nagoya, Japan
and Michel Roux
University of Illinois, Urbana, Illinois, U.S.A.

(Received February 16, 1961)

The interaction of microwave with gaseous plasmas is used to study weak shock waves in low pressure gases. In order to study by this method shock waves of low Mach number, which are incapable of ionizing the gaseous medium in which they propagate, this medium is weakly preionized.

In a tube of 5 mm in diameter, condenser discharges are fired for the production of shock waves up to 200 joules, in a pressure range of 4–13 mm Hg in Neon and Argon and with Mach number up to 5, and it is found that the measured electron density increase across the discontinuity is in the ratio of the gas density ratio. The electron temperature, deduced from the measured electron-ion collision frequency, is, as expected, lower than the gas temperature estimated from the Mach number.

§ 1. Introduction

It is now known that shock waves may be produced, particularly in gases at relatively low pressure, by strong electrical condenser discharges. Fowler[1] first found that a shock wave was produced in T-shaped gas tube, in which a pulse discharge was fired between internal electrodes. More recently, measurements have been performed on shock waves and many papers reported results on optically and spectroscopically studied shock waves. Trials[2], [3] by microwave techniques have also been reported to measure parameter associated with shocks. Schultz[3] noticed that it would be possible but difficult to determine by microwave techniques both the electron density and collision frequency in a plasma produced by an ionizing shock wave. On the other hand, since generally a microwave signal, is highly attenuated[4], when it propagates through plasmas produced in low pressure gas, in which the plasma frequency associated with the electron density reaches a critical value corresponding to the microwave frequency, the propagation method with such microwaves is restricted in its application.

The impedance of a small plasma volume can be measured at higher densities, provided a condition[5] is satisfied. If the method reported here satisfies this condition, the range of measurements can be extended to electron densities higher than the critical value. In this experiment the transient impedance of a small plasma post is measured by modification[6] of the standard microwave method. Since this impedance is related to the electron density and the collision frequencies, time resolved photographs of microwave standing wave amplitudes can yield both the electron density and collision frequency in a transient non-recurrent plasma. By using these techniques, shock waves produced by electrical discharges have been investigated.

The method requires a minimum detectable electron density. When strong shocks are studied, this is provided by the ionizing shock waves themselves. However in order to study weak, that is non-ionizing shocks, a plasma with the appropriate electron density has to be provided by auxiliary pre-ionization, as used by der Agobian[2].

§ 2. Experimental apparatus and procedures

The apparatus consists of a shock tube and a microwave circuit. The shock tube of 40 cm. in length and 0.5 cm. in diameter is placed across two waveguides as shown in Fig. 1, in which X-band low level microwave is propagated. These waveguides may be placed at any desirable distance from one another; they are connected through a directional coupler to the same microwave source. In order to increase the resolution, at least one of these waveguides is tapered to a flat section, as seen in the upper left corner of Fig. 1. The first waveguide is terminated with a movable short. The probe detectors 1 and 2 are located in this waveguide, as seen in the figure in each side of the shock tube. The fraction of the microwave energy taken from the first waveguide through a directional coupler, propagates in the second waveguide, and is detected there by the probe detector 3.

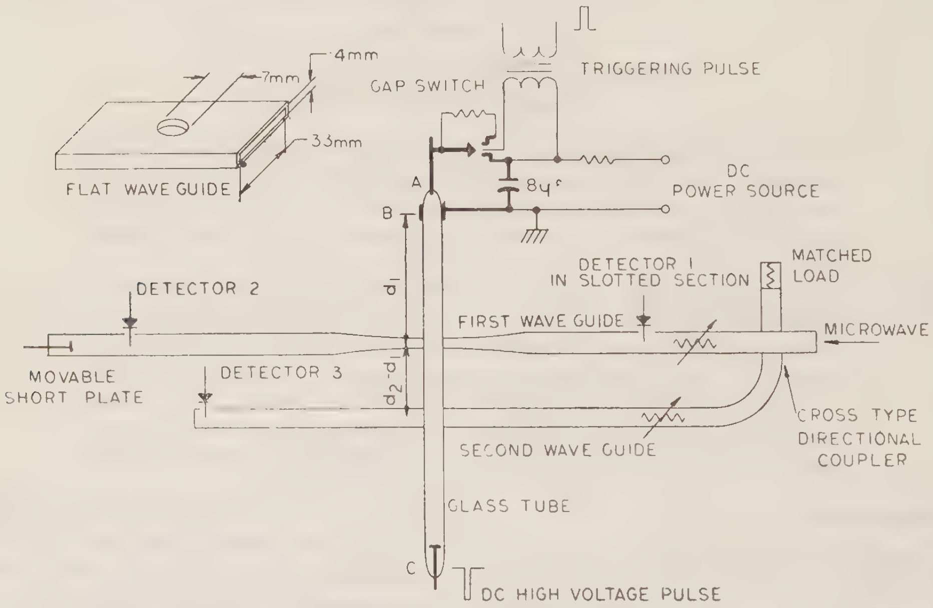

Fig. 1. Diagram of the experimental apparatus.

The shock waves are produced in the tube, filled with a gas at the desired pressure, by discharging between electrodes A and B an $8\,\mu$F condenser charged up to 7 KV. The ringing frequency of this circuit is 130 KC. The maximum stored energy and the discharge current are respectively 200 joules and 10^4 A. In order to reduce the ignition delay time, the condenser discharge path is very weakly ionized by a small DC current passing between the electrodes A and B through a high resistance shunting the gap switch. In order to provide the plasma in which the shock wave will propagate, a pulsed DC discharge pre-ionizes the gas between electrodes B and C. The shock wave is initiated in the course of the decay of this pre-ionization and timed in such a way as to reach the wave guide section at some easily detectable values of the electron density n and collision frequency ν in the decaying plasma. Probes 1 and 2 detect the time varying standing wave that is established in the first waveguide by the movable short, modulated by the decaying plasma and further altered by the passage of the shock wave in the waveguide. Their signals are displayed on a dual trace oscilloscope. From the time varying amplitude of each of these signals, the momentaneous impedance of the plasma post can be determined, which in turn yields the plasma parameters n and ν in the absence as well as in the presence of the shock wave.

The signals from detectors 3 and 1 or 2 yield the time interval for the shock wave to propagate from the first to the second waveguide and hence its local velocity. Since the discharge is non-recurrent, the displayed traces on the oscilloscope are recorded photographically for analysis. Concurrently with the microwave observation, a photomultiplier is used for the detection of any discontinuity in the visible light intensity which is produced by propagating shock waves in the plasma afterglow.

An evacuating system evacuates the tube down to pressure of 10^{-7} mm Hg. However an appreciable amount of impurities of metal vapor comes out of the electrodes during each condenser discharge. The effect of these impurities can be observed either directly by the change in color of the plasma column or by the shortened decay of the repeated disintegrating plasma. Running the recurrent pulsed discharge in the tube for a short time, however, it is observed that the plasma decay and the color soon recover to its original condition. Apparently most of the metallic impurities from the electrodes are thought to deposite on the electrodes and glass surfaces. Since it is inconvenient to replace the gas in the tube after each condenser discharge, several such discharges were shot in the same gas after the recovery of the above mentioned original conditions. The situation is improved by the use of activated charcoal maintained at low temperature in a side tube close to the electrodes A and B.

§ 3. Principles of the Measurements

The method is capable of yielding the velocity of shock waves in plasmas and the variation of background plasma parameters, n and ν as a result of shock wave propagation. The velocity of the propagating shock wave decreases as it proceeds along the tube. Hence one can speak about an average velocity over a length of propagation path and of a local or instantaneous velocity, if the path is short with respect to the total path. When the distance d covered by the shock wave in time t takes the form $d=t^{\beta}$, the local velocity $v_t=\beta\,(d/t)=\beta\times(\text{mean velocity})=\beta\bar{v}$. When the time for a wave to reach the distances d_1 and d_2 respectively are measured to be t_1 and t_2, β is determined from

$$\beta=\frac{\log d_2/d_1}{\log t_2/t_1}, \tag{1}$$

and $\bar{v}$ is proportional to $d^{(\beta-1)/\beta}$.

For the reason mentioned above, the initial conditions of the discharge can not be reproduced exactly. These are isolated (one shot transients repeated at a few seconds intervals. Hence the usual microwave techniques applicable to study the phenomena occurring regularly at high repetition rate are here inapplicable. In particular, the standard techniques to find the plasma impedance from the shift of the minimum position and the ratio of a standing wave produced in the waveguide by a recurrent plasma cannot be used here. Thus the modified method to measure the transient plasma impedance under the conditions of these experiments has been used.

The principle of the method is the two probe observation of an existing wave pattern modified by the changing parameters of a gaseous plasma post located in a certain position in the waveguide. To analyze the change in the standing wave pattern, these two probes, 1 and 2, are positioned on each side of the plasma post. The one in the input side of the post is placed at a minimum position of the standing wave pattern in the absence of the plasma. The other is placed preferably at a maximum of the standing wave pattern. The introduction of a plasma and change of its parameters shift the standing wave pattern. From the change in the signal amplitudes of probes 1 and 2, displaced simultaneously on the oscilloscope, the impedance of the plasma post is obtained. This impedance then yields the plasma parameters n and ν. The method, contrary to the other microwave propagation methods, is not strictly limited in measuring electron densities up to that value which corresponds to the plasma frequency, provided that the electron density along the tube axis is uniform. Although it is not strictly the case, in these experiments, in view of the small height of the plasma involved in the flat waveguide (4 mm.) this assumption appears to be approximately justified.

At this point, attention should be drawn to the following. The amplitude of the signal without plasma, at the minimum of the standing wave is 0.005 of the amplitude at the maximum of the standing wave. The existence of the detectable signal at the standing wave minimum is due to various losses in the microwave circuit. A large fraction of this loss is due to the energy leaking from the waveguide through the hole, accomodating the glass tube. The total microwave energy loss in the presence of the plasma obviously includes the energy radiated through the hole-increases and is a function of the plasma parameters n and ν. In view of the lack of precise knowledge of this enhanced radiated energy loss, which occurs for some large values of the electron density the method at present time is restricted in its application for values of the electron density smaller than this value. This fact also limits the range in which the electron collision frequency can be determined.

§ 4. Compressing and Heating Processes by Shock Waves

The ratio of the pressure p_2 and gas density ρ_2 behind the shock front to p_1 and ρ_1 in the undisturbed region before the shock front are known from the thermodynamical theory,[7]

$$p_2/p_1=\frac{2\gamma M^2-(\gamma-1)}{\gamma+1},$$

$$\rho_2/\rho_1=\frac{M^2(\gamma+1)}{M^2(\gamma-1)+2}. \qquad (2)$$

where M is the Mach number, or the ratio of the propagation velocity of the shock wave to the sound velocity in the undisturbed medium, and γ is the ratio of the specific heats. From the relation between gas temperature, pressure and density $T\sim p/\rho$, the ratio T_2/T_1 of the gas temperature behind and before the shock wave is written as

$$T_2/T_1=\left\{1+\frac{M^2(\gamma-1)}{2}\right\}\left\{\frac{4\gamma M^2-2(\gamma-1)}{M^2(\gamma+1)^2}\right\} \qquad (3)$$

The undisturbed region referred to above in this experiment is the decaying gaseous plasma. In view of its low degree of ionization and low ion temperature the medium is unaltered for sound wave propagation. Hence the above relation apply. When the medium which is the mixture of three gases, the electron, ion and neutral gases, is compressed by a propagating weak (non-ionizing) shock discontinuity, it may be assumed that any constituents of this mixture are compressed in the same ratio, that is $n_2/n_1\sim\rho_2/\rho_1$, where n_1 and n_2 refer to the electron density in the undisturbed plasma and behind the shock front respectively.*

This is so, if during the short time compression, the electron and ion losses are negligible. The theoretical value of the rare gas density and temperature ratio n_2/n_1 and T_2/T_1, where $\gamma=1.67$, are plotted as functions of the Mach No. M in Figs. 5 and 7.

It is well known that in electrical discharges in gases, the electron temperature T_e, is generally higher than the ion temperature T_i, which is nearly equal or somewhat higher than the gas temperature T_g. However, in an already weakly ionized gas, the passage of a weak shock wave heats the neutral atom and the ion gases more efficiently than the electrons. As a result,

$$T_e\leq T_g \text{ or } T_i \qquad (4)$$

The time rate of the electron temperature increase in this case is described by the following equation,

$$\frac{dT_e}{dt}=\frac{1}{\tau_{ei}}(T_i-T_e)+\frac{1}{\tau_{en}}(T_g-T_e)+K\nabla^2T_e \qquad (5)$$

The symbols τ_{ei} and τ_{en} represent respectively the characteristic times for equipartition of the temperature between ions and electrons and atoms and electrons, K is a coefficient due to thermal conduction. Then Eq. (5) and the relation $n_2/n_1\sim\rho_2/\rho_1$ show that when the plasma is heated by the shock wave, the electron density immediately follows the gas density increase, while the electron temperature reaches its maximum value with some delay.

§ 5. Experimental Results

At first the shock propagation velocity was measured by using the probes 2 and 3. The lower trace in Fig. 2 shows the signal from the first waveguide. There are two noticeable discontinuities in each trace: the first one, pointed by (a), is due to the shock wave, the second one (b) is thought to correspond to the plasma expanding from the condenser discharge region. Without pre-ionization, (a) disappears, because the relatively weak shock wave does not produce enough electrons to be detected by the microwave method described here. The discontinuity (b) in the microwave signals, resulting from the interaction of the wave with the electrons in the expanding plasma, which appear clealy even without any pre-ionization, decays rapidly over the distance from its origin; and so does its velocity.

---

* Strictly speaking, the ion gas density is first increased by the propagating shock in view of the large collision cross section for momentum transfer of the heavy particles involved, and then, as a consequence of the resulting space charge in the plasma, the increasing electron density follows in a time interval (during a few plasma oscillations), which is short with respect to the shock propagation time scale.

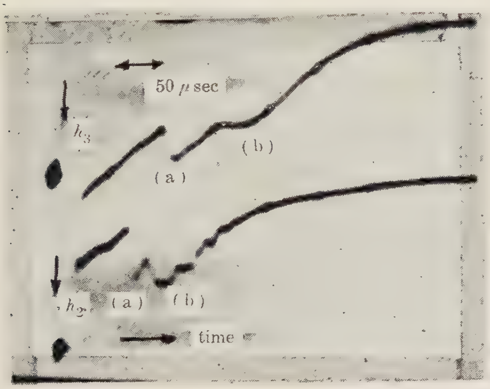

Fig. 2. Microwave signal amplitudes h_2 and h_3 versus time from the first and second waveguids, 50 μ sec/division, Ne, $p=5.8$ mm Hg, 5 K.V. 8 μF.

For the arrival time t_1 and t_2 of the peak (a) at the first and the second wave guide and for distances $d_1=23.5$ cm and $d_2=29.5$ cm, a value of the exponent β in Eq. (1) was found to be 0.47 ± 0.02 in Neon gas. The pressure and the condenser voltage ranged respectively between 4–13 mm Hg and 3–7 KV. The local shock velocity (Mach No.) at the level of the waveguide then can be easily calculated from the measured mean velocity (d_1/t_1) and β.

The plasma background for weak shock wave propagation studies by microwaves is also useful in another way. Indeed the decaying plasma gives rise to an afterglow which can be observed by means of a photomultiplier at any position along the tube, and in particular in the waveguide. In the course of the shock propagation in the plasma, the afterglow must also be altered. Hence optical observations on the afterglow, correlated with microwave measurements, provides an additional mean of investigation in these studies, as illustrated in Fig. 3. However, when the condenser discharge giving rise to the shock wave is produced between electrodes A and B in Fig. 1, a small discharge current is also flowing simultaneously between electrodes B and C. This stray current enhances the pre-ionization. The associated afterglow is shown in Fig. 3 (trace (II)). For very intense condenser discharge, the intensity of this visible enhanced afterglow may be such that the discontinuity in this light intensity, produced by the propagating weak shock wave illustrated by (a) in Fig. 3 is difficult to observe.

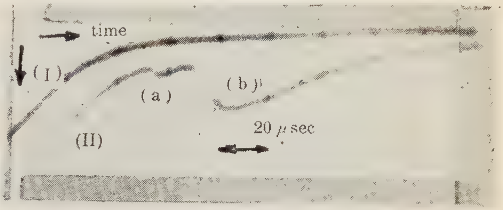

Fig. 3. Light signals versus time. (I): with pre-ionization; (II): with condenser discharge and pre-ionization. 20 μ sec/division, Ne, $p=4.5$ mm Hg, 5 K.V. 8 μF. Light intensity in arbitrary units.

The visible afterglow is generally attributed to recombination of electrons and positive ions in decaying plasmas. The discontinuity in the visible light of this afterglow, at any one time and space position in the shock tube, may provably be attributed to the alteration of the recombination procedure by the weak shock discontinuity. It is known that the light intensity of recombination, which is proportional to the number densities of the recombining charge and the recombination coefficient is dependent upon the relative velocities (temperatures) of these charges. Hence a sudden variation either in the densities of the recombining charges and or in their temperature should bring about a change in the visible light intensity. However, the effects on the light intensity of the change in densities are opposite to those of the change in temperatures, because the recombination coefficient decreases with increasing temperatures. As a result of these compensating effects, the discontinuity in the visible afterglow, due to shock waves, may be small. The enhanced visible intensity in the afterglow, indicated by (b) in Fig. 3, is again thought to be related to the expanding plasma following the shock discontinuity. The light signals (a) and (b) in this figure, obtained from the first waveguide, correspond to the microwave signals (a) and (b) in Fig. 2, observed in this same wave guide.

(B): Ne, p=7.6 mm Hg, 4.5 K.V. 8 μF.

Fig. 4. Microwave Signal amplitudes h_1 and h_2 versus time in the shock wave experiments, 20 μ sec/division, 8 μF

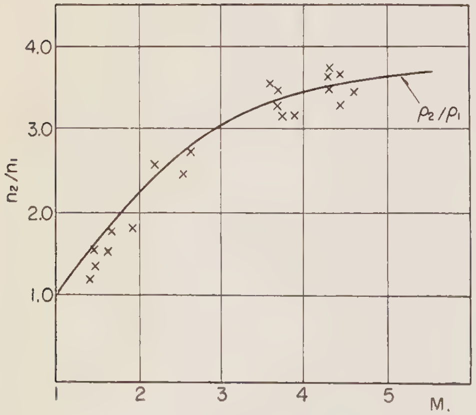

Fig. 5. Comparison between the gas density ratio ρ_2/ρ_1 calculated from the Mach no., and the measured electron density ratio n_2/n_1. Ne, p= 4~13 mm Hg.

Next, the electron density n_2 and n_1 across the shock front was calculated from the photographically recorded traces of the two microwave signals detected by the two probes 1 and 2. Figs. 4 (A) and (B) show examples of two signal h_1 and h_2. The ratio of the electron densities n_2/n_1 is calculated and plotted versus Mach No. in Fig. 5 (crosses). For comparision, the theoretically predicted ratio of gas density ρ_2/ρ_1 as a function of Mach No. is also shown in the figure (solid line). It is apparent that the variation of the ratio of electron densities across the shock discontinuity as a function of shock velocity follows quite closely that of the gas densities. It appears therefore reasonable to assume that the electron density increase, due to weak shock wave propagating in such plasmas, is a consequence of the compression of the weakly ionized gas. The possible discrepancy in the range of small Mach No. (1~2) is likely due to the duration of the compression, which is then comparable to (or longer than) the characteristic time for recombination and/or diffusion losses of electrons. In the plasma considered, since the electron-atom collision frequence ν_{en} for momentum transfer is negligibly smaller than the electron-ion collision frequency ν_{ei} in the temperature range involved, the electron temperature is obtained from the electron temperature dependence, $\nu_{ei}/n \sim T_e^{-3/2}$.

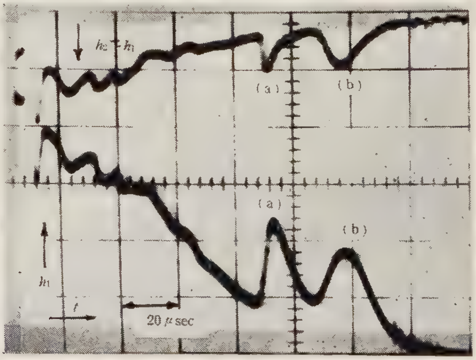

Fig. 6. (A) Microwave signal amplitudes h_1 and h_2-h_1 versus time. 20 μ sec/division, Argon, p=12.4 mm Hg, 5 K.V. 8 μF.

From the recorded typical microwave probe signals, illustrated in Fig. 6 (A), the variation of the electron density and the electron temperature of the plasma, in the presence of a propagating shock wave, is computed and plotted in Fig. 6(B). Another example of such electron density and electron temperature variation, due to weak shock waves propagated in plasmas under different conditions, is seen in Fig. 6 (C). It is seen on these figures that the electron temperature does not reach its maximum at the same time as the electron density does. As discussed above, since the energy transfer from the propagating shock wave is very efficient only to the ions, the electron gas should be heated by the warm gas of the ions. This process, however, proceeds with a rather long time constant τ_{ei}; hence a delay in the temperature rise of the electron gas. This delay is obviously shorter for shocks of higher Mach No. These observations appear to justify our assumption in Eq. (5). Although no delay is expected in the electron density rise due to compression, there is some observed. The observed rate of electron density increase may depend upon the shape of the shock discontinuity and the length of the shock tube comprised in the waveguide, which in these experiments was 4 mm. Fig. 7 compares the theoretical neutral gas temperature behind the shock front (upper line), calculated from the measured Mach No. by Eq. (3), to the measured corresponding electron temperature, where both temperatures are normalized to 300°K.

The shock velocity (Mach No.) increases with decreasing gas pressure at constant condenser

voltage and at constant gas pressure but increasing condenser voltage. It is observed that in addition to an enhanced shock velocity, in particular at lower gas pressures, the time separation of the discontinuities (a) and (b) (Fig. 6 (A)) of the probe detected microwave signals is shortened. This indicates an increased velocity of the expanding initially highly ionized gas.

§ 6. Summary and Conclusion

The method described above, which is based on the known interaction of low level microwaves with free electrons in weakly ionized low pressure gases at relatively low temperatures, proved to be a convenient one for the study on non-ionizing shock waves. The main shock characteristics, which are accessible to direct determination, are the instaneous and average velocities of shock discontinuities which are propagated in low pressure and low temperature (~300°K) weakly ionized gases. Associated with the change in shock propagation velocities, the exchange between the propagating shock discontinuities and the ionized gaseous medium is studied in some detail through the intermediary of the electron gas. Indeed, as known from previous plasma studies, the electron gas of the plasma interacts strongly with both the charged (and the neutral) heavy particles of the background plasma, with which the propagating shock wave exchange energy with great efficiency.

In addition to the electro-magnetic behavior, the optical properties of the background plasma are also put to contribution in these studies. Since these latter properties are also essentially dependent upon the energy state (or temperature) of the electron gas in the plasma, any change of the energy state of the electrons brought about-in particular, by the propagating shock waves-provides us with independent but complementary means of observation and information, which are directly correlated with the microwave measurements.

While the microwave measurements described in this paper are relative to **X**-band (-9000 MC) frequencies, the method is not limited to this frequency band; higher or lower microwave frequencies could be used in principle. The best appropriate microwave frequencies for these studies can generally be determined by geometrical considerations. Similarly the background gases to be used for weak shock wave propagation studies, their pressure and degree of ionization, are not limited to the cases reported here.

Scattering of Microwaves from a Cylindrical Plasma in the Born Approximation. II.

By Yukio MIDZUNO

Department of Physics, Faculty of Science, University of Tokyo

(Received March 29, 1961)

The scattering of a microwave, which is fed by an oscillating electric dipole, is treated in the Born approximation. When the source is a dipole $p_0 e^{j\omega t}\boldsymbol{e}_z$, where $\boldsymbol{e}_z$ is a unit vector in the z direction, the scattered field from a collisionless cylindrical plasma is given by

$$\boldsymbol{E}_s(\boldsymbol{r}, t)=p_0\sqrt{\frac{\pi}{2}}e^{(3/4)\pi j}\frac{k^4}{\sqrt{kl\rho(l+\rho)}}e^{j(\omega t-kl-k\rho)}\int_0^\infty \eta(\rho')J_0\left(2k\rho'\sin\frac{\theta}{2}\right)\rho' d\rho' \boldsymbol{e}_z\,,$$

where $(l, \pi, 0)$ and $(\rho, \theta, 0)$ are the cylindrical coordinates of the source and the observing point, respectively, $\eta(\rho')$ is $\omega_p{}^2/\omega^2$ with the plasma frequency ω_p and here only the term lowest in $1/kl$ and $1/k\rho$ is retained. Formulas are also derived to the next order in $1/kl$ and $1/k\rho$, when the plasma has collision loss and the dipole source has the axis in any one of the three independent directions. Remarks and discussions are given on the nature and the accuracy of the formulas. Finally the cases, where the observing point does not lie on the plane $z=0$, are treated in the lowest order in $1/kl$ and $1/k\rho$.

§1. Introduction

In a previous paper[1)], the scattering of a plane microwave from a cylindrical plasma was discussed in the Born approximation[1)], hereafter the paper is refered as Paper I. But, being radiated from an electromagnetic horn in real experiments[2)], the incident wave has rather a spherical character. Since there is an essential difference between a plane wave and a spherical wave, it would be desirable to treat also the scattering of an incident wave of the latter type.

In paper I, two methods were given for deriving the scattering formula for a plane incident wave in the Born approximation. One of them consists of deriving a wave equation for a medium with an effective dielectric constant, separating it into equations for the incident wave of E-type and for that of H-type, and solving them by means of the Fourier transforms. But unless the incident wave is uniform along the axis of the cylindrical plasma, the separation into equations of E-type and H-type cannot be effected and this method cannot be applied. In the other method, the scattered field is obtained by summing all radiations from electrons in the plasma, which are forced to oscillate by the electric field of the incident wave. This method can be applied to spherical waves, too, and has an advantage of elucidating the mechanism of the scattering.

Our method has a resemblance to that in the theory of the Rayleigh scattering[3)], which was developed for the purpose of discussing the scattering of light by the sky. It is also akin to the method which is used to deal with the scattering of microwaves by a small conducting object. The latter consists of the evaluation of the current density in the object induced by the incident wave and the summation of the radiation from the current distribution. But it seems that no one has yet derived a compact formula of the scattered wave from an object with a finite dimension in this method.

In this paper, we treat the scattering of an electric dipole radiation by a cylindrical plasma. In section 2, an outline of our method of calculation is given. Section 3 deals with the scattered field at a point on such a plane, which contains the source point and is perpendicular to the axis of the cylinder. Subsection 3.1 treats the case where the source is an oscillating electric dipole with a moment parallel to the axis of the cylinder, demonstrating our method in some detail. Subsections 3.2 and 3.3 treat the cases where the axes of the dipole sources are perpendicular to the axis of the cylinder and each other. Section 4 gives some remarks concerning our formulas. In section 5 the accuracy of our formulas is discussed. Section 6 deals with the scattered field when the observing point is arbitrary except that it lies at a great distance from the cylinder. Subsections 6.1 and 6.2 are devoted to the derivation of the formulas for the sources treated in the first part.

§ 2. Method of Calculation

We take a coordinate system such that the z-axis coincides with the axis of the cylindrical plasma and the source of the incident wave lies at a point S on the negative x-axis. We assume that the distance l between S and the origin is very large compared with the radius ρ_0 of the cylinder. We shall use also the cylindrical coordinate system (ρ, θ, z) with the same z-axis in which the line $\theta=0$ coincides with the x-axis. (Fig. 1)

When the source at S is an oscillating electric dipole $\boldsymbol{p}_0(t)$, the electric field produced by it at another point Q, whose coordinates are $\boldsymbol{r}'(x', y', z')$ or (ρ', θ', z'), is given by[4)]

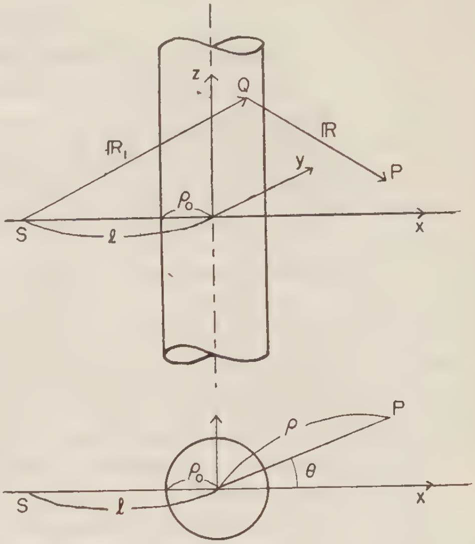

Fig. 1.

$$\boldsymbol{E}_0(\boldsymbol{r}', t)=\boldsymbol{E}_0^{(1)}(\boldsymbol{r}', t)+\boldsymbol{E}_0^{(2)}(\boldsymbol{r}', t)+\boldsymbol{E}_0^{(3)}(\boldsymbol{r}', t)\,, \tag{2.1}$$

with

$$\boldsymbol{E}_0^{(1)}(\boldsymbol{r}', t)=-\frac{\ddot{\boldsymbol{p}}_0}{c^2R_1}+\frac{\boldsymbol{R}_1(\ddot{\boldsymbol{p}}_0\cdot\boldsymbol{R}_1)}{c^2R_1^3}\,, \tag{2.2}$$

$$\boldsymbol{E}_0^{(2)}(\boldsymbol{r}', t)=-\frac{\dot{\boldsymbol{p}}_0}{cR_1^2}+\frac{3\boldsymbol{R}_1(\dot{\boldsymbol{p}}_0\cdot\boldsymbol{R}_1)}{cR_1^4}\,, \tag{2.3}$$

$$\boldsymbol{E}_0^{(3)}(\boldsymbol{r}', t)=-\frac{\boldsymbol{p}_0}{R_1^3}+\frac{3\boldsymbol{R}_1(\boldsymbol{p}_0\cdot\boldsymbol{R}_1)}{R_1^5}\,, \tag{2.4}$$

where $\boldsymbol{R}_1$ is the vector from S to Q, $R_1\equiv|\boldsymbol{R}_1|$, c is the light speed and

$$\boldsymbol{p}_0\equiv\boldsymbol{p}_0\left(t-\frac{R_1}{c}\right), \quad \dot{\boldsymbol{p}}_0\equiv\frac{\partial}{\partial t}\boldsymbol{p}_0\left(t-\frac{R_1}{c}\right), \quad \ddot{\boldsymbol{p}}_0\equiv\frac{\partial^2}{\partial t^2}\boldsymbol{p}_0\left(t-\frac{R_1}{c}\right). \tag{2.5}$$

Let us consider the motion of an electron under the influence of the electric field of the incident wave. We neglect the thermal motion of the electron and let the electron oscillate about the point Q. We consider the case where there is a uniform static external magnetic field $\boldsymbol{B}_0$ parallel to the z-axis and no external electric field exists. Further we assume that the amplitude of the oscillation of the electron is much smaller than the wave length of the incident wave. Then the equation of motion for the electron with the coordinate denoted by $\tilde{\boldsymbol{r}}$ is given by

$$m\frac{d^2\tilde{\boldsymbol{r}}}{dt^2}=-e\boldsymbol{E}_0(\boldsymbol{r}', t)-\frac{e}{c}\frac{d\tilde{\boldsymbol{r}}}{dt}\times\boldsymbol{B}_0-m\nu\frac{d\tilde{\boldsymbol{r}}}{dt}\,, \tag{2.6}$$

where m, $-e$, and ν is the mass, charge and the collision frequency of an electron respectively. If $\boldsymbol{p}_0(t)$ is proportional to $e^{j\omega t}$, $\boldsymbol{E}_0(\boldsymbol{r}', t)$ has the same property. Then, on assuming that $\tilde{\boldsymbol{r}}-\boldsymbol{r}'$ is also proportional to $e^{j\omega t}$, the equation (2.6) is easily solved and the dipole moment $\boldsymbol{p}(t)$ due to this electron is obtained as

$$\boldsymbol{p}(t)=-\frac{e^2}{m\omega^2}\begin{pmatrix} L & jM & 0 \\ -jM & L & 0 \\ 0 & 0 & N \end{pmatrix}\cdot \boldsymbol{E}_0(\boldsymbol{r}', t)\,, \tag{2.7}$$

where

$$L=\frac{1-j\beta}{(1-j\beta)^2-\gamma^2}\,,\qquad M=\frac{\gamma}{(1-j\beta)^2-\gamma^2}\,,\qquad N=\frac{1}{1-j\beta}\,, \tag{2.8}$$

with $\beta=\nu/\omega$, $\gamma=\omega_c/\omega$ and ω_c is the electron cyclotron frequency, $\omega_c=e|\boldsymbol{B}_0|/mc$.

When $\boldsymbol{p}(t)$ is obtained, the scattered electric field at a point P due to this electron is given by an expression similar to (2.1):

$$(\boldsymbol{E}_s(\boldsymbol{r}, t))_{\mathrm{Q}}=(\boldsymbol{E}_s^{(1)}(\boldsymbol{r}, t))_{\mathrm{Q}}+(\boldsymbol{E}_s^{(2)}(\boldsymbol{r}, t))_{\mathrm{Q}}+(\boldsymbol{E}_s^{(3)}(\boldsymbol{r}, t))_{\mathrm{Q}}\,, \tag{2.9}$$

where

$$(\boldsymbol{E}_s^{(1)}(\boldsymbol{r}, t))_{\mathrm{Q}}=-\frac{\ddot{\boldsymbol{p}}}{c^2R}+\frac{\boldsymbol{R}(\ddot{\boldsymbol{p}}\cdot\boldsymbol{R})}{c^2R^3}\,, \tag{2.10}$$

$$(\boldsymbol{E}_s^{(2)}(\boldsymbol{r}, t))_{\mathrm{Q}}=-\frac{\dot{\boldsymbol{p}}}{cR^2}+\frac{3\boldsymbol{R}(\dot{\boldsymbol{p}}\cdot\boldsymbol{R})}{cR^4}\,, \tag{2.11}$$

$$(\boldsymbol{E}_s^{(3)}(\boldsymbol{r}, t))_{\mathrm{Q}}=-\frac{\boldsymbol{p}}{R^3}+\frac{3\boldsymbol{R}(\boldsymbol{p}\cdot\boldsymbol{R})}{R^5}\,. \tag{2.12}$$

Here we have denoted by $\boldsymbol{R}$ the vector from Q to P, whose coordinates are $\boldsymbol{r}(x, y, z)$ or (ρ, θ, z), $R=|\boldsymbol{R}|$ and $\boldsymbol{p}$, $\dot{\boldsymbol{p}}$, $\ddot{\boldsymbol{p}}$ are given by expressions similar to (2.5):

$$\boldsymbol{p}\equiv\boldsymbol{p}\left(t-\frac{R}{c}\right),\qquad \dot{\boldsymbol{p}}\equiv\frac{\partial}{\partial t}\boldsymbol{p}\left(t-\frac{R}{c}\right),\qquad \ddot{\boldsymbol{p}}\equiv\frac{\partial^2}{\partial t^2}\boldsymbol{p}\left(t-\frac{R}{c}\right). \tag{2.13}$$

The total scattered field observed at P is evaluated by summing the contributions of all electrons in the plasma.

$$\begin{aligned}\boldsymbol{E}_s(\boldsymbol{r}, t)&=\int n(\boldsymbol{r}')(\boldsymbol{E}_s(\boldsymbol{r}, t))_{\mathrm{Q}}d\boldsymbol{r}' \\ &=\frac{m\omega^2}{4\pi e^2}\iiint \eta(\rho')(\boldsymbol{E}_s(\boldsymbol{r}, t))_{\mathrm{Q}}dz'd\theta'\rho'd\rho'\,,\end{aligned} \tag{2.14}$$

where $n(\boldsymbol{r}')$ is the number density of electrons, which is assumed to be independent of z' and θ', $\eta(\rho')=\omega_p^2/\omega^2$ with the plasma frequency ω_p $(=(4\pi e^2 n(\rho')/m)^{1/2})$ and the integration should be carried out over the entire space.

The integral is very complicated in general. But since our object is to get the formulas only for very large kl and $k\rho$, where $k=\omega/c$ is the wave number of the incident wave, we need only the asymptotic expressions of these integrals for such cases. This enables us to perform the integration with respect to z' and θ' analytically, and we get the final result in the form of an expansion with respect to $1/kl$, $1/k\rho$ and $1/k(l+\rho)$.

When $kl\gg 1$, it is clear from their expressions that $\boldsymbol{E}_0^{(2)}(\boldsymbol{r}', t)$ is smaller than $\boldsymbol{E}_0^{(1)}(\boldsymbol{r}', t)$ by one order in $1/kl$, and that $\boldsymbol{E}_0^{(3)}(\boldsymbol{r}', t)$ is in turn smaller than $\boldsymbol{E}_0^{(2)}(\boldsymbol{r}', t)$ by one order. Similarly when $k\rho$ is very large, $(\boldsymbol{E}_s^{(2)}(\boldsymbol{r}, t))_{\mathrm{Q}}$ and $(\boldsymbol{E}_s^{(3)}(\boldsymbol{r}, t))_{\mathrm{Q}}$ are smaller than $(\boldsymbol{E}_s^{(1)}(\boldsymbol{r}, t))_{\mathrm{Q}}$ by one and two orders with respect to $1/k\rho$, respectively. Therefore, if we wish to have the dominant term of the scattered field, we need only to retain $\boldsymbol{E}_0^{(1)}(\boldsymbol{r}', t)$ in (2.1), $(\boldsymbol{E}_s^{(1)}(\boldsymbol{r}, t))_{\mathrm{Q}}$ in (2.10) and the leading term of the asymptotic expansion of the integral with respect to z'. If we wish to get the terms of next order, we need to consider each case separately where the terms of next order are taken in only one of three steps of the procedure mensioned above, and to add up their contributions, and so on. This procedure shows us very clearly the origin of each term in the final result.

§ 3. The Scattered Field at a Point with $z=0$.

In this section we derive formulas for the scattered field at a point with $z=0$. Since this case would be most important for real experiments, we derive the leading terms and the terms of next order in $1/kl$ and $1/k\rho$.

3.1. *An electric dipole source with a moment parallel to the z-axis.*

Let us first put an electric dipole of the following type at S.

$$\boldsymbol{p}_0(t)=p_0e^{j\omega t}\boldsymbol{e}_z\ , \tag{3.1}$$

where p_0 is a constant and $\boldsymbol{e}_z$ is the unit vector in the z-direction. The field of the incident wave at Q is given by (2.1). The dominant term $\boldsymbol{E}_0^{(1)}(\boldsymbol{r}',t)$ is written explicitly as

$$\boldsymbol{E}_0^{(1)}(\boldsymbol{r}',t)=k^2p_0\exp\left[j(\omega t-kR_1)\right]\frac{1}{R_1^3}\left[-(l+x')z'\boldsymbol{e}_x-y'z'\boldsymbol{e}_y+\xi_1^2\boldsymbol{e}_z\right]\ , \tag{3.2}$$

where

$$\left.\begin{aligned}&R_1^2=(l+x')^2+y'^2+z'^2\equiv\xi_1^2+z'^2\ ,\\&\xi_1^2=l^2+2l\rho'\cos\theta+\rho'^2\ ,\end{aligned}\right\} \tag{3.3}$$

and $\boldsymbol{e}_x$ and $\boldsymbol{e}_y$ are the unit vectors in x and y directions respectively. Here again we can handle the contributions from the x, y and z components of $\boldsymbol{E}_0^{(1)}(\boldsymbol{r}',t)$ separately. It will be shown later that the dominant term of the scattered field comes from the z-component of $\boldsymbol{E}_0^{(1)}(\boldsymbol{r}',t)$, which we denote by $E_{0z}(\boldsymbol{r}',t)$. $E_{0x}(\boldsymbol{r}',t)$, the x-component of $\boldsymbol{E}_0^{(1)}(\boldsymbol{r}',t)$, gives a contribution smaller than $E_{0z}^{(1)}(\boldsymbol{r}',t)$ by one order in $1/kl$, and $E_{0y}^{(1)}(\boldsymbol{r}',t)$ gives that smaller than $E_{0z}^{(1)}(\boldsymbol{r},t)$ by two order. Therefore, we need to consider only $E_{0z}^{(1)}(\boldsymbol{r}',t)$ and $E_{0x}^{(1)}(\boldsymbol{r}',t)$ of the three components of $\boldsymbol{E}_0^{(1)}(\boldsymbol{r}',t)$ for our purpose. Similarly $\boldsymbol{E}_0^{(2)}(\boldsymbol{r}',t)$ is given by

$$\boldsymbol{E}_0^{(2)}(\boldsymbol{r},t)=-jkp_0\exp\left[j(\omega t-kR_1)\right]\frac{1}{R_1^4}\left[-3(l+x')z'\boldsymbol{e}_x-3y'z'\boldsymbol{e}_y+(R_1^2-3z'^2)\boldsymbol{e}_z\right]\ , \tag{3.4}$$

of which we need to retain $E_{0z}^{(2)}(\boldsymbol{r},t)$ only.

(a) *The dominant term*

At first we derive the dominant term. Inserting the expression for $E_{0z}^{(1)}(\boldsymbol{r},t)$ into (2.7), we get

$$\boldsymbol{p}(t)=-\frac{e^2}{m\omega^2}k^2p_0N\exp\left[j(\omega t-kR_1)\right]\frac{\xi_1^2}{R_1^3}\boldsymbol{e}_z\ , \tag{3.5}$$

Then (2.10) gives

$$(\boldsymbol{E}(\boldsymbol{r},t))_{\mathrm{Q}}=-\frac{e^2}{m\omega^2}k^4p_0N\exp\left[j(\omega t-kR_1-kR)\right]\frac{\xi_1^2}{R_1^3R^3}\{\xi^2\boldsymbol{e}_z+(x-x')z'\boldsymbol{e}_x+(y-y')z'\boldsymbol{e}_y\}\ , \tag{3.6}$$

where

$$\left.\begin{aligned}&R^2=(x-x')^2+(y-y')^2+z'^2\equiv\xi^2+z'^2\ ,\\&\xi^2=\rho^2-2\rho\rho'\cos(\theta-\theta')+\rho'^2\ .\end{aligned}\right\} \tag{3.7}$$

The total scattered field at P is given by (2.14). The x and y components vanish in the course of the integration with respect to z', and we have

$$\boldsymbol{E}_s(\boldsymbol{r},t)=-\frac{1}{4\pi}k^4p_0e^{j\omega t}\int_0^\infty N\eta(\rho')\rho'd\rho'\int_0^{2\pi}d\theta'\xi_1^2\xi^2\int_{-\infty}^{\infty}\frac{1}{R_1^3R^3}\exp\left[-jk(R_1+R)\right]dz'\boldsymbol{e}_z\ . \tag{3.8}$$

Here we need the asymptotic expression of this integral for large kl and $k\rho$. From (3.3) and (3.7) this means that we need the asymptotic expansion for the case where $k\xi_1\gg1$ and $k\xi\gg1$. This expansion is accomplished in Appendix A with the result,

$$\int_{-\infty}^{\infty} \frac{1}{R_1{}^3 R^3} \exp\left[-jk(R_1+R)\right] dz'$$
$$= \frac{\sqrt{2\pi}}{\xi_1{}^2\xi^2\sqrt{k\xi_1\xi(\xi_1+\xi)}} \exp\left[-jk(\xi_1+\xi)-\frac{\pi}{4}j\right]\left\{1-\frac{1}{8}j\left[15\frac{1}{k(\xi_1+\xi)}-9\frac{1}{k\xi_1}-9\frac{1}{k\xi}\right]\right.$$
$$\left. +O\left(\frac{1}{(k\xi_1)^2}, \frac{1}{k^2\xi_1\xi}, \frac{1}{(k\xi)^2}\right)\right\}. \tag{3.9}$$

When we demand the dominant term, only the leading term of (3.9) is needed and ξ_1 and ξ can be replaced by l and ρ, respectively, except in the argument of the exponential function, where these should be replaced by the first and second terms in their expansions:

$$\left.\begin{aligned} \xi_1 &= l+\rho'\cos\theta'+\frac{1}{2}\frac{\rho'^2}{l}\sin^2\theta'+\cdots, \\ \xi &= \rho-\rho'\cos(\theta'-\theta)+\frac{1}{2}\frac{\rho'^2}{\rho}\sin^2(\theta'-\theta)+\cdots. \end{aligned}\right\} \tag{3.10}$$

Inserting these expressions into (3.8), we get the dominant term as follows.

$$\boldsymbol{E}_{s0}(\boldsymbol{r}, t) = \frac{1}{2\sqrt{2\pi}} e^{(3/4)\pi j} k^4 p_0 \frac{1}{\sqrt{kl\rho(l+\rho)}} e^{j(\omega t-kl-k\rho)}$$
$$\times \int_0^{\infty} N\eta(\rho')\rho' d\rho' \int_0^{2\pi} \exp\left[2jk\rho'\sin\frac{\theta}{2}\sin\left(\theta'-\frac{\theta}{2}\right)\right] d\theta' \boldsymbol{e}_z$$
$$= p_0\sqrt{\frac{\pi}{2}} e^{(3/4)\pi j} \frac{k^4}{\sqrt{kl\rho(l+\rho)}} e^{j(\omega t-kl-k\rho)} \int_0^{\infty} N\eta(\rho') J_0\left(2k\rho'\sin\frac{\theta}{2}\right)\rho' d\rho' \boldsymbol{e}_z. \tag{3.11}$$

Here $J_n(x)$ is the Bessel function of nth order, and we have used the formula

$$\int_0^{2\pi} e^{ja\cos\theta}\cos n\theta d\theta = 2\pi j^n J_n(a), \tag{3.12}$$

(b) *Terms of the next order*

The terms of the next order consist of the following contributions:

1) the next order terms of equation (3.8),
2) the terms which come from $E_{0z}^{(1)}(\boldsymbol{r}', t)$ and $(\boldsymbol{E}_s{}^{(1)}(\boldsymbol{r}, t))_Q$,
3) the terms which come from $E_{0z}^{(1)}(\boldsymbol{r}', t)$ and $(\boldsymbol{E}_s{}^{(2)}(\boldsymbol{r}, t))_Q$,
4) the terms which come from $E_{0z}^{(2)}(\boldsymbol{r}', t)$ and $(\boldsymbol{E}_s{}^{(1)}(\boldsymbol{r}, t))_Q$.

In the latter three contributions, only the leading terms need to be retained.

When we insert (3.9) and (3.10) into (3.8), expand it, retain only the terms of next order in $1/kl$ and $1/k\rho$ and perform the integration with respect to θ', we get

$$\boldsymbol{E}_{s0}(\boldsymbol{r}, t)+\boldsymbol{E}_{s1}^{(1)}(\boldsymbol{r}, t) = \frac{1}{2\sqrt{2\pi}} e^{(3/4)\pi j} k^4 p_0 \frac{1}{\sqrt{kl\rho(l+\rho)}} e^{j(\omega t-kl-k\rho)}$$
$$\times \int_0^{\infty} N\eta(\rho')\rho' d\rho' \int_0^{2\pi} \exp\left[2jk\rho'\sin\frac{\theta}{2}\sin\left(\theta'-\frac{\theta}{2}\right)\right] d\theta'$$
$$\times\left\{1+\frac{1}{kl}\left[-\frac{k\rho'}{2}\cos\theta'-\frac{j(k\rho')^2}{2}\sin^2\theta'+\frac{9}{8}j\right]\right.$$
$$+\frac{1}{k\rho}\left[\frac{k\rho'}{2}\cos(\theta'-\theta)-\frac{j(k\rho')^2}{2}\sin^2(\theta'-\theta)+\frac{9}{8}j\right]$$
$$\left.+\frac{1}{k(l+\rho)}\left[k\rho'\sin\frac{\theta}{2}\sin\left(\theta'-\frac{\theta}{2}\right)-\frac{15}{8}j\right]\right\}\boldsymbol{e}_z$$

$$
\begin{aligned}
&= p_0\sqrt{\frac{\pi}{2}}\,e^{(3/4)\pi j}\frac{1}{\sqrt{kl\rho(l+\rho)}}e^{j(\omega t-kl-k\rho)}\int_0^\infty N\eta(\rho')\rho'd\rho'\Big\{J_0\Big(2k\rho'\sin\frac{\theta}{2}\Big)\\
&\quad+\frac{1}{8}j\Big(\frac{1}{kl}+\frac{1}{k\rho}\Big)\Big[(9-2k^2\rho'^2\cos\theta)J_0\Big(2k\rho'\sin\frac{\theta}{2}\Big)+2k^2\rho'^2J_2\Big(2k\rho'\sin\frac{\theta}{2}\Big)\Big]\\
&\quad+\frac{1}{8}j\frac{1}{k(l+\rho)}\Big[-15J_0\Big(2k\rho'\sin\frac{\theta}{2}\Big)+8k\rho'\sin\frac{\theta}{2}J_1\Big(2k\rho'\sin\frac{\theta}{2}\Big)\Big]\Big\}\boldsymbol{e}_z\,, \qquad (3.13)
\end{aligned}
$$

where we have used (3.12). The first term of this expression is the dominant term derived in the last sub-section and the other terms are the contributions of the first type mensioned above.

In dealing with the contribution of the second type, we can replace $l+x'$ by l in $E_{0x}^{(1)}(\boldsymbol{r}, t)$:

$$
E_{0x}^{(1)}(\boldsymbol{r}', t)=-k^2p_0\exp[j(\omega t-kR_1)]\frac{lz'}{R_1{}^3}. \qquad (3.14)
$$

Then from (2.7) and (2.10) we get

$$
\boldsymbol{p}(t)=\frac{e^2}{m\omega^2}k^2p_0\exp[j(\omega t-kR_1)]\frac{lz'}{R_1{}^3}(L\boldsymbol{e}_x-jM\boldsymbol{e}_y)\,, \qquad (3.15)
$$

$$
\begin{aligned}
(\boldsymbol{E}_s{}^{(1)}(\boldsymbol{r}, t))_Q=&\frac{e^2}{m\omega^2}k^4p_0\exp[j(\omega t-kR_1-kR)]\frac{lz'}{R_1{}^3R^3}\{z'(Lx-jMy)\boldsymbol{e}_z+[L(R^2-x^2)+jMxy]\boldsymbol{e}_x\\
&-[jM(R^2-y^2)+Lxy]\boldsymbol{e}_y\}\,, \qquad (3.16)
\end{aligned}
$$

where we have used the fact that when only the leading terms are desired, we can replace $x-x'$ and $y-y'$ by x and y, respectively. The x and y components vanish in the course of the integration with respect to z'. Here we need the asymptotic expression of the following integral, which is easily obtained from the formula in Appendix A.

$$
\begin{aligned}
&\int_{-\infty}^{\infty}\frac{z'^2}{R_1{}^3R^3}\exp[-jk(R_1+R)]dz'\\
&=\int_{-\infty}^{\infty}\frac{R^2-\xi^2}{R_1{}^3R^3}\exp[-jk(R_1+R)]dz'\\
&=\frac{\sqrt{2\pi}}{\xi_1\xi\sqrt{k\xi_1\xi(\xi_1+\xi)}}\frac{1}{k(\xi_1+\xi)}\exp\Big[-jk(\xi_1+\xi)-\frac{3}{4}\pi j\Big], \qquad (3.17)
\end{aligned}
$$

Thus we have the following contribution.

$$
\begin{aligned}
\boldsymbol{E}_{s1}^{(2)}(\boldsymbol{r}, t)=&p_0\sqrt{\frac{\pi}{2}}\,e^{(3/4)\pi j}\frac{k^4}{\sqrt{kl\rho(l+\rho)}}e^{j(\omega t-kl-k\rho)}\\
&\times\frac{1}{k(l+\rho)}j\int_0^\infty(L\cos\theta-jM\sin\theta)\eta(\rho')J_0\Big(2k\rho'\sin\frac{\theta}{2}\Big)\rho'd\rho'\boldsymbol{e}_z\,. \qquad (3.18)
\end{aligned}
$$

Similarly the contributions of the third and the fourth type are obtained as follows.

$$
\boldsymbol{E}_{s1}^{(3)}(\boldsymbol{r}, t)=-p_0\sqrt{\frac{\pi}{2}}\,e^{(3/4)\pi j}\frac{k^4}{\sqrt{kl\rho(l+\rho)}}e^{j(\omega t-kl-k\rho)}\frac{1}{k\rho}j\int_0^\infty N\eta(\rho')J_0\Big(2k\rho'\sin\frac{\theta}{2}\Big)\rho'd\rho'\boldsymbol{e}_z\,. \qquad (3.19)
$$

$$
\boldsymbol{E}_{s1}^{(4)}(\boldsymbol{r}, t)=-p_0\sqrt{\frac{\pi}{2}}\,e^{(3/4)\pi j}\frac{k^4}{\sqrt{kl\rho(l+\rho)}}e^{j(\omega t-nl-k\rho)}\frac{1}{kl}j\int_0^\infty N\eta(\rho')J_0\Big(2k\rho'\sin\frac{\theta}{2}\Big)\rho'd\rho'\boldsymbol{e}_z\,. \qquad (3.20)
$$

(c) *The total result*

The scattered field at P due to the cylindrical plasma is the sum of expressions (3.13), (3.18), (3.19) and (3.20).

$$
\begin{aligned}
\boldsymbol{E}_s(\boldsymbol{r},t)=p_0\sqrt{\frac{\theta}{2}}\,e^{(3/4)\pi j}\frac{k^4}{\sqrt{kl\rho(l+\rho)}}e^{j(\omega t-kl-k\rho)}&\left\{\int_0^\infty N\eta(\rho')J_0\left(2k\rho'\sin\frac{\theta}{2}\right)\rho'd\rho'\right.\\
&+\frac{1}{8}j\left(\frac{1}{kl}+\frac{1}{k\rho}\right)\int_0^\infty N\eta(\rho')\left[(1-2k^2\rho'^2\cos\theta)J_0\left(2k\rho'\sin\frac{\theta}{2}\right)\right.\\
&\left.+2k^2\rho'^2J_2\left(2k\rho'\sin\frac{\theta}{2}\right)\right]\rho'd\rho'\\
&+\frac{1}{8}j\frac{1}{k(l+\rho)}\int_0^\infty\left[(8(L\cos\theta-jM\sin\theta)-15N)\eta(\rho')J_0\left(2k\rho'\sin\frac{\theta}{2}\right)\right.\\
&\left.\left.+8N\eta(\rho')k\rho'\sin\frac{\theta}{2}J_1\left(2k\rho'\sin\frac{\theta}{2}\right)\right]\rho'd\rho'+\cdots\right\}\boldsymbol{e}_z\,.
\end{aligned}
\tag{3.21}
$$

This expression is symmetric in l and ρ, as expected from the symmetry of our problem.

3.2. *The dipole source parallel to the y-axis*

Next, we consider an electric dipole source with a moment parallel to the y-axis.

$$
\boldsymbol{p}_0(t)=p_0'e^{j\omega t}\boldsymbol{e}_y\,. \tag{3.22}
$$

Then the electric field of the incident wave is given by

$$
\boldsymbol{E}_0(\boldsymbol{r}',t)=\boldsymbol{E}_0^{(1)}(\boldsymbol{r}',t)+\boldsymbol{E}_0^{(2)}(\boldsymbol{r}',t)+\boldsymbol{E}_0^{(3)}(\boldsymbol{r}',t)\,, \tag{3.23}
$$

with

$$
\left.
\begin{aligned}
\boldsymbol{E}_0^{(1)}(\boldsymbol{r}',t)&=k^2p_0'\exp[j(\omega t-kR_1)]\frac{1}{R_1^3}[-(l+x')y'\boldsymbol{e}_x+(R_1^2-y'^2)\boldsymbol{e}_y-z'y'\boldsymbol{e}_z]\,,\\
\boldsymbol{E}_0^{(2)}(\boldsymbol{r}',t)&=-jkp_0'\exp[j(\omega t-kR_1)]\frac{1}{R_1^4}[-3(l+x')y'\boldsymbol{e}_x+(R_1^2-3y'^2)\boldsymbol{e}_y-3z'y'\boldsymbol{e}_z]\,.
\end{aligned}
\right\}
\tag{3.24}
$$

$\boldsymbol{E}_0^{(3)}(\boldsymbol{r},t)$ is smaller than $\boldsymbol{E}_0^{(2)}(\boldsymbol{r}',t)$ by one order in $1/kl$ and is negligible. Here the dominant contribution comes from $E_{0x}^{(1)}(\boldsymbol{r}',t)$. In the following the calculation proceeds much the same way as that in the last section with a little more tedious labor. Here we give only the final result.

$$
\begin{aligned}
\boldsymbol{E}_s(\boldsymbol{r}',t)=p_0'\sqrt{\frac{\pi}{2}}\,e^{(3/4)\pi j}\frac{k^4}{\sqrt{kl\rho(l+\rho)}}e^{j(\omega t\ \ kl-k\rho)}&\left\{\int_0^\infty(L\cos\theta-jM\sin\theta)\eta(\rho')J_0\left(2k\rho'\sin\frac{\theta}{2}\right)\rho'd\rho'\boldsymbol{e}_\theta\right.\\
+\int_0^\infty\eta(\rho')\rho'd\rho'&\left\{\left(\frac{1}{k(l+\rho)}+\frac{1}{k\rho}\right)jJ_0\left(2k\rho'\sin\frac{\theta}{2}\right)(L\sin\theta+jM\cos\theta)\right.\\
&\left.+\frac{1}{k\rho}jk\rho'\cos\frac{\theta}{2}J_1\left(2k\rho'\sin\frac{\theta}{2}\right)(L\cos\theta-jM\sin\theta)\right\}\boldsymbol{e}_\rho\\
+\int_0^\infty\eta(\rho')\rho'd\rho'&\left\{\frac{1}{8}\left(\frac{1}{kl}+\frac{1}{k\rho}\right)j\left[(L\cos\theta-jM\sin\theta)\left(-7J_0\left(2k\rho'\sin\frac{\theta}{2}\right)\right.\right.\right.\\
&\left.+2k^2\rho'^2\left(-\cos\theta\,J_2\left(2k\rho'\sin\frac{\theta}{2}\right)+J_2\left(2k\rho'\sin\frac{\theta}{2}\right)\right)\right)\\
&\left.+(L\sin\theta+jM\cos\theta)8k\rho'\cos\frac{\theta}{2}J_1\left(2k\rho'\sin\frac{\theta}{2}\right)\right]\\
+\frac{1}{8}\frac{1}{k(l+\rho)}j(L\cos\theta-jM\sin\theta)&\left.\left.\left(J_0\left(2k\rho'\sin\frac{\theta}{2}\right)+8k\rho'\sin\frac{\theta}{2}J_1\left(2k\rho'\sin\frac{\theta}{2}\right)\right)\right\}\boldsymbol{e}_\theta+\cdots\right\}\,,
\end{aligned}
\tag{3.25}
$$

where $\boldsymbol{e}_\rho$ and $\boldsymbol{e}_\theta$ are the unit vectors of the directions of ρ and θ respectively.

3.3. *The dipole source parallel to the x-axis*

When an electric dipole parallel to the x-axis is placed at S, the leading term of the scattered field corresponds to the terms of the next order terms for the dipole source parallel to other axis. Thus we need only the lowest terms in $1/kl$ and $1/k\rho$, and the analysis is very simple compared with other two cases. Here again we give the final result only.

$$\boldsymbol{p}_0(t)=p^{0\prime\prime}e^{j\omega t}\boldsymbol{e}_x\,, \tag{3.26}$$

$$\begin{aligned}\boldsymbol{E}_s(\boldsymbol{r},t)=p_0''\sqrt{\frac{\pi}{2}}\,e^{(3/4)\pi j}\frac{k^4}{\sqrt{kl\rho(l+\rho)}}e^{j(\omega t-kl-k\rho)}\int_0^\infty \eta(\rho')J_0\left(2k\rho'\sin\frac{\theta}{2}\right)\rho'd\rho'\\ \times\frac{1}{k(l+\rho)}\,j\left\{N\boldsymbol{e}_\rho+\frac{\rho}{l}(L\sin\theta+jM\cos\theta)\boldsymbol{e}_\theta\right\}+\cdots\,.\end{aligned} \tag{3.27}$$

§4. Remarks

In this section we give some remarks concerning our formulas. The dominant terms of the electric fields of the incident waves at the origin are

$$\boldsymbol{E}_0(0,t)=E_{0z}(0,t)\boldsymbol{e}_z\,,$$

where

$$E_{0z}(0,t)=k^2p_0\frac{1}{l}\exp\left[j(\omega t-kl)\right]\,, \tag{4.1}$$

for the dipole source parallel to the z-axis and

$$\boldsymbol{E}_0(0,t)=E_{0y}(0,t)\boldsymbol{e}_y\,,$$

where

$$E_{0y}(0,t)=k^2p_0'\frac{1}{l}\exp\left[j(\omega t-kl)\right]\,, \tag{4.2}$$

for the dipole parallel to the y-axis. Thus the dominant terms of the scattered field at P are given by

$$\boldsymbol{E}_{s0}(\boldsymbol{r},t)=\sqrt{\frac{\pi}{2}}\,e^{(3/4)\pi j}\frac{1}{\sqrt{1+(\rho/l)}}E_{0z}(0,0)\frac{1}{\sqrt{k\rho}}e^{j(\omega t-k\rho)}\int_0^\infty k^2N\eta(\rho')J_0\left(2k\rho'\sin\frac{\theta}{2}\right)\rho'd\rho'\boldsymbol{e}_z\,, \tag{4.3}$$

for the dipole source parallel to the z-axis and

$$\begin{aligned}\boldsymbol{E}_{s0}(\boldsymbol{r},t)=\sqrt{\frac{\pi}{2}}e^{(3/4)\pi j}\frac{1}{\sqrt{1+(\rho/l)}}E_{0y}(0,0)\\ \times\frac{1}{\sqrt{k\rho}}e^{j(\omega t-k\rho)}\int_0^\infty k^2(L\cos\theta-jM\sin\theta)\eta(\rho')\,J_0\left(2k\rho'\sin\frac{\theta}{2}\right)\rho'd\rho'\boldsymbol{e}_\theta\,,\end{aligned} \tag{4.4}$$

for the dipole parallel to the y-axis, respectively. These expressions show us that, when $l\gg\rho$, these scattered fields tend to those for the plane incident waves of the respective type, which were derived in Paper I. On the other hand, if $\rho\gg l$, these scattered fields are proportional to $(k\rho)^{-1}\exp\left[j(\omega t-k\rho)\right]$, which is the characteristic factor of the spherical wave, as should be.

Since the expression (4.3) for the dominant term depends only on the field intensity at the origin, it seems to be valid for more general types of sources than a dipole. In fact we shall show in Appendix C that it is valid independently of the details of the angular distribution of the incident wave, provided that its intensity at the origin is given by (4.1) and some weak conditions are satisfied. Similarly the expression (4.4) is also valid for any incident wave under similar conditions as above. Thus they may be applied to real experiments, too, where horns are used as the source of the incident wave.

In Paper I, it was shown that for some special types of the density distributions of the plasma, the integration in the scattering formulas can be performed analytically. For the distributions mensioned there, the integrations of our formulas are also performed analytically. For example, let us take the density distribution of J_0 type[5];

$$\eta(\rho)=\begin{cases}\eta_0J_0(\zeta_1\rho/\rho_0) & \text{for}\quad \rho<\rho_0\\ 0 & \text{for}\quad \rho>\rho_0\,,\end{cases} \tag{4.5}$$

where η_0 is a constant and ζ_1 $(=2.4048\cdots)$ is the least zero point of $J_0(x)$. Then we have

$$\int_0^1 zJ_0(\alpha z)J_0(\xi_1 z)dz=\frac{\zeta_1}{\zeta_1^2-\alpha^2}J_0(\alpha)J_1(\zeta_1)\,, \tag{4.6}$$

and, on differentiating this by α once and twice, we get

$$\int_0^1 z^2J_1(\alpha z)J_0(\zeta_1 z)dz=-\frac{\zeta_1 J_1(\zeta_1)}{(\zeta_1^2-\alpha^2)^2}[2\alpha J_0(\alpha)-(\zeta_1^2-\alpha^2)J_1(\alpha)]\,, \tag{4.7}$$

$$\int_0^1 z^3J_2(\alpha z)\,J_0(\zeta_1 z)dz=\frac{\zeta_1 J_1(\zeta_1)}{(\zeta_1^2-\alpha^2)^3}[8\alpha^2J_0(\alpha)-4\alpha(\zeta_1^2-\alpha^2)J_1(\alpha)+(\zeta_1^2-\alpha^2)^2J_2(\alpha)]\,. \tag{4.8}$$

Using these expressions, we get, e.g., from (3.21) the following expressions for the dipole source parallel to the z-axis.

$$\begin{aligned}\boldsymbol{E}_s(\boldsymbol{r},t)=p_0\sqrt{\frac{\pi}{2}}e^{(3/4)\pi j}\frac{k^2}{\sqrt{kl\rho(l+\rho)}}e^{j(\omega t-kl-k\rho)}\frac{\zeta_1J_1(\zeta_1)}{\zeta_1^2-\alpha^2}(k\rho_0)^2\eta_0\Big\{NJ_0(\alpha)+\frac{1}{8}j\left(\frac{1}{kl}+\frac{1}{k\rho}\right)N\\ \times\left[\left(1-2(k\rho_0)^2\left(1-\frac{4}{\zeta_1^2-\alpha^2}\right)\left(\cos\theta+\frac{2\alpha^2}{\zeta_1^2-\alpha^2}(1+\cos\theta)\right)\right)J_0(\alpha)\right.\\ \left.+2(k\rho_0)^2\left(1-\frac{2\alpha^2}{\zeta_1^2-\alpha^2}(1+\cos\theta)\right)J_2(\alpha)\right]\\ +\frac{1}{8}j\frac{1}{k(l+\rho)}\left[\left(8(L\cos\theta-jM\sin\theta)-N\left(15+\frac{8\alpha^2}{\zeta_1^2-\alpha^2}\right)\right)J_0(\alpha)\right.\\ \left.+4\alpha NJ_1(\alpha)\right]+\cdots\Big\}\boldsymbol{e}_z\,,\end{aligned} \tag{4.9}$$

where $\alpha=2k\rho_0\sin(\theta/2)$.

§ 5. Accuracy of the Dominant Terms

Our formulas are asymptotic expressions valid for very large kl and $k\rho$. Since these are quantities of order of several tens in real experiments, dominant terms seem to give a sufficiently accurate field. But here it should be noted that the coefficients of the correction terms are functions of $k\rho_0$ as seen, e.g., from (4.9). Since these coefficients have terms of higher powers of $k\rho_0$ than the dominant term, there would be some fear that the correction terms may overcome the dominant terms when $k\rho_0$ is large compared with 1 in the real experiments, where kl and $k\rho$ are not sufficiently large. This means merely that when $k\rho_0$ is large, the incident wave cannot be regarded as the far field of the source unless the distance to the source is very large and the scattered field cannot be regarded as the far field from the scatterer unless the observing point lies at very remote place. In other words, the condition for the far field depends not only on the distances to the source and the observing point compared with the wave length and the dimension of the scatterer, but also on the ratio of the latter two.

It would be, therefore, desirable that the comparison of our formulas with real experiments is carried out for such a large kl and $k\rho$ that the correction terms have only small effect on the scattered field. An estimation for the advisable value of kl and $k\rho$ is obtained when we compare terms of the next order with the dominant term for the special case of $\theta=0$. For example, we take the case given by the expression (4.9), and put it in the following form.

$$\begin{aligned}\boldsymbol{E}_s(\boldsymbol{r},t)=p_0\sqrt{\frac{\pi}{2}}e^{(3/4)\pi j}\frac{k^2}{\sqrt{kl\rho(l+\rho)}}e^{j(\omega t-kl-k\rho)}\,\eta_0(k\rho_0)^2\frac{J_1(\zeta_1)}{\zeta_1}\\ \times\left\{F_0(\theta)+\frac{1}{2}\left(\frac{1}{kl}+\frac{1}{k\rho}\right)jF_1^{(1)}(\theta)+\frac{2}{k(l+\rho)}jF_1^{(2)}(\theta)+\cdots\right\}\boldsymbol{e}_z\,.\end{aligned} \tag{5.1}$$

When the plasma is collisionless and there is no external magnetic field, $L=N=1$, $M=0$ and the expression for $\theta=0$ reduces to

$$\left.\begin{aligned} &F_0(0)=1\,, \\ &F_1^{(1)}(0)=\frac{1}{4}\left(1-2\left(1-\frac{4}{\zeta_1^2}\right)(kp_0)^2\right), \\ &\qquad=0.25-0.15417(k\rho_0)^2\,, \\ &F_1^{(2)}(0)=-\frac{7}{16}=-0.4375\,. \end{aligned}\right\} \tag{5.2}$$

Table I.

$k\rho_0$	$F_1^{(1)}(0)$
2	−0.37
4	−2.22
6	−5.30
8	−9.62
10	−15.17

Table 1 gives the values of $F_1^{(1)}(0)$ as a function of $k\rho_0$; kl and $k\rho$ should be at least ten fold larger than the absolute value of $F_1^{(1)}(0)$ given in this table. When the radius of the discharge tube is equal to the wave length, $k\rho_0\approx6$. The table tells us that then we should choose l and ρ larger than 9 times of the wave length, which is of reasonable scale in practical experiments, too. But even when we choose kl and $k\rho$ as such, we must be careful when $F_0(\theta)$ tends to zero if we wish to use the dominant term only.

§ 6. The Scattered Field at an Arbitrary Point

In this section we derive the scattered field at an arbitrary point. The observing point is located at $P(\rho, \theta, z)$ with $k\rho\gg1$ and arbitrary θ and z. Because of the complexity of the calculation, we give here only the dominant terms of the scattered field. In this case we need only to retain the lowest terms with respect to $1/kl$ and $1/k\rho$ at every step of the calculation. This simplifies our analysis considerably.

6.1. *The dipole source parallel to the z-axis*

Let us put the dipole source given by (3.1) at S. Then the field of the incident wave at Q is given by (3.2). It should be noted here that, contrary to the previous case, $E_{0x}^{(1)}(\boldsymbol{r}', t)$ gives a term of the same order as that given by $E_{0z}^{(1)}(\boldsymbol{r}', t)$. $E_{0y}^{(1)}(\boldsymbol{r}', t)$ gives a higher order term than other two and can be neglected here, too. At first we consider the contribution from $E_{0z}^{(1)}(\boldsymbol{r}', t)$.

$$E_{0z}^{(1)}(\boldsymbol{r}', t)=k^2p_0\exp[j(\omega t-kR_1)]\frac{\xi_1^2}{R_1^3}\,, \tag{6.1}$$

where R_1 and ξ_1 are the same as that defined by (3.3). Using (2.7) and (2.10) we find the contribution of the electron located at Q as follows.

$$(\boldsymbol{E}^{(1)}(\boldsymbol{r}, t))_Q=-\frac{e^2}{m\omega^2}k^4p_0N\exp[j(\omega t-kR_1-kR)]\frac{\xi_1^2}{R_1^3R^3}\{\xi^2\boldsymbol{e}_z-(x-x')(z-z')\boldsymbol{e}_x-(y-y')(z-z')\boldsymbol{e}_y\}\,, \tag{6.2}$$

where

$$R^2=|\boldsymbol{R}|^2=\xi^2+(z-z')^2\,, \tag{6.3}$$

with ξ defined by (3.7). In summing the contributions from all electrons in the cylindrical plasma, we need the asymptotic expression of the following integral for large kl and $k\rho$:

$$I_{m,n}=\int_{-\infty}^{\infty}\frac{1}{R_1^mR^n}\exp[-jk(R_1+R)]dz'\,. \tag{6.4}$$

This is accomplished in Appendix B and the result is

$$I_{m,n}=\sqrt{2\pi}\,e^{-(\pi/4)j}\frac{(\xi_1+\xi)^{m+n-2}\exp[-jk\sqrt{(\xi_1+\xi)^2+z^2}]}{\xi_1^{m-1}\xi^{n-1}\sqrt{k\xi_1\xi}\,[(\xi_1+\xi)^2+z^2]^{(1/2)(m+n)-(3/4)}}\,. \tag{6.5}$$

On the other hand, in the course of the derivation of (6.5), we find that the following rule can be used in the evaluation of the integral, when we want to get the dominant terms only.

For example, let us take an integral of the following form;

$$\int_{-\infty}^{\infty}\frac{\xi_1^2}{R_1^3R^3}(x-x')(z-z')\exp[-jk(R_1+R)]dz'\,. \tag{6.6}$$

Then we regard the integrand as the product of $(R_1R)^{-3}\exp[-jk(R_1+R)]$ and $\xi_1^2(x-x')(z-z')$. The former factor gives the contribution given by (6.5). In other factors, we replace

$$\left.\begin{array}{lll} z' & \text{by} & lz/(l+\rho)\,, \\ z-z' & \text{by} & \rho z/(l+\rho)\,, \\ x-x' & \text{by} & \rho\cos\theta\,, \\ y-y' & \text{by} & \rho\sin\theta\,. \end{array}\right\} \tag{6.7}$$

Finally we make the product of these factors and get the dominant term of the asymptotic expansion of the integral. When it is convenient, some R^2 can be also regarded as an extra factor in the integrand and is replaced by $\rho^2[1+z^2/(l+\rho)^2]$. In this way the integral (6.6) can be evaluated to be

$$\begin{aligned}&\sqrt{2\pi}e^{-(\pi/4)j}\frac{(l+\rho)^4\exp[-jk\sqrt{(\xi_1+\xi)^2+z^2}]}{l^2\rho^2\sqrt{kl\rho}\,[(l+\rho)^2+z^2]^{9/4}}\times l^2\rho\cos\theta\frac{\rho z}{l+\rho}\\ &=\sqrt{2\pi}e^{-(\pi/4)j}\frac{(l+\rho)^3z\cos\theta}{\sqrt{kl\rho}\,[(l+\rho)^2+z^2]^{9/4}}\exp[-jk\sqrt{(\xi_1+\xi)^2+z^2}]\,.\end{aligned} \tag{6.8}$$

At the final step of our calculation, we have to perform the integration with respect to θ'. Inserting the expansion of the argument of the exponential function

$$\sqrt{(\xi_1+\xi)^2+z^2}=\sqrt{(l+\rho)^2+z^2}+\frac{l+\rho}{\sqrt{(l+\rho)^2+z^2}}\rho'(\cos\theta'-\cos(\theta'-\theta))+\cdots\,, \tag{6.9}$$

into the integrand and retaining the terms of lowest order only, we have

$$\int_0^{2\pi}[-jk\sqrt{(\xi_1+\xi)^2+z^2}]d\theta'=\exp[-jk\sqrt{(l+\rho)^2+z^2}]\cdot 2\pi J_0\left(\frac{l+\rho}{\sqrt{(l+\rho)^2+z^2}}2k\rho'\sin\frac{\theta}{2}\right). \tag{6.10}$$

In this way the contribution to the scattered field from the z-component of the incident wave is found to be

$$\begin{aligned}&-\frac{1}{4\pi}k^4p_0\int_0^{\infty}N\eta(\rho')\rho'd\rho'\int_0^{2\pi}d\theta'\int_{-\infty}^{\infty}dz'\exp[j(\omega t-kR_1-kR)]\\ &\quad\times\frac{\xi_1^2}{R_1^3R^3}\{\xi^2e_z-(x-x')(z-z')e_x-(y-y')(z-z')e_y\}\\ &=p_0\sqrt{\frac{\pi}{2}}\,e^{(3/4)\pi j}\frac{k^4(l+\rho)^4}{\sqrt{kl\rho}\,[(l+\rho)^2+z^2]^{9/4}}\exp[j(\omega t-k\sqrt{(l+\rho)^2+z^2})]\\ &\quad\times\int_0^{\infty}N\eta(\rho')J_0\left(\frac{l+\rho}{\sqrt{(l+\rho)^2+z^2}}2k\rho'\sin\frac{\theta}{2}\right)\rho'd\rho'\left[e_z-\frac{z}{l+\rho}e_\rho\right].\end{aligned} \tag{6.11}$$

Similarly the contribution from the x component of the incident wave are evaluated. Thus adding these two contributions, we get the total scattered field:

$$\boldsymbol{E}_s(\boldsymbol{r}, t) = p_0\sqrt{\frac{\pi}{2}}e^{(3/4)\pi j}\frac{k^4(l+\rho)^4}{\sqrt{kl\rho}\,[(l+\rho)^2+z^2]^{9/4}}\exp\left[j(\omega t - k\sqrt{(l+\rho)^2+z^2})\right]$$
$$\times\int_0^\infty \eta(\rho')J_0\left(\frac{l+\rho}{\sqrt{(l+\rho)^2+z^2}}2k\rho'\sin\frac{\theta}{2}\right)\rho' d\rho'\left\{\left[N+\frac{z^2}{(l+\rho)^2}(L\cos\theta - jM\sin\theta)\right]\boldsymbol{e}_z\right.$$
$$-\frac{z}{l+\rho}\left[N+\frac{z^2}{(l+\rho)^2}(L\cos\theta - jM\cos\theta)\right]\boldsymbol{e}_\rho$$
$$\left.+\frac{z}{l+\rho}\left(1+\frac{z^2}{(l+\rho)^2}\right)(L\sin\theta + jM\cos\theta)\,\boldsymbol{e}_\theta\right\}. \tag{6.12}$$

6.2. *The dipole source parallel to the y or x-axis*

When the dipole cource has a moment parallel to the y or x-axis, the calculation is similar as that in the previous subsection. In this subsection we give only the result.

When a dipole source

$$\boldsymbol{p}_0(t) = p_0' e^{j\omega t}\boldsymbol{e}_y\,, \tag{6.13}$$

is located at S, the scattered field at P is given by

$$\boldsymbol{E}_s(\boldsymbol{r}, t) = p_0'\sqrt{\frac{\pi}{2}}e^{(3/4)\pi j}\frac{k^4(l+\rho)^2}{\sqrt{kl\rho}\,[(l+\rho)^2+z^2]^{5/4}}\exp\left[j(\omega t - k\sqrt{(l+\rho)^2+z^2})\right]$$
$$\times\int_0^\infty \eta(\rho')J_0\left(\frac{l+\rho}{\sqrt{(l+\rho)^2+z^2}}2k\rho'\sin\frac{\theta}{2}\right)\rho' d\rho'\left\{\left(1+\frac{z^2}{(l+\rho)^2}\right)(L\cos\theta - jM\sin\theta)\boldsymbol{e}_\theta\right.$$
$$\left.+\frac{z^2}{(l+\rho)^2}(L\sin\theta + jM\cos\theta)\boldsymbol{e}_\rho - \frac{z}{l+\rho}(L\sin\theta + jM\cos\theta)\,\boldsymbol{e}_z\right\}. \tag{6.14}$$

When a dipole source is of the following form

$$\boldsymbol{p}_0(t) = p_0'' e^{j\omega t}\boldsymbol{e}_x\,, \tag{6.15}$$

we have

$$\boldsymbol{E}_s(\boldsymbol{r}, t) = p_0''\sqrt{\frac{\pi}{2}}e^{(3/4)\pi j}\frac{k^4(l+\rho)^3 z}{\sqrt{kl\rho}\,[(l+\rho)^2+z^2]^{9/4}}\exp\left[j(\omega t - k\sqrt{(l+\rho)^2+z^2})\right]$$
$$\times\int_0^\infty \eta(\rho')J_0\left(\frac{l+\rho}{\sqrt{(l+\rho)^2+z^2}}2k\rho'\sin\frac{\theta}{2}\right)\rho' d\rho'\left\{\frac{z}{l+\rho}\left[N+\frac{z^2}{(l+\rho)^2}(L\cos\theta - jM\sin\theta)\right]\boldsymbol{e}_\rho\right.$$
$$\left.-\frac{z}{l+\rho}\left(1+\frac{z^2}{(l+\rho)^2}\right)(L\sin\theta + jM\cos\theta)\,\boldsymbol{e}_\theta - \left[N+\frac{z^2}{(l+\rho)^2}(L\cos\theta - jM\sin\theta)\right]\boldsymbol{e}_z\right\}. \tag{6.16}$$

§ 7. Conclusion

So far we have derived the scattered field from a cylindricol plasma in the Born approximation, when an incident wave is radiated from a point source of an oscillating electric field. Generally speaking, our formulas are useful when $k\rho_0$ is not large, and the comparison with experiments should be carried out under the condition that the dominant terms have sufficient accuracy. When $k\rho_0$ is very large, the conventional method[2] of regarding the plasma as a plane slab may be a good approximation. It is hoped anyhow that our formulas would be of help for analysis of experiments of the scattering of microwaves from a cylindrical plasma.

The author wishes to express his sincere thanks to Professor T. Kihara for his continual guidance and his kindness in reading the original manuscript.

Appendix A. Derivation of Equation (3.9)

Here we handle a little more general integral of the following type.

$$
\begin{aligned}
I_{m\ n}&=\int_{-\infty}^{\infty}\frac{1}{R_1{}^m R^n}\exp\left[-jk(R_1+R)\right]dz'\\
&=2\int_0^{\infty}\frac{1}{(z'^2+\xi_1{}^2)^{m/2}(z'^2+\xi^2)^{n/2}}\exp\{-jk[(z'^2+\xi_1{}^2)^{1/2}+(z'^2+\xi^2)^{1/2}]\}dz' \,. \qquad (A.1)
\end{aligned}
$$

Introducing a new variable u by

$$u=k[(z'^2+\xi_1{}^2)^{1/2}+(z'^2+\xi^2)^{1/2}]-(\lambda_1+\lambda)\,, \qquad (A.2)$$

where $\lambda_1\equiv k\xi_1$ and $\lambda\equiv k\xi$, we get

$$
\begin{aligned}
I_{m,n}=2^{m+n}k^{m+n-1}\exp\left[-j(\lambda_1+\lambda)\right]\int_0^{\infty}&\frac{(u+\lambda_1+\lambda)^{m+n-2}[(u+\lambda_1+\lambda)^4-(\lambda_1{}^2-\lambda^2)^2]e^{-ju}}{[(u+\lambda_1+\lambda)^2+\lambda_1{}^2-\lambda^2]^m[(u+\lambda_1+\lambda)^2-\lambda_1{}^2+\lambda^2]^n}\\
\times&\frac{du}{[(u+\lambda_1+\lambda)^4-2(u+\lambda_1+\lambda)^2(\lambda_1{}^2+\lambda^2)+(\lambda_1{}^2-\lambda^2)^2]^{1/2}}\,. \qquad (A.3)
\end{aligned}
$$

We assume that $\lambda_1+\lambda\equiv A$ is very large and introduce g_1, g and x by

$$\lambda_1=g_1A\,, \qquad \lambda=gA \qquad \text{and} \qquad u=Ax\,. \qquad (A.4)$$

Then we have

$$I_{m,n}=\left(\frac{k}{A}\right)^{m+n-1}e^{-jA}\frac{\sqrt{2}}{g_1{}^{m-(1/2)}g^{n-(1/2)}}\int_0^{\infty}s(x)e^{-jAx}dx\,, \qquad (A.5)$$

where $s(x)$ is independent of A and has the following asymptotic properties:

$$
s(x)\longrightarrow\begin{cases}\dfrac{1}{\sqrt{x}}\left\{1+\left(m+n-\dfrac{9}{4}-\left(m-\dfrac{3}{4}\right)\dfrac{1}{g_1}-\left(n-\dfrac{3}{4}\right)\dfrac{1}{g}\right)x+\mathrm{O}(x^2)\right\} & \text{as} \quad x\to 0\,,\\[2ex] 2^{m+n-(1/2)}\,g_1{}^{m-(1/2)}\,g^{n-(1/2)}\dfrac{1}{x^{m+n}}\left(1+\mathrm{O}\left(\dfrac{1}{x}\right)\right) & \text{as} \quad x\to\infty\,.\end{cases} \qquad (A.6)
$$

We divide the integral (A.5) into two parts. The first part is obtained as follows.

$$\int_0^{\infty}\frac{1}{\sqrt{x}}e^{-jAx}dx=\frac{1}{\sqrt{A}}\int_0^{\infty}\frac{e^{-ju}}{\sqrt{u}}du=\sqrt{\frac{\pi}{A}}e^{-(\pi/4)j}\,. \qquad (A.7)$$

The second part is evaluated by the integration by parts:

$$
\begin{aligned}
&\int_0^{\infty}\left[s(x)-\frac{1}{\sqrt{x}}\right]e^{-jAx}dx\\
&=\frac{1}{jA}\int_0^{\infty}\frac{\partial}{\partial x}\left[s(x)-\frac{1}{\sqrt{x}}\right]e^{-jAx}dx\\
&=\frac{1}{2jA}\left(m+n-\frac{9}{4}-\left(m-\frac{3}{4}\right)\frac{1}{g_1}-\left(n-\frac{3}{4}\right)\frac{1}{g}\right)\int_0^{\infty}\frac{e^{-jAx}}{\sqrt{x}}dx\left(1+\mathrm{O}\left(\frac{1}{A}\right)\right)\\
&=\frac{1}{2jA}\sqrt{\frac{\pi}{A}}e^{-(\pi/4)j}\left(m+n-\frac{9}{4}-\left(m-\frac{3}{4}\right)\frac{1}{g_1}-\left(n-\frac{3}{4}\right)\frac{1}{g}\right)\left(1+\mathrm{O}\left(\frac{1}{A}\right)\right)\,. \qquad (A.8)
\end{aligned}
$$

Substituting these into (A.5), we have the desired result,

$$
\begin{aligned}
I_{m,n}=&\frac{\sqrt{2\pi}}{\xi_1{}^{m-1}\xi^{n-1}\sqrt{k\xi_1\xi(\xi_1+\xi)}}\exp\left[-jk(\xi_1+\xi)-\frac{\pi}{4}j\right]\\
&\times\left\{1-\frac{1}{2}j\left[\left(m+n-\frac{9}{4}\right)\frac{1}{k(\xi_1+\xi)}-\left(m-\frac{3}{4}\right)\frac{1}{k\xi_1}-\left(n-\frac{3}{4}\right)\frac{1}{k\xi}\right]+\cdots\right\}\,. \qquad (A.9)
\end{aligned}
$$

Appendix B. Derivation of Equation (6.5)

$$I_{m,n} \equiv \int_{-\infty}^{\infty} \frac{1}{(\xi_1^2+z'^2)^{m/2}(\xi^2+(z-z')^2)^{n/2}} \exp\{-jk[(\xi_1^2+z'^2)^{1/2}+(\xi^2+(z-z')^2)^{1/2}]\} dz' . \tag{B.1}$$

Let us introduce a new variable v by

$$v=(\xi_1^2+z'^2)^{1/2}+(\xi^2+(z'-z)^2)^{1/2} . \tag{B.2}$$

(B.2) is a quadratic equation for z' and can be easily solved.

$$z'=\frac{1}{2(v^2-z^2)}\{z(v^2+\xi_1^2-\xi^2-z^2)\pm v\sqrt{(v^2-\xi_1^2-\xi^2-z^2)^2-4\xi_1^2\xi^2}\} , \tag{B.3}$$

The v takes its minimum value $[(\xi_1+\xi)^2+z^2]^{1/2}$ at $z'=z\xi_1/(\xi_1+\xi)$ and at this point two roots (B.3) for z' coincide each other. Thus we divide the integral (B.1) into two parts

$$I_{m,n}=\int_{z\xi_1/(\xi_1+\xi)}^{\infty} dz' + \int_{-\infty}^{z\xi_1/(\xi_1+\xi)} dz' . \tag{B.4}$$

When we deal with the first term, we take in the expression (B.3) the upper sign, and for the second integral we take the lower sign.

Further we introduce a variable u as in the previous section.

$$u=kv-\sqrt{(\lambda_1+\lambda)^2+\lambda_2^2} , \tag{B.5}$$

where λ_1 and λ were defined in the previous section and $\lambda_2 \equiv kz$. Then the analysis proceeds as before. We get an integral of the form:

$$\int_0^{\infty} s(u)e^{-ju}du . \tag{B.6}$$

If we want the dominant terms, we need only to retain the leading term of the expansion of $s(u)$ for small u. The factor $1/\sqrt{u}$ is provided by dz'/du, and we get the final results,

$$I_{m,n}=\sqrt{2\pi}\, e^{-(\pi/4)j} k^{m+n-1} \frac{(\lambda_1+\lambda)^{m+n-2}\exp[-j\sqrt{(\lambda_1+\lambda)^2+\lambda_2^2}]}{\lambda_1^{m-1}\lambda^{n-1}\sqrt{\lambda_1\lambda}\,[(\lambda_1+\lambda)^2+\lambda_2^2]^{(1/2)(m+n)-3/4}} . \tag{B.7}$$

In the course of the derivation mentioned above, we find that, if there is some extra factor in the integrand, it can be replaced by the leading term of the expansion in u of itself. Thus it is allowed to use the rule of the replacement given by (6.7) used in section 6.

Appendix C. The generality of the Dominant Terms

The formulas for the dominant terms given by expressions (4.3) and (4.4) are valid for more general spherical waves than that radiated by an oscillating electric dipole, provided the fields of the incident waves at the origin are $E_{0z}(0, t)$ and $E_{0y}(0, t)$ respectively. This is shown in the following.

Let us put, for example, an electromagnetic horn at S toward the origin of our coordinate system. The electric field of the incident wave at the origin is assumed to be of z direction. Then the dominant contribution to the scattered field at a point P with $z=0$ comes from the z component of the incident wave, which would be of the following form in the cylindrical plasma.

$$E_{0z}(r, t)=E_{0z}^{(0)}\frac{1}{R_1}\exp[j(\omega t-kR_1)]\tilde{F}\left(\frac{x'}{l}, \frac{y'}{l}, \frac{z'}{l}\right) , \tag{C.1}$$

where $\tilde{F}(x'/l, y'/l, z'/l)$ is a slowly varying function of the arguments and finite for all points in the cylinder and $\tilde{F}(0, 0, 0)=1$. Since the radius of the cylinder ρ_0 is much smaller than

l, we can replace $\tilde{F}(x'/l, y'/l, z'l)$ by $\tilde{F}(0, 0, z'/l) \equiv F(z')$ provided we wish to get the dominant term only. Thus we have

$$E_{0z}(r', t) = E_{0z}^{(0)} \frac{1}{R_1} \exp\left[j(\omega t - kR_1)\right] F(z') , \tag{C.2}$$

and the integral corresponding to (3.9) is

$$\int_{-\infty}^{\infty} \frac{1}{R_1 R^3} F(z') \exp\left[-jk(R_1 + R)\right] dz' . \tag{C.3}$$

When we introduce new variables used in Appendix A, we find that in the extra factor of the integrand such as $F(z')$, we need only the leading term in the power expansion with respect to z'. Thus the asymptotic expression of (C.3) depends only on $F(0)=1$ and not on the details of the angular distributions. The same is true for (4.4) and this proves our statement at the beginning of this appendix.

Temperature Dependences of the Fundamental Absorption Tail of KCl and the Absorption due to Bromines in KCl

By Koichi KOBAYASHI
Institute for Solid State Physics, University of Tokyo, Tokyo
and Tetsuhiko TOMIKI
Department of Physics, Tohoku University, Sendai

(Received March 7, 1961)

Optical absorptions of the fundamental absorption tail of specially purified KCl and those due to bromines in KCl were measured between room temperature and 196°C. The latters were estimated from the differences between the fundamental absorption tails of pure KCl and KCl with bromine of which concentration was 1.3×10^{-4} in mole fractian. Measured absorption coefficients were corrected by considering the errors due to the finite band width of the spectrometer. The fundamental absorption tail of KCl was found to be represented by the Urbach rule with $\sigma = 0.80 \pm 0.02$ and $h\nu_0 = 7.76 \pm 0.10$ ev. The long wavelength side of the bromine absorption was able to be described by the same rule where $\sigma = 0.51 \pm 0.03$ and $h\nu_0 = 7.35 \pm 0.15$ ev.

§1. Introduction

The absorption coefficients of some ionic crystals at their fundamental absorption tails have been known to change in an exponential manner as a function of photon energy and of temperature. This is known as the Urbach rule and was first found by Urbach[1] in silver bromide. For alkali halides, Martienssen[2] has made the measurement of the absorption tail on pure KBr, and Haupt[3] on pure KI, and they have found that these tails can be described fairly well by the Urbach rule over a very wide range of temperature and absorption coefficient. The tails of these crystals are believed to be due to exciton absorptions so that their results have given important informations to an exciton picture in alkali halides.

The purpose of this study is of twofold. The following is the first one. No work relating to the Urbach rule has been made on the fundamental absorption tail of KCl, the most typical substance among potassium halides. As has been reported in our previous paper[4)], we have succeeded to prepare pure KCl with clean fundamental absorption tail by an elimination of impurity bromines which are present in fairly large amount in crystals commonly used. Therefore, it would be worthwhile to investigate the fundamental absorption tail of this *pure* KCl.

Secondly, studies on the absorption tails which have been made so far are on pure alkali halides and the observed exciton absorptions are due to halide ions which are surrounded by halide ions of the same kind and alkaline ions. If one replaces the environment around halide ion, of which optical excitation we are interested in, with other halides but the same alkalines and compares its absorption to that of pure one, one might be able to obtain some other informations on excitons in alkali halides through an effect of a local change of a lattice constant and an electronic configuration.

We have found the absorption band due to bromine in KCl at the tail of the fundamental absorption of the host crystal[4)]. The concentration of bromine in this case was as low as 10^{-4} in mole fraction and the bromines were beleived to be distributed randomly throughout the crystal, so that the interaction between bromine ions was considered to be almost negligble. Therefore, if one uses this crystal, one might be able to investigate the exciton absorption due to bromine in an isolated state in KCl lattice. This situation would be almost an ideal one for the present purpose.

In the present study, we have measured absorption coefficients of the long wavelength tail of the fundamental absorptions of *pure* KCl and KCl containing bromine of 1.3×10^{-4} in mole fraction at several different temperatures. The fundamental absorption tail of KCl has been obtained from the measurement on the former crystal. The absorption due to bromine has been estimated from the results of both crystals. It has been found that both the fundamental absorption tail of *pure* KCl and the long wavelength side of the absorption due to bromine in KCl can be described fairly well by the Urbach rule.

§ 2. Measurements and Results

The specially purified KCl crystal used in this study as a *pure* one was KCl-aK-1[4)] which contained bromines of 9×10^{-6} in mole fraction and divalent metallic ion impurities of 1×15^{15} per cc. KCl-bK-1[4)] was the KCl crystal, which we were interested in measuring its bromine absorption, contained bromines of 1.3×10^{-4} in mole fraction and divalent metallic ion impurities of 4×10^{15} per cc. Hydroxyl ions of the concentration of 2×10^{15} per cc[4)] were found in both crystals.

Optical transmissions at the absorption tails of both crystals were measured with a vacuum ultraviolet spectrometer at 26, 56, 100, 147, and 196°C. The temperature was held constant within ±1°C throughout a run. In determining absorption coefficients from transmission measurements, it is necessary to take into account the light losses due to scattering at the surface and in the volume of the crystal, as well as the specular reflection losses at the surface. However, as have been shown in our previous paper[4)], the scatter correction is found to be negligible in these crystals and the absorption coefficient can be estimated fairly well from the observed transmittance and the reflectivity calculated from the refractive index. The refrative indices at room temperature used in this study were those given by Gyulai[5)] and by Hartman *et al*[6)], the latter of which were normalized to the former at 185 mμ.

The values of refractive index of KCl at higher temperatures were not available. Thus the room temperature dispersion curve was shifted to the longer wavelength side by an amount corresponding to the wavelength difference between the positions of the absorption tails at room temperature and higher temperature so as to estimate the high temperature dispersion curves. In order to justify this method, absorption coefficients were estimated from the observed transmittances of crystals with different thicknesses and the assumed dispersion curves at different temperatures. All of them were found to be zero within our experimental error at 240 mμ where no absorption have been found in these crystals[4]. This would indicate that the above procedures are suitable to the estimation of refractive indices at higher temperatures, and the absorption coefficients at 56, 100, 147, and 196°C were calculated by using the assumed curves.

It has been pointed out by Moser and Urbach[7] that an appreciable error might be introduced into a determination of an absoption coefficient, K, as a result of using a finite band width in a measurement of a transmission where an absorption coefficient changes markedly with a wavelength, λ. Their analysis shows that if a band width is finite and an absorption coefficient is represented by $K = K_1 \exp(-b\lambda)$, where K_1 and b are constants, an absorption coefficient calculated from a measured transmittance of a crystal with certain thickness must be different from that of a crystal with other thickness, and only an observed absorption coefficient which satisfy the condition, $Kd=1$, is a *true* absorption coefficient of a crystal with a thickness, d.

Figs. 1 and 2 are examples of the present measurements of the absorption coefficients at the tails of KCl-aK-1 and KCl-bK-1 at 56°C and 147°C. They were calculated from the measured transmittances of the crystals with different thicknesses of which magnitudes are indicated at the upper right hand of the figures. One may readily see that the observed absorption coefficients are always higher for the crystal with smaller d. This is the tendency which can be derived from the analysis by Moser and Urbach[7]. Double circles in both figures are the points where Kd is unity. These points are well represented by straight lines in log K *versus* photon energy plots as indicated as dashed lines.

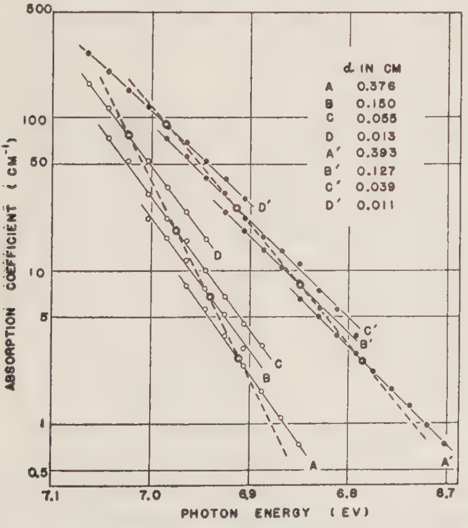

Fig. 1. Absorption spectra at the fundamental absorption tails of *pure* KCl (KCl-aK-1) and KCl containing bromines (KCl-bK-1) at 56°C. The open circles are the absorption coefficients calculated from the observed transmittances of KCl-aK-1 with different thicknesses and the filled ones are those of KCl-bK-1. The dashed lines are those which connect the points where $Kd=1$ (double circles).

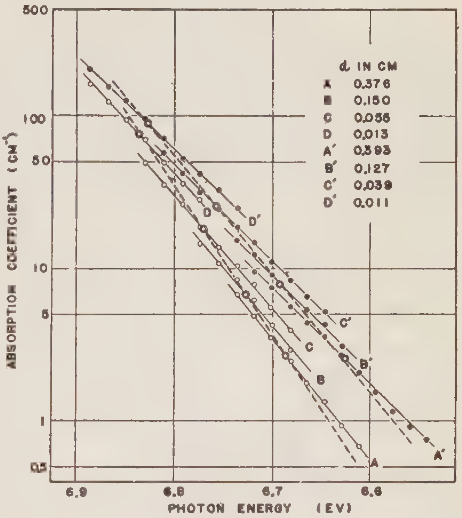

Fig. 2. Absorption spectra at the fundamental absorption tails of *pure* KCl (KCl-aK-1) and KCl containing bromines (KCl-bK-1) at 147°C. The open circles are the absorption coefficients calculated from the observed transmittances of KCl-aK-1 with different thicknesses and the filled ones are those of KCl-bK-1. The dashed lines are those which connect the points where $Kd=1$ (double circles).

This exponential behavior of the absorption coefficient to the photon energy may indicate that the analysis by Moser and Urbach is applicable to the present observed values since the exponential behavior may hold to photon energy as well as to wavelength if the range of wavelength is small. Therefore, the points at $Kd=1$ are the absorption coefficients free from errors due to the finite band width, and the dashed lines may be the *true* absorption tails of both crystals.

Measurements on crystals with different thicknesses at other temperatures have indicated also the same features as described above. Fig. 3 shows the absorption tails of *pure* KCl (KCl-aK-1) at five different temperatures. The open circles are the points which satisfy the condition, $Kd=1$, in observed absorption curves of crystals with different thickcesses. The lines which connect these points are linear in $\log K$ *versus* photon energy diagram and their slopes are decreased as the temperature is increased. Fig. 4 shows the photon energies corresponding to constant absorption coefficient in the curves in Fig. 3 as a function of temperature. The dashed lines are the extrapolations of the lines which connect the points with constant K. They are found to cross one another at zero degree Kelvin.

From Figs. 3 and 4, it might be found that the fundamental absorption tail of KCl can be represented by the Urbach rule,

$$K=K_0 \exp\left[-\frac{\sigma(h\nu_0-h\nu)}{kT}\right], \qquad (1)$$

where K_0 and σ are constants, $h\nu$ the photon energy at K and T, and $h\nu_0$ the extrapolated photon energy at zero degree Kelvin. Taking into account the errors due to the measure-

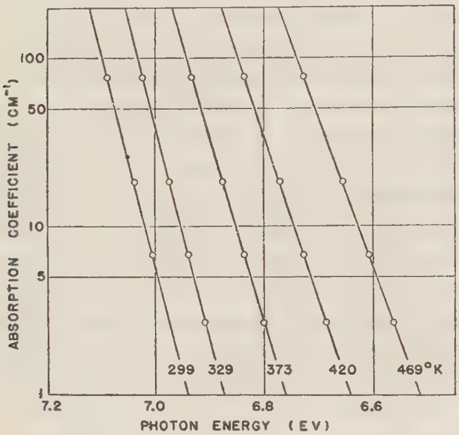

Fig. 3. Fundamental absorption tails of *pure* KCl at seveval different temperatures. The open circles are the points which satisfy the condition, $Kd=1$. in observed absorption curves of crystals with different thicknesses. Temperatures are indicated in this figure in an absolute scale.

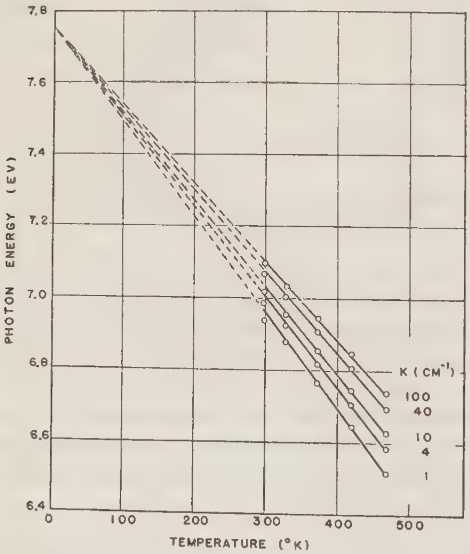

Fig. 4. Photon energies corresponding to a constant absorption coefficient in the curves in Fig. 3 as a function of temperature. They are represented by full lines for constant K of which magnitudes are indicated at the right hand side of this figure. The dashed lines are their linear extrapolations.

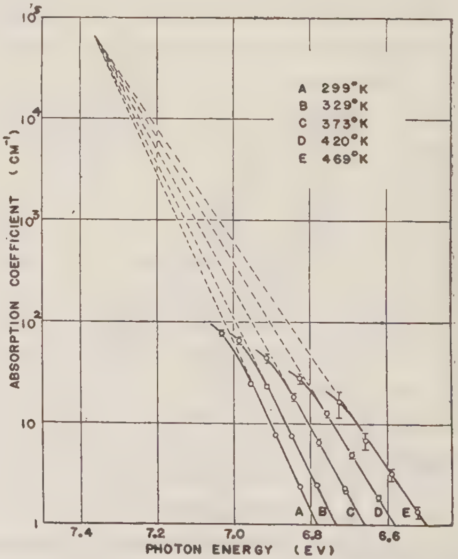

Fig. 5. Absorption Spectra at the long wavelength side of the absorption band due to bromine in KCl at different temperatures which are indicated in this figure in an absolute scale. The full lines are those which connect the observed absorption coefficents and the dashed ones are those extrapolated linearly to high absorption coefficient.

ments, it was found that $h\nu_0$ is 7.76±0.10 ev and σ is 0.80±0.02.

The absorptions due to bromine in KCl-bK-1 were estimated at five different temperatures by subtracting the *true* absorption curves of KCl-aK-1 from those of KCl-bK-1. The results are shown in Fig. 5. One may note that these absorptions are due to bromines with their concentrations of 1.2×10^{-4} in mole fraction since the concentration of bromine in KCl-aK-1 is 9×10^{-6} and in KCl-bK-1 is 1.3×10^{-4}. In the low absorption coefficient region, absorption curves are linear in log K *versus* photon energy plots and their slopes are decreased as the temperature is increased. The dashed lines are their linear extrapolations to high K value where they are found to cross one another at one point. The highest points among the observed ones are found to deviate from the linear relationship since they are the points which are close to the maxima of the absorption bands[4].

Fig. 6 shows the photon energies where K is constant in the absorption curves of bromine for different temperatures. The open circles in this figure are the values obtained from the observed curves and the filled ones are from the linearly extrapolated lines in Fig. 5. The dashed lines in Fig. 6 are the extrapolations of the lines which connect the points with constant K. They are found to cross one another at zero degree Kelvin.

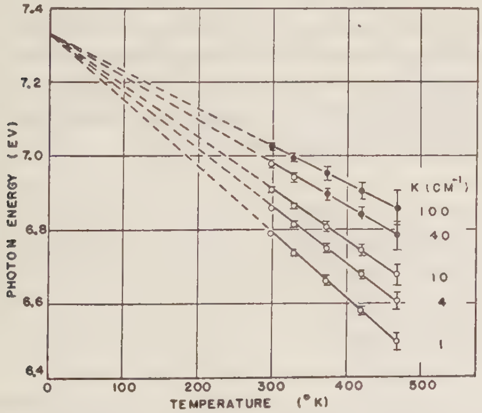

Fig. 6. Photon energies corresponding to a constant absorption coefficient in the absorption curves of bromine in KCl as a function of temperature. The open circles are taken from the observed curves in Fig. 5 and the filled ones are from the linearly extrapolated lines as indicated as dashed lines in Fig. 5. They are represented by full lines for constant K of which magnitudes are indicated at the right hand side of this figure. The dashed lines are their linear extrapolations.

From Figs. 5 and 6, it might be found that the absorption due to bromine in KCl can be described fairly well by the Urbach rule with $h\nu_0=7.35\pm0.15$ ev and $\sigma=0.51\pm0.03$ in equation (1). The absorptions shown in Figs. 5 and 6 are of bromines of 1.2×10^{-4} in mole fraction and thus the magnitude of K_0 was estimated as being in the range between 3×10^9 and 2×10^8 cm^{-1} with such a condition that all chlorine ions in KCl are supposed to be replaced by bromine ions without introducting both the change in lattice constant and the interaction between bromine ions. If the lattice constant of KBr is used in the above estimation, K_0 may be smaller by about ten percent.

§ 3. Discussion

In the present study, σ of the fundamental absorption tail of pure KCl has been obtained as 0.80±0.02. σ of KBr has been given by Martienssen[2] as 0.79 and of KI by Haupt[3] as 0.82. Their magnitudes are almost the same in spite of their different lattice constants and halogens. The fundamental absorption tails of these crystals are believed to be due to exciton excitations of halogens. According to Toyozawa[8], σ may be represented by $C/|E_2|$ where C is an appropriate elastic constant and E_2 a constant to a quadratic term of deformation in the expression of electronic energy change as a function of deformation. Therefore, the differences of the lattice constant and the kind of halogen seem to be rather insensitive to the determination of the magnitude of $C/|E_2|$ of the exciton excitation of pure potassium halides.

It has been known that KCl and KBr make a good solid solution. The concentration of bromine in KCl-bK-1 is as small as 1.3×10^{-4}. Therefore, the bromines may be distributed randomly and the interaction between bromines through the host matrix may be negligible in this crystal. Thus the absorptions due to the presence of bromine in KCl investigated in this study may be due to the isolated bromine ions which simply occupy the chlorine lattice sites.

An exact nature of this absorption due to bromine in KCl is hardly to be known. However, the position of the maximum of this absorption band can be estimated roughly by the assumption that the absorption is due to bromines themselves. The electron affinity of chlorine is 87.1 Kcal and of bromine is 81.2 Kcal⁹⁾, and the maximum of the first absorption peak of the exciton doublet of KCl is at somewhere around 7.52 ev at room temperature¹⁰⁾. Then the bromine absorption in KCl is expected to have its maximum at around 7.26 ev at room temperature which is not far different from 7.12 ev⁴⁾, the observed position of the maximum. The maximum absorption coefficient of the bromine absorption in KCl after being normalized to such a condition that all chlorine ions in KCl are replaced by bromine ions, can be estimated as about $1\times 10^6\,\mathrm{cm}^{-1}$ from the maximum height of the bromine absorption in KCl-bK-1⁴⁾. This magnitude is of a comparable order to the maximum hight of the exciton absorption in KBr²⁾. Therefore, it would be rather unlikely that this absorption is due to optical excitations of twelve chlorines at the second nearest neighbour sites around the bromine, but is very likely to be due to the bromines themselves.

It has been shown that the bromine absorption in KCl can be described by the Urbach rule. However, the magnitude of σ of the bromine absorption in KCl is 0.51 ± 0.03 which is far smaller than 0.79 of bromine in KBr²⁾ and 0.80 ± 0.02 of chlorine in KCl. The small magnitude of σ of the bromine absorption in KCl might be understood by different C and /or different E_2 from those of pure potassium halides as a result of strong distortion around the bromine ions. It may be desirable to study further on the absorption bands of halogens in mixed crystals of other combinations, such as I in KCl and in KBr, to investigate an effect of distortion on an exciton excitation through a magnitude of σ.

On the Commencement of the Hartmann Flow of Conducting Fluid

By Akira OGAWA
Institute of Polytechnics, Osaka City University
Yoshio SONE
Faculty of Engineering, Kyoto University

(Received February 16, 1961)

The effect of the transverse magnetic field on the commencement of the two dimensional Poiseuille flow of conducting fluid between two parallel walls is discussed. Owing to the invariance of the flow characteristics in the direction parallel to the walls, the fundamental equations reduce to linear equations and can be solved exactly. Several limiting cases are surveyed on the basis of the solution obtained. Detailed numerical calculation is also made for a special case in which the values of the Reynolds number, the magnetic Reynolds number and the pressure number are all equal to unity.

§ 1. Introduction

In the present paper we study the commencement of the so-called Hartmann flow of a conducting fluid. Suppose that the fluid is at rest between two infinitely large and parallel flat plates of perfect conductor and that the uniform magnetic field is applied normal to the plate for $t<0$. From the time $t=0$ on, uniform pressure gradient $\partial p/\partial x$ which is constant in later time is applied along the walls. Then, the fluid will begin to move under the influence of the viscous, the inertia and the Lorentz forces. The velocity profile and the magnetic field will approach asymptotically those of Hartmann flow.

For this flow, it can be expected that the fluid velocity as well as the magnetic field do not change in the direction parallel to the plates. The fundamental equations governing the fields then reduce to linear equations which can be solved by the method of Fourier expansion.

On examination of the solution it turns out that the flow and magnetic field converge with time to those in Hartmann flow monotonically or in damped vibration in general. The latter case (vibration) could not be found in ordinary viscous flow. When the conductivity of the fluid is infinite, there can be no steady flow but an ultimate state of equilibrium or of undamped oscillation according as the viscosity is finite or zero.

§ 2. Fundamental Equations

The fundamental equations of magneto-hydrodynamics (in rationalized M. K. S. units) are:

$$\mathrm{div}\,\hat{B}=0 \tag{1}$$

$$\mathrm{rot}\,\hat{H}=\hat{j} \tag{2}$$

$$\mathrm{rot}\,\hat{E}=-\frac{\partial\hat{B}}{\partial\hat{t}} \tag{3}$$

$$\hat{j}=\sigma(\hat{E}+\hat{v}\times\hat{B}) \tag{4}$$

$$\frac{D}{D\hat{t}}\hat{v}=-\frac{1}{\rho}\,\mathrm{grad}\,\hat{p}+\nu\Delta\hat{v}+\frac{1}{\rho}(\hat{j}\times\hat{B}) \tag{5}$$

$$\mathrm{div}\,\hat{v}=0 \tag{6}$$

where $\hat{E}$ is the electric field, $\hat{H}$ the magnetic field, $\hat{B}$ the magnetic induction, $\hat{j}$ the current density, σ the electrical conductivity, $\hat{v}$ the fluid velocity, $\hat{p}$ the pressure, ρ the density, ν the kinematic viscosity and $\hat{t}$ the time. The fluid is assumed to be homogeneous and isotropic so that $\hat{B}=\mu\hat{H}$ where μ is the mag-

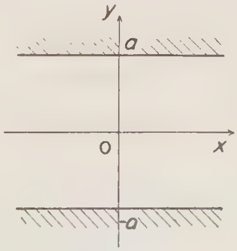

Fig. 1. Coordinate system.

netic permeability.

We choose the Cartesian coordinate system $(\hat{x}, \hat{y}, \hat{z})$ in such a way that the walls are normal to the $\hat{y}$-axis and situated at $\hat{y}=\pm a$ and that the pressure gradient is in the direction of $\hat{x}$-axis (Fig. 1).

It may by assumed in the present problem that

$$\hat{\boldsymbol{v}}=(\hat{u}, 0, 0)\,, \qquad \hat{\boldsymbol{B}}=(\hat{B}_x, \hat{B}_y, 0) \qquad (7)^*$$

and that $\hat{u}$, $\hat{B}_x$ and $\hat{B}_y$ are all independent of $\hat{x}$. Then $\hat{\boldsymbol{v}}$ satisfies the equation (6) evidently. With the assumption (7) the equation (1) to (5) are simplified as follows: From (1)

$$\frac{\partial \hat{B}_y}{\partial \hat{y}}=0$$

that is, $\hat{B}_y$ is a function of $\hat{t}$ only. Then, if we eliminate $\hat{\boldsymbol{j}}$ and $\hat{\boldsymbol{E}}$ from (2), (3) and (4), we obtain

$$\frac{1}{\mu\sigma}\frac{\partial^2 \hat{B}_x}{\partial \hat{y}^2}+\hat{B}_y\frac{\partial \hat{u}}{\partial \hat{y}}=\frac{\partial \hat{B}_x}{\partial \hat{t}} \qquad (8)$$

and

$$0=\frac{d\hat{B}_y}{d\hat{t}} \quad \text{or} \quad \hat{B}_y=\text{const.}=B_0 \qquad (9)$$

Later, B_0 will be equated to the applied magnetic induction. Using (9), Eq. (8) becomes:

$$\frac{1}{\mu\sigma}\frac{\partial^2 \hat{B}_x}{\partial \hat{y}^2}+B_0\frac{\partial \hat{u}}{\partial \hat{y}}=\frac{\partial \hat{B}_x}{\partial \hat{t}} \qquad (8')$$

Further, elimination of $\hat{\boldsymbol{j}}$ from (2) and (5) yields

$$\frac{\partial \hat{u}}{\partial \hat{t}}=-\frac{1}{\rho}\frac{\partial \hat{p}}{\partial \hat{x}}+\nu\frac{\partial^2 \hat{u}}{\partial \hat{y}^2}+\frac{B_0}{\rho\mu}\frac{\partial \hat{B}_x}{\partial \hat{y}} \qquad (10)$$

$$0=\frac{1}{\rho}\frac{\partial \hat{p}}{\partial \hat{y}}+\frac{\hat{B}_x}{\rho\mu}\frac{\partial \hat{B}_x}{\partial \hat{y}} \qquad (11)$$

Here $\partial\hat{p}/\partial\hat{x}$ is applied pressure gradient which is assumed to be constant and will be denoted by $-A$.

Boundary and initial conditions are as follows:

$$\left.\begin{array}{ll} \text{on } \hat{y}=a, & \hat{u}=0 \quad \text{(no slip condition)} \\ & \dfrac{\partial \hat{B}_x}{\partial \hat{y}}=0 \quad \left(\begin{array}{l}\text{walls are assumed to}\\ \text{be perfect conductor}\end{array}\right) \\ \text{on } \hat{y}=0, & \dfrac{\partial \hat{u}}{\partial \hat{y}}=0 \quad \text{(symmetry)} \\ & \hat{B}_x=0 \quad \text{(symmetry)} \end{array}\right\} \qquad (12)$$

$$\text{at} \quad \hat{t}=0, \quad \hat{u}=0, \quad \hat{B}_x=0, \quad \hat{B}_y=B_0 \qquad (13)$$

Hereafter we use for the sake of convenience the non-dimensional quantities

$$u=\hat{u}/\sqrt{Aa/\rho}\,, \quad B_x=\hat{B}_x/B_0\,, \quad y=\hat{y}/a\,,$$
$$p=\hat{p}/Aa \quad \text{and} \quad t=\hat{t}/\sqrt{\rho a/A}\,.$$

With these transformations the fundamental equations become

$$\frac{\partial B_x}{\partial t}=\frac{1}{R_m}\frac{\partial^2 B_x}{\partial y^2}+\frac{\partial u}{\partial y} \qquad (8'')$$

$$\frac{\partial u}{\partial t}=1+\frac{1}{R}\frac{\partial^2 u}{\partial y^2}+s^2\frac{\partial B_x}{\partial y} \qquad (10')$$

$$0=\frac{\partial p}{\partial y}+s^2 B_x\frac{\partial B_x}{\partial y} \qquad (11')$$

where $R=\sqrt{Aa/\rho}\cdot(a/\nu)$ is the Reynolds number, $R_m=\sigma\mu a\sqrt{Aa/\rho}$ the magnetic Reynolds number and $s^2=B_0{}^2/\mu Aa$ the pressure number. Also the boundary and initial conditions are written as

$$\left.\begin{array}{lll} \text{on} & y=1\,, & u=0 \\ & & \dfrac{\partial B_x}{\partial y}=0 \\ \text{on} & y=0\,, & \dfrac{\partial u}{\partial y}=0 \\ & & B_x=0 \end{array}\right\} \qquad (12')$$

$$\text{at} \quad t=0\,, \quad u=0\,, \quad B_x=0 \qquad (13')$$

§ 3. Solution

We seek the solution by dividing it into steady and unsteady parts, that is

$$\left.\begin{array}{l} B_x=B^0(y)+B(y, t) \\ u\;\;=u^0(y)+U(y, t) \end{array}\right\} \qquad (14)$$

where B^0, u^0 are the steady parts and B, U the unsteady parts. Each satisfies the following equations and boundary conditions:

$$\left.\begin{array}{l} 0=\dfrac{1}{R_m}\dfrac{d^2B^0}{dy^2}+\dfrac{du^0}{dy} \\ 0=1+\dfrac{1}{R}\dfrac{d^2u^0}{dy^2}+s^2\dfrac{dB^0}{dy} \end{array}\right\} \qquad (15)$$

$$\left.\begin{array}{lll} y=1; & u^0=0\,, & \dfrac{dB^0}{dy}=0 \\ y=0; & \dfrac{du^0}{dy}=0\,, & B^0=0 \end{array}\right\} \qquad (16)$$

$$\left.\begin{array}{l} \dfrac{\partial B}{\partial t}=\dfrac{1}{R_m}\dfrac{\partial^2 B}{\partial y^2}+\dfrac{\partial U}{\partial y} \\ \dfrac{\partial U}{\partial t}=\dfrac{1}{R}\dfrac{\partial^2 U}{\partial y^2}+s^2\dfrac{\partial B}{\partial y} \end{array}\right\} \qquad (17)$$

---

* The quantities in the parentheses represent the $\hat{x}$, $\hat{y}$, $\hat{z}$ components respectively.

$$\left.\begin{aligned} y=1;\quad & U=0\,,\quad \frac{\partial B}{\partial y}=0 \\ y=0;\quad & \frac{\partial U}{\partial y}=0\,,\quad B=0 \end{aligned}\right\} \tag{18}$$

$$t=0;\quad U=-u^0\,,\quad B=-B^0 \tag{19}$$

Steady solution.

Eq. (15) for the steady motion may be integrated once by using (16), i. e.

$$\left.\begin{aligned} 0&=\frac{1}{R_m}\frac{dB^0}{dy}+u^0 \\ 0&=y+\frac{1}{R}\frac{du^0}{dy}+s^2B^0 \end{aligned}\right\} \tag{15′}$$

The solution of these equations can be found in closed forms*. For later convenience, however, we shall obtain here the solution in a form of Fourier series. That is, we assume

$$\left.\begin{aligned} u^0&=\sum_{n=1}^{\infty} M_n\cos\alpha_n y \\ B^0&=\sum_{n=1}^{\infty} N_n\sin\alpha_n y \end{aligned}\right\} \tag{20}$$

$$\alpha_n=(2n-1)\pi/2$$

On substitution of (20) into (15′), we obtain M_n and N_n in the forms:

$$\left.\begin{aligned} M_n&=\frac{(-1)^{n-1}\times 2R}{\alpha_n(\alpha_n^2+H^2)} \\ N_n&=\frac{(-1)^n\times 2RR_m}{\alpha_n^2(\alpha_n^2+H^2)} \end{aligned}\right\} \tag{21}$$

where $H=(RR_ms^2)^{1/2}$ is the Hartmann number.

Unsteady solution.

For solving Eq. (17) we assume the following expansions:

$$\left.\begin{aligned} U&=\sum_{n=1}^{\infty} f_n(t)\cos\alpha_n y \\ B&=\sum_{n=1}^{\infty} g_n(t)\sin\alpha_n y \end{aligned}\right\} \tag{22}$$

Substitution of (22) into (17) yields the equations for $f_n(t)$ and $g_n(t)$:

$$\left.\begin{aligned} \alpha_nf_n+\left(g_n'+\frac{\alpha_n}{R_m}g_n\right)&=0 \\ \left(f_n'+\frac{\alpha_n^2}{R}f_n\right)-s^2\alpha_ng_n&=0 \end{aligned}\right\} \tag{23}$$

where the prime denotes differentiation with respect to t. Also, from (19) and (20) the initial conditions for $f_n(t)$, $g_n(t)$ are found to be

$$\left.\begin{aligned} f_n(0)&=-M_n \\ g_n(0)&=-N_n \end{aligned}\right\}\ (n=1,2,\cdots) \tag{24}$$

The general solutions of (23) may be given by

$$\left.\begin{aligned} f_n&=F_n^{(1)}\exp(\lambda_n^{(1)}t)+F_n^{(2)}\exp(\lambda_n^{(2)}t) \\ g_n&=G_n^{(1)}\exp(\lambda_n^{(1)}t)+G_n^{(2)}\exp(\lambda_n^{(2)}t) \end{aligned}\right\} \tag{25}$$

$$(\lambda_n^{(1)}\neq\lambda_n^{(2)})$$

where

$$\begin{aligned} \lambda_n^{(1),(2)}&=\frac{\alpha_n^2}{2}\left\{-\left(\frac{1}{R}+\frac{1}{R_m}\right)\pm\sqrt{\left(\frac{1}{R}-\frac{1}{R_m}\right)^2-\frac{4s^2}{\alpha_n^2}}\right\} \\ &=\frac{\alpha_n^2}{2RR_m}\left\{-(R+R_m)\pm\sqrt{(R_m-R)^2-\frac{4H^2}{\alpha_n^2}}\right\} \end{aligned}$$

$$G_n^{(1),(2)}=\kappa_n^{(1),(2)}F_n^{(1),(2)}$$

$$\kappa_n^{(1),(2)}=\frac{RR_m(\lambda_n^{(1),(2)}+(\alpha_n^2/R))}{H^2\alpha_n}$$

Two arbitrary constants $F_n^{(1)}$ and $F_n^{(2)}$ can be determined by the initial conditions (24), that is

$$\left.\begin{aligned} F_n^{(1)}&=\frac{N_n-\kappa_n^{(2)}M_n}{\kappa_n^{(2)}-\kappa_n^{(1)}} \\ F_n^{(2)}&=\frac{\kappa_n^{(1)}M_n-N_n}{\kappa_n^{(2)}-\kappa_n^{(1)}} \end{aligned}\right\} \tag{26}$$

If $\lambda_n^{(1)}$ is a complex root, $F_n^{(1)}$ and $F_n^{(2)}$ are complex conjugate of each other, and then putting $\lambda_n^{(1)}=-\beta_n+i\gamma_n$, $F_n^{(1)}=\sigma_n+i\omega_n$, we may obtain the expression for f_n, g_n in real variables β_n, γ_n, σ_n, ω_n. That is

$$f_n=2\exp(-\beta_nt)\{\sigma_n\cos\gamma_nt-\omega_n\sin\gamma_nt\} \tag{27}$$

and similar expression for g_n may be easily obtained by only replacing σ_n and ω_n by the real and imaginary parts of $G_n^{(1)}$ respectively.

If $\lambda_n^{(1)}=\lambda_n^{(2)}\equiv\lambda_n$, above expressions for f_n, g_n become invalid. For this case, the solutions may be written as

$$\left.\begin{aligned} f_n&=(F_n^{(1)}t+F_n^{(2)})\exp(\lambda_nt) \\ g_n&=(G_n^{(1)}t+G_n^{(2)})\exp(\lambda_nt) \end{aligned}\right\} \tag{28}$$

where

$$F_n^{(1)}=\frac{\alpha_n^2}{2}\left(\frac{1}{R_m}-\frac{1}{R}\right)F_n^{(2)}+s^2\alpha_nG_n^{(2)}$$

$$G_n^{(1)}=-\alpha_nF_n^{(2)}+\frac{\alpha_n^2}{2}\left(\frac{1}{R}-\frac{1}{R_m}\right)G_n^{(2)}$$

$$s^2=\frac{\alpha_n^2}{4}\left(\frac{1}{R}-\frac{1}{R_m}\right)^2$$

---

* $u^0=\dfrac{R}{H^2}\left(1-\dfrac{\cosh Hy}{\cosh H}\right)$,

$B^0=-\dfrac{RR_m}{H^2}\left(y-\dfrac{\sinh Hy}{H\cosh H}\right)$.

Two arbitrary constants $F_n^{(2)}$, $G_n^{(2)}$ are determined by the initial conditions (24) as follows:

$$\left.\begin{aligned} F_n^{(2)} &= -M_n \\ G_n^{(2)} &= -N_n \end{aligned}\right\} \tag{29}$$

§ 4. Special Cases

We shall here examine some limiting cases of the preceding solution as for the parameters R, R_m and s^2.

i) $R \to \infty$

In the limit $t \to \infty$, fluid velocity becomes constant and uniform.

ii) $R_m \to \infty$

All the fluid motion dies out for $t \to \infty$ and a new equilibrium condition is attained monotonically or in damped oscillation according to the value of λ_n.

iii) $R_m \to \infty$ and $R \to \infty$

For this case we may find an analogy with vibrating string under uniform gravity. That is, the displacement of the fluid particles or of the line of magnetic induction corresponds to that of the string, A/ρ to gravitational acceleration g and $B_0^2/\rho\mu$ to the tension of the string divided by the linear density.

iv) $R_m \to 0$

This is the case of purely viscous flow. The flow approaches the so-called plane Poiseuille flow monotonically.

v) $R_m \to 0$ and $s^2 R_m$=finite

Applied magnetic field does not change and remains uniform, but the flow is affected by the magnetic field and approaches a modified Poiseuille flow monotonically.

§ 5. Numerical Calculations

Numerical calculations of the velocity distribution and of the displacement of line of magnetic induction have been carried out for the case $R = R_m = s^2 = 1$. The results are given in Fig. 2.

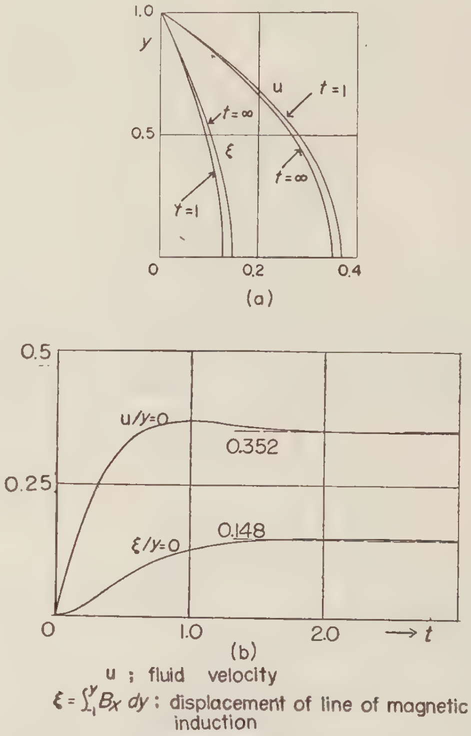

Fig. 2. Fluid velocity and displacement of line of magnetic induction.

The Hall Effect in the Viscous Flow of Ionized Gas between Parallel Plates under Transverse Magnetic Field

By Hiroshi SATO

Aeronautical Research Institute, University of Tokyo, Tokyo

(Received March 2, 1961)

The electrical conductivity of an ionized gas is anisotropic in the presence of magnetic field (Hall effect). The conductivity is expressed by a tensor in the same form for both fully and partially ionized gases. By the use of modified Ohm's law and conventional magnetohydrodynamical equations the incompressible viscous flow between parallel plates under the transverse magnetic field is analyzed and an exact solution is obtained when the magnetic Reynolds number is small. The numerical results reveal a remarkable effect of anisotropy of conductivity. The acceleration and deceleration of viscous ionized gas under combined electric and magnetic fields are also calculated.

§ 1. Introduction

The effect of transverse magnetic field on the flow of electrically-conducting fluid in a two-dimensional channel has been treated theoretically by Hartmann[1]. He has obtained an exact solution of magnetohydrodynamical equations of viscous incompressible fluid. The theoretical results showed a fair agreement with experimental results obtained by Hartmann and Lazarus[2]. It is obvious that nothing is to be added to Hartmann's result as far as the fluid remains ohmic and of isotropic conductivity. These two conditions hold for the liquid metal, but they do not hold for an ionized gas in many cases. The mechanism of conduction in ionized gases is different from that in metallic substances. The electric current in ionized gas is usually carried by electrons which undergo successive collisions with other charged or neutral particles. Exactly speaking, the ionized gas is not an ohmic conductor. The current is not proportional to the applied potential except when the electric field is very weak. The conventional magnetohydrodynamical treatment is no more valid under the strong electric field. In the second place, the conductivity of ionized gas is affected by the magnetic field. Due to the gyration and drift of charged particles the conductivity parallel to the electric field is reduced and the current is induced in the direction normal to both electric and magnetic fields. This phenomenon has been known as the "Hall effect". The effect can be taken into account within the range of magnetohydrodynamical approximation. An example of Hall effect was shown by Tani in the viscous flow in a square channel[3]. In the following treatment the proportionality of current and applied electric field is assumed and the conductivity is expressed by a tensor instead of a scalar. A conventional magnetohydrodynamical calculation is carried out for the viscous incompressible flow between two parallel plates under the transverse electric and magnetic fields.

The author expresses his thanks to Professor Itiro Tani for may valuable suggestions. Acknowledgement is extended to Mrs. M. Nakai who has carried out the numerical calculations.

§ 2. Considerations on the Anisotropy of Conductivity

Equations of motion and current for the steady flow of neutral fully-ionized gas are under proper assumptions expressed as[4)]

$$\boldsymbol{j}\times\boldsymbol{B}-\nabla p+\rho\nu\Delta\boldsymbol{v}=0 \qquad (1)$$

$$\boldsymbol{E}+\boldsymbol{v}\times\boldsymbol{B}+\boldsymbol{E}_e-\frac{c}{en}\boldsymbol{j}\times\boldsymbol{B}-\frac{\boldsymbol{j}}{\sigma_0}=0 \qquad (2)$$

in which vectors, $\boldsymbol{j}$, $\boldsymbol{B}$ and $\boldsymbol{E}$ are the current density, the magnetic flux density and the electric field, respectively. Also p is the pressure, ρ the density, ν the kinematic viscosity, $-e/c$ the electron charge in e. m. u. and n is the number density of ions which is equal to that of electrons. $\boldsymbol{E}_e$ denotes the equivalent electric field due to the gradient of electron pressure p_e, namely, $\boldsymbol{E}_e=(c/en)\nabla p_e$.

The conductivity σ_0 is defined as a coefficient of proportionality between the current density and the collision term in the equation of motion of charged particles as is shown in reference 4. From equation (2) the current density is expressed as

$$\left.\begin{aligned} \boldsymbol{j}_\perp &= \sigma_1(\boldsymbol{E}+\boldsymbol{v}\times\boldsymbol{B}+\boldsymbol{E}_e)_\perp \\ &\quad -\sigma_2(\boldsymbol{E}+\boldsymbol{v}\times\boldsymbol{B}+\boldsymbol{E}_e)_\perp\times\frac{\boldsymbol{B}}{B} \\ \boldsymbol{j}_{/\!/} &= \sigma_0(\boldsymbol{E}+\boldsymbol{E}_e)_{/\!/} \end{aligned}\right\} \tag{3}$$

in which B is the magnitude of $\boldsymbol{B}$, subscripts $\perp$ and $/\!/$ denote component vectors normal and parallel to $\boldsymbol{B}$, respectively and

$$\sigma_1=\frac{\sigma_0}{1+\sigma_0^2(cB/en)^2}, \qquad \sigma_2=\frac{\sigma_0^2(cB/en)}{1+\sigma_0^2(cB/en)^2}$$

The conductivity σ_0 is defined in the absence of magnetic field and σ_1 and σ_2 are the modified conductivities parallel and normal to the direction of electric field, respectively, when the magnetic field is present. Using the mean collision time between ion and electron τ, the conductivity is expressed as

$$\sigma_0=\frac{ne^2\tau}{c^2m_e}$$

where m_e is the mass of electron. Substituting this in the expressions for σ_1 and σ_2, and using the gyration frequency of electron ω_e $(=eB/cm_e)$, we obtain

$$\sigma_1=\frac{\sigma_0}{1+\omega_e^2\tau^2}$$

$$\sigma_2=\frac{\sigma_0\omega_e\tau}{1+\omega_e^2\tau^2}$$

In the case of partially-ionized gas a similar simplified treatment gives the equation of current as[5]

$$\boldsymbol{E}+\boldsymbol{v}\times\boldsymbol{B}+\boldsymbol{E}_e-\frac{c}{en}\boldsymbol{j}\times\boldsymbol{B}$$

$$-B\left(\kappa+\kappa_e+\frac{f^2}{\kappa_i}\right)\boldsymbol{j}-\frac{f^2}{B\kappa_i}\boldsymbol{E}_e\times\boldsymbol{B}=0 \tag{4}$$

in which f is the ratio of number density of neutral particles to the total number density, and

$$\kappa_i=\frac{1}{2\omega_i\tau_i}, \qquad \kappa_e=\frac{1}{\omega_e\tau_e}, \qquad \kappa=\frac{1}{\omega_e\tau}$$

ω_i is the gyration frequency of ions and τ_e, τ_i and τ are the mean collision time between electron and neutral particle, ion and neutral particle and electron and ion, respectively.

The above equation is reduced to

$$\begin{aligned} \boldsymbol{j}_\perp &= \frac{1}{B^2\{1+(\kappa+\kappa_e+f^2/\kappa_i)^2\}}\frac{en}{c} \\ &\quad \times\left[\left(\kappa+\kappa_e+\frac{f^2}{\kappa_i}\right)(\boldsymbol{E}+\boldsymbol{v}\times\boldsymbol{B}+\boldsymbol{E}_e)_\perp B\right. \\ &\quad -(\boldsymbol{E}+\boldsymbol{v}\times\boldsymbol{B}+\boldsymbol{E}_e)_\perp\times\boldsymbol{B} \\ &\quad \left.-\frac{f^2}{\kappa_i}\left\{(\boldsymbol{E}_{e\perp}\times\boldsymbol{B})\left(\kappa+\kappa_e+\frac{f^2}{\kappa_i}\right)+B\boldsymbol{E}_{e\perp}\right\}\right] \end{aligned} \tag{5}$$

In the absence of magnetic field this becomes

$$\boldsymbol{j}_\perp=\frac{e^2n}{c^2m_e}\cdot\frac{1}{1/\tau+1/\tau_e}(\boldsymbol{E}+\boldsymbol{E}_e)_\perp$$

The conductivity σ_0 might be defined as

$$\sigma_0=\frac{e^2n}{c^2m_e}\Big/(1/\tau+1/\tau_e)$$

The magnitude of $f^2/\kappa_i=2f^2\omega_i\tau_i$ is estimated as follows. For the partially-ionized gas f^2 is of the order of unity. Since the gyration frequency of ions ω_i is equal to $\omega_e m_e/m_i$, $\omega_i\tau_i$ is very small compared with unity unless the magnetic field is extremely strong and the gas is very tenuous. Therefore, f^2/κ_i is in many cases very small in comparison with unity. Then, by neglecting small quantities the equation (5) is simplified as

$$\begin{aligned} \boldsymbol{j}_\perp &= \sigma_1(\boldsymbol{E}+\boldsymbol{v}\times\boldsymbol{B}+\boldsymbol{E}_e)_\perp \\ &\quad -\sigma_2(\boldsymbol{E}+\boldsymbol{v}\times\boldsymbol{B}+\boldsymbol{E}_e)_\perp\times\frac{\boldsymbol{B}}{B} \end{aligned} \tag{6}$$

in which

$$\sigma_1=\frac{\sigma_0}{1+\omega_e^2\{1/(1/\tau+1/\tau_e)\}^2}$$

$$\sigma_2=\frac{\sigma_0\omega_e\{1/(1/\tau+1/\tau_e)\}}{1+\omega_e^2\{1/(1/\tau+1/\tau_e)\}^2}$$

The above expression for $\boldsymbol{j}$ agrees with that of fully ionized gas when τ_e approaches infinity. The generalized forms for σ_1 and σ_2 are

$$\left.\begin{aligned} \sigma_1 &= \frac{\sigma_0}{1+\alpha^2} \\ \sigma_2 &= \frac{\sigma_0\alpha}{1+\alpha^2} \end{aligned}\right\} \tag{7}$$

When the tensor notation is used for the conductivity as $\boldsymbol{\sigma}=(\sigma_{ij})$, the current density is expressed by

$$\boldsymbol{j}=\boldsymbol{\sigma}(\boldsymbol{E}+\boldsymbol{v}+\boldsymbol{B}+\boldsymbol{E}_e)$$

Taking the direction of magnetic field as the y-axis the conductivity tensor becomes

$$\boldsymbol{\sigma}=\begin{pmatrix} \sigma_1 & 0 & \sigma_2 \\ 0 & \sigma_0 & 0 \\ -\sigma_2 & 0 & \sigma_1 \end{pmatrix} \tag{8}$$

§ 3. Fundamental Equations for the Flow between Parallel Plates

The viscous flow of ionized gas between two parallel plates is considered. Fig. 1 shows the co-ordinate system. The x-axis is taken in the direction of hydrodynamic pressure gradient in the plane parallel to the channel walls—not in the direction of flow. A parallel, uniform magnetic field B_0 is applied in the y-direction. The height of channel is denoted by $2h$ and the width is assumed to be very large compared with $2h$.

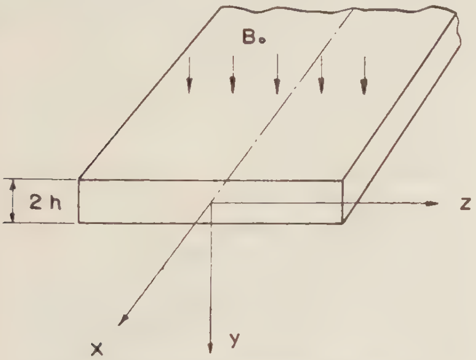

Fig. 1. The co-ordinate system.

Following assumptions are made.

1. The density of gas is everywhere constant.
2. The ionization is in equilibrium which is not affected by the applied electric and magnetic fields.
3. The effect of space charge is neglected.
4. The flow is fully developed and stationary, that is $\partial/\partial x=0$, $\partial/\partial t=0$ except $\partial p/\partial x \neq 0$
5. The magnetic Reynolds number R_m is small, namely, the induced magnetic field is small compared with the applied field. Therefore, components in the conductivity tensor are expressed in terms of B_0.
6. The flow is "two-dimensional", namely, $\partial/\partial z=0$.

The fundamental equations to be solved are equations (1) and (2) together with continuity relations

$$\operatorname{div} \boldsymbol{v}=0\,, \qquad \operatorname{div} \boldsymbol{j}=0$$

Boundary conditions are $\boldsymbol{v}=0$ at $y=\pm h$.

The fundamental equations are simplified by above-mentioned assumptions and boundary conditions as

$$-\frac{\partial p}{\partial x}\left[1-s\left(1-\frac{\sigma_1}{\sigma_0}\right)\right]+\rho\nu\frac{d^2u}{dy^2}$$
$$+B_0[-\sigma_1(E_z+uB_0)+\sigma_2(E_x-wB_0)]=0$$

$$s\frac{\partial p}{\partial x}\frac{\sigma_2}{\sigma_0}+\rho\nu\frac{d^2w}{dy^2}$$
$$+B_0[\sigma_1(E_x-wB_0)+\sigma_2(E_z+uB_0)]=0$$

in which $s=p_e/p$ is the ratio of the electron pressure to the total pressure. The value of s is 1/2 for neutral fully-ionized plasma and approximately zero for weakly-ionized gas. u, w and E_x, E_z are x- and z-components of velocity and electric field, respectively. The conductivity is expressed by the equation (8).

In order to make above two equations non-dimensional, the characteristic length h and velocity $u_p=-(\partial p/\partial x)(h^2/\nu\rho)$ are introduced. For the simple Poiseuille flow, the mean velocity over the cross-section is 1/3 in u_p unit. Using the same notations u, w for u/u_p and w/u_p and y for y/h, we obtain non-dimensional equations:

$$k_1+\frac{d^2u}{dy^2}-\frac{\sigma_1}{\sigma_0}H_a{}^2(m_z+u)+\frac{\sigma_2}{\sigma_0}H_a{}^2(m_x-w)=0 \tag{9}$$

$$k_2+\frac{d^2w}{dy^2}+\frac{\sigma_1}{\sigma_0}H_a{}^2(m_x-w)+\frac{\sigma_2}{\sigma_0}H_a{}^2(m_z+u)=0 \tag{10}$$

in which

$$k_1=1-s\left(1-\frac{\sigma_1}{\sigma_0}\right), \qquad k_2=-s\frac{\sigma_2}{\sigma_0}$$
$$m_x=\frac{E_x}{B_0u_p}, \qquad m_z=\frac{E_z}{B_0u_p}$$

and the Hartmann number H_a is defined as

$$H_a{}^2=B_0{}^2h^2\sigma_0/\nu\rho$$

When w is eliminated from equations (9) and (10), a fourth order linear differential equation is obtained for u. Considering boundary conditions, the solution is in a form

$$u=A_1\cosh py\cos qy+A_2\sinh py\sin qy+C_1$$

in which

$$p=\frac{H_a}{\sqrt{2}}\left(\frac{\sqrt{\sigma_1{}^2+\sigma_2{}^2}+\sigma_1}{\sigma_0}\right)^{1/2}$$
$$q=\frac{H_a}{\sqrt{2}}\left(\frac{\sqrt{\sigma_1{}^2+\sigma_2{}^2}-\sigma_1}{\sigma_0}\right)^{1/2}$$
$$C_1=-m_z+\frac{\sigma_0(k_1\sigma_1-k_2\sigma_2)}{H_a{}^2(\sigma_1{}^2+\sigma_2{}^2)}$$

The solution for w is

$$w=A_2\cosh py\cos qy-A_1\sinh py\sin qy+C_2$$

with

$$C_2=m_x+\frac{\sigma_0(k_1\sigma_2+k_2\sigma_1)}{H_a{}^2(\sigma_1{}^2+\sigma_2{}^2)}$$

Coefficients A_1 and A_2 are determined from boundary conditions as

$$A_1=\frac{-C_1\cosh p\cos q+C_2\sinh p\sin q}{\sinh^2 p+\cos^2 q}$$

$$A_2=\frac{-C_1\sinh p\sin q+C_2\cosh p\cos q}{\sinh^2 p+\cos^2 q}$$

The non-dimensional electric field m_x and m_z are to be determined by boundary conditions at large x and z.

The mean velocity over the cross-section is given by

$$\bar{u}=\int_0^1 u dy\,, \qquad \bar{w}=\int_0^1 w dy$$

In the solution obtained above w has non-zero values varying in the y-direction. Therefore, side walls at large z must have a shape which is adapted to the flow direction there. This is not a realistic configuration. The present solution is considered to be useful at the central part of a very wide channel and for the flow between two concentric cylinders which have a very large radius compared with the gap of both cylinders.

Another solution is obtained under the condition, $w=0$ instead of $\partial/\partial z=0$. If $\partial^2 u/\partial z^2$ is neglected compared with $\partial^2 u/\partial y^2$, the solution for u is the same as that obtained by Hartmann except the reduction of Hartmann number due to the reduction of conductivity by the magnetic field. The hydrodynamic pressure gradient $\partial p/\partial z$ appears for balancing the magnetic pressure. This solution was first suggested by Yoichi Mimura[6]. There is no reason to reject the flow pattern of this kind. However, it is obvious that the assumption $\partial/\partial z=0$ is more general than $w=0$ everywhere.

§ 4. Calculated Results

Numerical results on the effect of transverse magnetic field are presented here for two cases, one for insulated side walls and the other, for short-circuited conducting side walls.

When the side walls—walls at large distance in z-direction—are made of the non-conducting material, the induced electric current does not go out of the channel but circulates in the fluid. Therefore, an additional condition for the current is

$$\int_0^1 j_z dy=0$$

If the insulation at large x is also assumed, another relation is obtained as

$$\int_0^1 j_x dy=0$$

These conditions of insulation at large distance are physically realized for instance, when the flow of ionized gas is surrounded by the cold non-conducting gas.

Constants in the solution are determined by these two conditions. Solutions for u, w, j_x and j_z are all independent of the partial pressure of electron gas s.

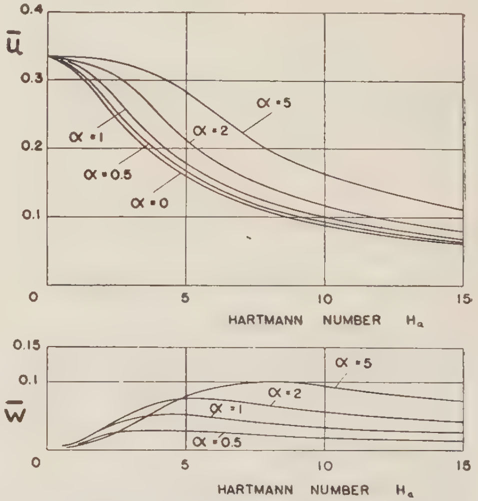

Fig. 2. Mean velocity. Insulated walls. $\bar{u}$ and $\bar{w}$ are non-dimensionalized by u_p. $H_a=B_0h\sqrt{\sigma_0/\nu\rho}$

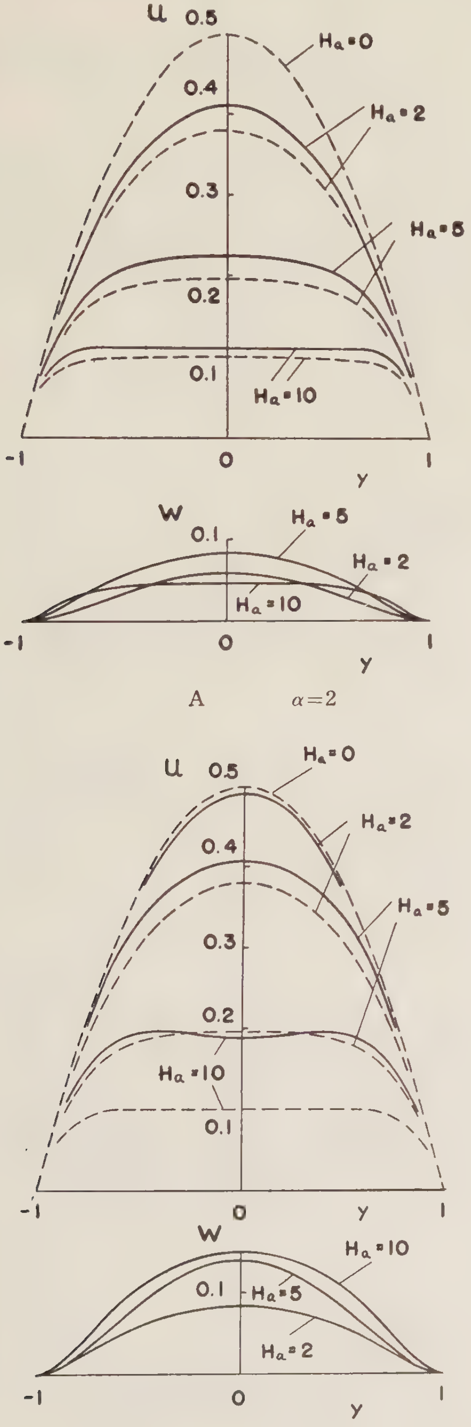
Numerical results are shown in Fig. 2 in which $\bar{u}$ and $\bar{w}$ are plotted against Hartmann number H_a based on the conductivity in the absence of magnetic field. The effect of magnetic field on the volume flow at a given pressure gradient becomes less remarkable as α is increased. This fact is easily understood by considering the more reduction of conductivity in the direction of induced electric field for larger α. The reduction of conductivity corresponds to the decrease of Hartmann number. The magnitude of $\bar{w}$ becomes large as α is increased but $\bar{w}$ never exceeds $\bar{u}$ for the same values of α and H_a.

Fig. 3 shows the velocity distribution u and w. Since velocity components are non-dimensionalized by u_p, the velocity on the centre-line for Poiseuille flow ($H_a=0$) is 0.5. As α

is increased, the deviation from the pure Hartmann flow becomes remarkable. The velocity gradient at the wall ($y=\pm 1$) remains unchanged for u and is kept to be zero for w for all values of α and H_a. This fact is of some physical interest. The shear flow having a zero velocity gradient at the wall is known as being very unstable—in other words, there is a great possibility of transition to turbulent flow. Even if the distribution of u is stable for external disturbances, the whole layer may become turbulent when the distribution of w is the unstable one. A similar situation has been pointed out on the three-dimensional boundary layer along a swept-back wing. Thus, it is expected that the Hall effect in ionized gas destabilizes the laminar flow.



A $\alpha=2$

B $\alpha=5$

Fig. 3. Velocity distribution. Insulated walls. Broken line: Hartmann's calculation.

When the side walls are made of conducting material and short-circuited by an external conductor, the induced electric current flows out of the channel. In this case no electric potential exists between side walls. If we assume the zero electric field also in x-direction, we have

$$m_x=0\ , \qquad m_z=0$$

These conditions are realized, for instance, for the flow between two concentric cylinders under the radial magnetic field with the pressure gradient parallel to the axis of cylinder.

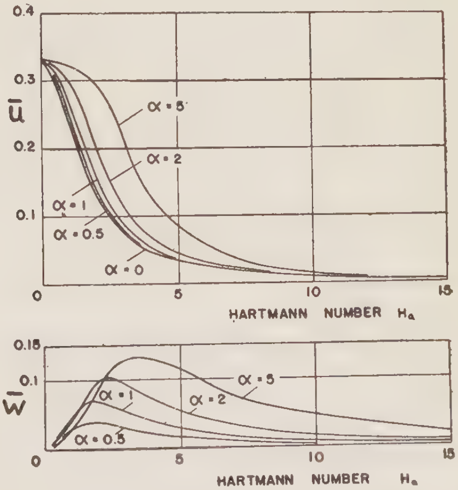


Fig. 4. Mean velocity. Conducting walls. $s=0$ $\bar{u}$ and w are non-dimensionalized by u_p.

Using above relations, $\bar{u}$ and $\bar{w}$ are calculated by the same procedure as the case of insulated walls. For conducting walls, the velocity distribution depends on s. Fig. 4 shows numerical results on $\bar{u}$ and $\bar{w}$ for $s=0$; —weakly-ionized gas. The effect of deceleration due to the magnetic field is more remarkable than the case of insulated walls, although the general trend of curves is the same. Results for $s=1/2$—fully-ionized neutral plasma are shown in Fig. 5. The more reduction of mass flow is obvious for both $\bar{u}$ and $\bar{w}$. In this case the limiting value of $\bar{u}$ at $H_a=0$ is not equal for various values of α.

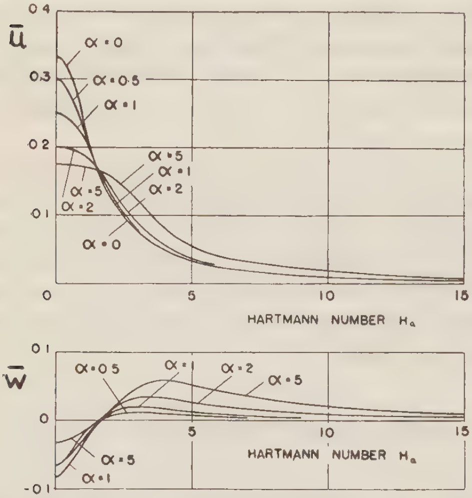

Fig. 5. Mean velocity. Conducting walls. $s=1/2$

The lateral component $\bar{w}$ starts from non-zero negative value and becomes positive at a certain Hartmann number. These situations are made clear by considering the effect of electron pressure in the case of vanishing magnetic field. The electric field induced by the pressure gradient of electron gas is expressed by $\boldsymbol{E}_e=(c/en)\nabla p_e$ and the current density vector $\boldsymbol{j}_e$ has components as

$$\boldsymbol{j}_e:\ \left(\frac{s}{B_0}\frac{\partial p}{\partial x}\frac{\sigma_2}{\sigma_0},\quad 0\,,\quad -\frac{s}{B_0}\frac{\partial p}{\partial x}\left(1-\frac{\sigma_1}{\sigma_0}\right)\right)$$

hence the electromagnetic body force is

$$\boldsymbol{j}_e\times\boldsymbol{B}_0:\ \left(s\left(1-\frac{\sigma_1}{\sigma_0}\right)\frac{\partial p}{\partial x},\quad 0\,,\quad s\frac{\sigma_2}{\sigma_0}\frac{\partial p}{\partial x}\right)$$

Since $\partial p/\partial x$ is negative, both components are negative and moreover they are independent of field strength as far as σ_1/σ_0 and σ_2/σ_0 remain constant. This means that the electromagnetic body force is present in the limiting case of vanishing magnetic field. Thus $\bar{u}$ at $H_a=0$ is reduced as α is increased and $\bar{w}$ at $H_a=0$ has a negative value. On the other hand, when $\boldsymbol{B}_0$ is exactly equal to zero, $\sigma_1=\sigma_0$ and $\sigma_2=0$, hence the electromagnetic body force is zero.

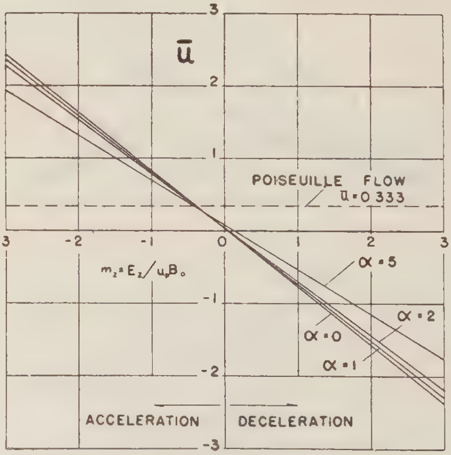
In the case of conducting side walls the velocity gradient at the wall is dependent on α and H_a for both u and w. The gradient for w is not zero in contrast with the case of insulated walls.

§ 5. Considerations on Power Generation and Acceleration by Crossed Electric and Magnetic Fields

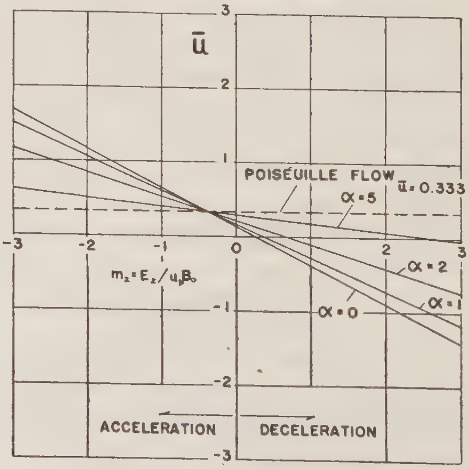
As shown above the transverse magnetic field decelerates the flow of ionized gas.

On the other hand, the electric power can be taken out when the side walls are made of conducting material. The total current in the z-direction is expressed by

$$J_z=\int_{-h}^{h} j_z dy=\sigma_0 u_p B_0\frac{2h}{1+\alpha^2}\left(\bar{u}+\alpha\bar{w}+\frac{s\alpha^2}{H_a{}^2}\right)$$



A $H_a=2$



B $H_a=5$

Fig. 6. Acceleration and deceleration due to combined electric and magnetic fields.

It is obvious that the Hall effect reduces the current output. When an external electric field is applied normal to the pressure gradient and magnetic field, the flow is either accelerated or decelerated depending on the direction of the field. Some examples of mean velocity $\bar{u}$ in the presence of transverse electric field are shown in Fig. 6 in which E_x is assumed to be zero and s is set to be zero. The flow rate can be several times that of simple Poiseuille flow or can be made zero with a proper choice of strength of electric field.

Here arises a serious question. Even if the magnetic Reynolds number is small when the external electric field is not applied, does the same assumption hold for the large value of m_z? The answer for this is following.

The magnitude of applied electric field is roughly m_z times the field induced by the flow. Therefore, the current, the magnetic field induced by the current and the magnetic Reynolds number in the presence of applied electric field are m_z times those in the absence of external field. Unless m_z is too large, the magnetic Reynolds number is still small and the present procedure of calculation is valid.

The voltage which makes $\bar{u}=0$ may be termed "choking voltage". It decreases as Hartmann number is increased. At the choke condition, there is no net flow in x-direction but this does not necessarily mean that the flow speed is zero everywhere. In general, there exist the flow in z-direction and a local flow in x-direction. When $\alpha=0$, u and w are everywhere zero at choking condition. For non-zero value of α, the fluid near the center of channel moves against the hydrodynamic pressure gradient whereas the fluid near the wall flows along the pressure gradient. A complete choking——$u=0$ everywhere——is realized at the infinite Hartmann number, for instance, for the inviscid flow.

§ 6. Concluding Remarks

The electrical conductivity of ionized gas under the magnetic field is expressed by a tensor. The investigation based on a simple model of ionized gas has ascertained the validity of tensor expression for both fully ionized and partially ionized gases. An incompressible, viscous channel flow has been analyzed by introducing the tensor conductivity under the condition of small magnetic Reynolds number. An exact solution has been obtained for the velocity as well as the electric current in cases of insulated and conducting side walls. The numerical results reveal the decrease of retarding effect of the transverse magnetic field for larger rate of anisotropy of conductivity. The magnitude of velocity component normal to the hydrodynamic pressure gradient and the magnetic field becomes remarkable as the anisotropy of conductivity increases. A possible role of the lateral velocity component in the transition to the turbulent flow has been pointed out.

The acceleration of flow by combined electric and magnetic fields is analyzed and numerical results are given.

Hydromagnetic Oseen Flow past an Elliptic Cylinder in a Uniform Magnetic Field

By Tosio MIYAGI

Junior College of Engineering, University of Osaka Prefecture,
Neyagawa, Osaka

(Received March 22, 1961)

This paper deals with the flow of a viscous, incompressible and electrically conducting fluid past an inclined elliptic cylinder in a parallel magnetic field, making use of a perturbation method similar to Oseen approximation. Approximate formulae for the forces experienced by the cylinder are obtained only to the lowest order of the Reynolds number and the magnetic Reynolds number. The drag and lift coefficients are then expressed as functions of five non-dimensional parameters, i.e., the Reynolds number, the magnetic Reynolds number, the pressure number, the thickness-ratio and the angle of incidence of the cylinder. Numerical calculations for the drag and lift coefficients as well as their ratio are carried out for various values of these five parameters. It may be noted in the numerical results that the angle of incidence of the cylinder at which the lift coefficient has a maximum value increases with the increase of the pressure number S when $S<1$, and the reverse is the case when $S>1$.

§ 1. Introduction

In the present paper is discussed the flow of a viscous, incompressible and electrically conducting fluid past an inclined elliptic cylinder in a magnetic field, which is uniform and parallel to the uniform main stream at infinity. The similar problem in ordinary hydrodynamics has been discussed by Imai[1] and Hasimoto[2] on the basis of Oseen's linearized equations of motion. In the present problem, however, the fluid is electrically conductive and flows in a magnetic field, so that the effect of interaction between the motion of the fluid and the magnetic field should be taken into account. Hence, we must solve simultaneously the hydrodynamic equations and the magnetic equations, viz. the modified Navier-Stokes equation and the Maxwell equations combined with the equation of continuity and the equation called Ohm's law, respectively.

Recently, the problem of the hydromagnetic flow past a fixed body in a parallel magnetic field has been treated by Yosinobu[3] by the use of a perturbation method similar to Oseen approximation in ordinary hydrodynamics. It is shown in his paper that the electric field must vanish throughout the whole field in the case of two-dimensional flow and that both the modified Navier-Stokes equation and the magnetic equation may be linearized by neglecting square and higher order terms of the perturbed velocity $\boldsymbol{u}$ and the perturbed magnetic field $\boldsymbol{h}$, which are assumed to be small compared with the uniform velocity U_0 and the uniform magnetic field H_0 at infinity, respectively. Hence, for the present problem, we can start from his linearized fundamental equations expressed in non-dimensional forms.

The approximate expressions for the drag and lift coefficients, C_D and C_L, are obtained only to the lowest order term with respect to the Reynolds and the magnetic Reynolds numbers. They are expressed as functions of five non-dimensional parameters, viz. the pressure number S, the thickness-ratio t and the angle of incidence of the cylinder α, in addition to the Reynolds number R and the magnetic Reynolds number R_m.

Numerical calculations for C_D, C_L and their ratio C_L/C_D are carried out for various values of the parameters R, R_m, S, t and α. The angle of incidence α_L at which C_L has a maximum value as well as the angle of incidence α_R at which C_L/C_D has a maximum value are numerically computed only for a flat plate. Some remarkable effects of the presence of the magnetic field are found in the numerical results and may be summed up as follows:

(1) C_D, C_L and C_L/C_D decrease with the increase of S when $S<1$ and the reverse is the case when $S>1$. (2) α_L increases slightly towards 45° with the increase of S when $S<1$ and the reverse is the case when $S>1$, and α_R, too, behaves in like manner.

§ 2. Fundamental Equations

Let us consider the two-dimensional steady flow of viscous, incompressible and electrically conducting fluid past an inclined elliptic cylinder in a magnetic field, which is uniform and parallel to the uniform main stream at infinity. We take the rectangular coordinates (x', y') in the plane of fluid motion in such a way that the origin coincides with the centre of the cylinder and the x'-axis is parallel to the uniform main stream at infinity. As the fundamental equations for the present problem, we here adopt a system of linearized equations which has been proposed by Yosinobu[3]. For the field outside the cylinder they can be written in the following non-dimensional forms:

$$R\frac{\partial u}{\partial x}=-\frac{\partial p}{\partial x}+\Delta u\,, \tag{1}$$

$$R\frac{\partial v}{\partial x}=-\frac{\partial p}{\partial y}+\Delta v+M^2(g-v)\,, \tag{2}$$

$$\frac{\partial g}{\partial x}-\frac{\partial f}{\partial y}=R_m(-v+g)\,, \tag{3}$$

$$\frac{\partial u}{\partial x}+\frac{\partial v}{\partial y}=0\,, \tag{4}$$

$$\frac{\partial f}{\partial x}+\frac{\partial g}{\partial y}=0\,, \tag{5}$$

where (x, y) are the non-dimensional rectangular coordinates referring to a characteristic length of the cylinder, L_0, (u, v) and (f, g) the x- and y-components of the perturbed velocity $\boldsymbol{u}/U_0$ and the perturbed magnetic field $\boldsymbol{h}/H_0$ respectively, p the non-dimensional pressure, and Δ stands for $\partial^2/\partial x^2+\partial^2/\partial y^2$. The system contains three independent non-dimensional parameters, the Reynolds number $R=L_0U_0/\nu$, the magnetic Reynolds number $R_m=\mu\sigma_e L_0U_0$, the Hartmann number $M=(\sigma_e/\rho\nu)^{1/2}L_0\mu H_0=(SRR_m)^{1/2}$, where ρ, ν, σ_e and μ are the density, the coeffieient of kinematic viscosity, the electric conductivity and the magnetic permeability of the fluid, respectively, and $S=\mu H_0^2/\rho U_0^2$ is the pressure number.

On the other hand, the governing equations for the magnetic field inside the cylinder can be written in the following non-dimensional forms, since no electric current exists there:

$$\frac{\partial g^*}{\partial x}-\frac{\partial f^*}{\partial y}=0\,, \tag{6}$$

$$\frac{\partial f^*}{\partial x}+\frac{\partial g^*}{\partial y}=0\,, \tag{7}$$

where (f^*, g^*) are the x- and y-components of the perturbed magnetic field inside the cylinder $\boldsymbol{h}^*/H_0$. Here and hereafter the asterisk (*) is added for the quantities inside the cylinder. The boundary conditions at the surface of the cylinder are the non-slip condition for the fluid velocity and the continuity of the lines of magnetic induction, and those at infinity are the uniformity of the flow and the magnetic fields. Thus we have

$$\left.\begin{array}{l} 1+u=0\,,\quad v=0\,, \\ \mu H_\perp=\mu^* H_\perp^*\,, \\ H_{/\!/}=H_{/\!/}^*\,, \end{array}\right\}\ \text{at the surface of the cylinder,} \tag{8}$$

$$u=v=f=g=0 \qquad \text{at infinity,} \tag{9}$$

where μ^* is the magnetic permeability of the cylinder, and the subscripts $\perp$ and $/\!/$ denote the normal and tangential components of the magnetic field at the surface of the cylinder, respectively.

Now, we introduce the stream function ψ and the magnetic stream functions χ and χ^*, sucy that

$$u=\frac{\partial\psi}{\partial y}\,,\qquad v=-\frac{\partial\psi}{\partial x}\,, \tag{10}$$

$$f=\frac{\partial\chi}{\partial y}\,,\qquad g=-\frac{\partial\chi}{\partial x}\,, \tag{11}$$

$$f^*=\frac{\partial\chi^*}{\partial y}\,,\qquad g^*=-\frac{\partial\chi^*}{\partial x}\,, \tag{12}$$

which satisfy identically Eqs. (4), (5) and (7), respectively. Substituting (10), (11) and (12) into Eqs. (1), (2), (3) and (6) and carrying out some calculations, we arrive at the following three partial differential equations for ψ, χ and χ^*:

$$\Delta\left[\Delta-2k_1\frac{\partial}{\partial x}\right]\left[\Delta-2k_2\frac{\partial}{\partial x}\right]\psi=0\,, \tag{13}$$

$$\Delta\left[\Delta-2k_1\frac{\partial}{\partial x}\right]\left[\Delta-2k_2\frac{\partial}{\partial x}\right]\chi=0\,, \tag{14}$$

$$\Delta\chi^*=0\,, \tag{15}$$

where

$$\left.\begin{array}{l} k_1=\frac{1}{4}[R+R_m+\{(R-R_m)^2+4M^2\}^{1/2}]\,, \\ k_2=\frac{1}{4}[R+R_m-\{(R-R_m)^2+4M^2\}^{1/2}]\,. \end{array}\right\} \tag{16}$$

Here, ψ and χ can be expressed by the sum of the solutions of the following three differential equations:

$$\left.\begin{aligned}&\left(\Delta-2k_1\frac{\partial}{\partial x}\right)(\psi_1,\ \chi_1)=0\ ,\\ &\left(\Delta-2k_2\frac{\partial}{\partial x}\right)(\psi_2,\ \chi_2)=0\ ,\\ &\Delta(\psi_3,\ \chi_3)=0\ .\end{aligned}\right\}\tag{17}$$

Since the flow field and the magnetic field are both uniform at infinity, ψ and χ can now be written down in the forms:

$$\left.\begin{aligned}\psi&=y+\psi_1+\psi_2+\psi_3\ ,\\ \chi&=y+\chi_1+\chi_2+\chi_3\ .\end{aligned}\right\}\tag{18}$$

Integrating Eq. (3) once with respect to x by making use of (17), we can readily find the following relations between ψ and χ:

$$\left.\begin{aligned}\psi_1&=\left(1-\frac{2k_1}{R_m}\right)\chi_1\ ,\\ \psi_2&=\left(1-\frac{2k_2}{R_m}\right)\chi_2\ ,\\ \psi_3&=\chi_3\ .\end{aligned}\right\}\tag{19}$$

Thus, we have obtained the set of linear differential equations (15) and (17) to be solved with the boundary conditions (8) and (9).

§ 3. Solution for an Inclined Elliptic Cylinder

Now, we introduce the elliptic coordinates $(\xi,\ \eta)$ related with $(x,\ y)$ by the equation:

$$x+iy=ce^{-i\alpha}\cosh(\xi+i\eta)\ ,\tag{20}$$

where α is the angle between the uniform flow and the major axis of the ellipse. Then, the surface of the elliptic cylinder is given by $\xi=\xi_0$. Taking the major diameter of the ellipse as the characteristic length L_0, the non-dimensional constant c in (20) is expressed as:

$$\left.\begin{aligned}&c=\frac{\sigma}{1+\sigma^2}\ ,\\ &\text{where}\\ &\sigma=e^{-\xi_0}\ .\end{aligned}\right\}\tag{21}$$

The thickness-ratio of the ellipse is then defined as:

$$t=\frac{1-\sigma^2}{1+\sigma^2}\ .\tag{22}$$

The fundamental equations in (17) are then transformed into

$$\left.\begin{aligned}&\left[\frac{\partial^2}{\partial\xi^2}+\frac{\partial^2}{\partial\eta^2}-k_1^2c^2(\cosh^2\xi-\cos^2\eta)\right](e^{-k_1x}\psi_1)=0\ ,\\ &\left[\frac{\partial^2}{\partial\xi^2}+\frac{\partial^2}{\partial\eta^2}-k_2^2c^2(\cosh^2\xi-\cos^2\eta)\right](e^{-k_2x}\psi_2)=0\ ,\\ &\left[\frac{\partial^2}{\partial\xi^2}+\frac{\partial^2}{\partial\eta^2}\right]\psi_3=0\ ,\end{aligned}\right\}\tag{23}$$

respectively. The general solutions satisfying Eqs. (23) and the boundary conditions (9) at infinity are

$$\left.\begin{aligned}\psi_1&=\sum_{n=0}^{\infty}[a_n^{(1)}F_n^{(1)}(\xi,\ \eta)+b_n^{(1)}G_n^{(1)}(\xi,\ \eta)]\ ,\\ \psi_2&=\sum_{n=0}^{\infty}[a_n^{(2)}F_n^{(2)}(\xi,\ \eta)+b_n^{(2)}G_n^{(2)}(\xi,\ \eta)]\ ,\\ \psi_3&=A_0\xi+B_0\eta+\sum_{n=1}^{\infty}\frac{e^{-n(\xi-\xi_0)}}{n}(A_n\cos n\eta+B_n\sin n\eta)\ ,\end{aligned}\right\}\tag{24}$$

where

$$\left.\begin{aligned}F_n^{(j)}(\xi,\ \eta)&=e^{k_jx}\mathrm{FEK}_n^{(j)}(\xi)\mathrm{ce}_n^{(j)}(\eta)\ ,\qquad (j=1,\ 2)\\ G_n^{(j)}(\xi,\ \eta)&=\int_{\eta_0}^{\eta}\left(\frac{\partial}{\partial\xi}-2k_j\frac{\partial x}{\partial\xi}\right)F_n^{(j)}(\xi,\ \eta)d\eta\\ &\quad-\int_{\xi}^{\infty}\left\{\frac{\partial}{\partial\eta_0}-2k_j\frac{\partial x(\xi,\ \eta_0)}{\partial\eta_0}\right\}F_n^{(j)}(\xi,\ \eta_0)d\xi\ ,\end{aligned}\right\}\tag{25}$$

and $a_n^{(j)}$'s, $b_n^{(j)}$'s, A_n's and B_n's are constants to be determined by the boundary conditions

(8). $\mathrm{ce}_n^{(j)}(\eta)$'s are fundamental solutions, periodic in η with period 2π, of the Methieu equation:

$$\left[\frac{d^2}{d\eta^2}+(\lambda_n^{(j)}+k_j^2c^2\cos^2\eta)\right]\mathrm{ce}_n^{(j)}(\eta)=0\,, \tag{26}$$

where $\lambda_n^{(j)}$ is a constant of separation and takes a characteristic value for $\mathrm{ce}_n(\eta)$. They can be expressed in Fourier series as[4]:

$$\left.\begin{aligned}\mathrm{ce}_{2m}^{(j)}(\eta)&=(-1)^m\sum_{p=0}^{\infty}a_{2p}^{(2m)}\cos 2p\eta\,,\\ \mathrm{ce}_{2m+1}^{(j)}(\eta)&=(-1)^m\sum_{p=0}^{\infty}a_{2p+1}^{(2m+1)}\cos(2p+1)\eta\,,\end{aligned}\right\} \tag{27}$$

where $a_{2p}^{(2m)}$'s and $a_{2p+1}^{(2m+1)}$'s are constants depending on $\lambda_n^{(j)}$ and $k_j^2c^2$. On the other hand, $\mathrm{FEK}_n^{(j)}(\xi)$'s are fundamental solutions of the associated Mathieu equation for the characteristic values of $\lambda_n^{(j)}$ in (26):

$$\left[\frac{d^2}{d\xi^2}-(\lambda_n^{(j)}+k_j^2c^2\cosh^2\xi)\right]\mathrm{FEK}_n^{(j)}(\xi)=0\,, \tag{28}$$

and tend to zero as ξ tends to infinity. They can be expressed in series of products of the modified Bessel functions[4]:

$$\left.\begin{aligned}\mathrm{FEK}_{2m}^{(j)}(\xi)&=\frac{1}{A_0^{(2m)}}\sum_{p=0}^{\infty}A_{2p}^{(2m)}I_p(v_1^{(j)})K_p(v_2^{(j)})\\ \mathrm{FEK}_{2m+1}^{(j)}(\xi)&=\frac{1}{B_1^{(2m+1)}}\sum_{p=0}^{\infty}B_{2p+1}^{(2m+1)}[I_p(v_1^{(j)})K_{p+1}(v_2^{(j)})-I_{p+1}(v_1^{(j)})K_p(v_2^{(j)})]\,,\end{aligned}\right\} \tag{29}$$

where

$$\left.\begin{aligned}&v_1^{(1)}=\tfrac{1}{2}k_1ce^{-\xi}\,, && v_2^{(1)}=\tfrac{1}{2}k_1ce^{\xi}\,,\\ &v_1^{(2)}=\tfrac{1}{2}|k_2|ce^{-\xi}\,, && v_2^{(2)}=\tfrac{1}{2}|k_2|ce^{\xi}\,,\\ &A_{2p}^{(2m)}=(-1)^{m+p}a_{2p}^{(2m)}\,, && B_{2p+1}^{(2m+1)}=(-1)^{m+p}a_{2p+1}^{(2m+1)}\,.\end{aligned}\right\} \tag{30}$$

The fundamental equation (15) for the magnetic stream function χ^* inside the cylinder is also transformed into $(\partial^2/\partial\xi^2+\partial^2/\partial\eta^2)\chi^*=0$. The general solution of this equation which is regular at $\xi=0$ is given in the form:

$$\chi^*=A_0^*+\sum_{n=1}^{\infty}\frac{c}{n}(A_n^*\cos n\eta+B_n^*\sin n\eta)\cosh n\xi\,, \tag{31}$$

where A_n^*'s and B_n^*'s are constants to be determined by the boundary conditions. Applying the boundary conditions (8) to the general solutions (24) and (31), we have

$$\left.\begin{aligned}&\left(\frac{\partial\psi}{\partial\xi}\right)_{\xi=\xi_0}=A_0+c(\cos\alpha\sin\eta\cosh\xi_0-\sin\alpha\cos\eta\sinh\xi_0)\\ &\qquad-\sum_{n=1}^{\infty}(A_n\cos n\eta+B_n\sin n\eta)+\sum_{n=0}^{\infty}\sum_{j=1}^{2}\left[\frac{\partial}{\partial\xi}\{a_n^{(j)}F_n^{(j)}+b_n^{(j)}G_n^{(j)}\}\right]_{\xi=\xi_0}=0\,,\\ &\left(\frac{\partial\psi}{\partial\eta}\right)_{\xi=\xi_0}=B_0+c(\cos\alpha\cos\eta\sinh\xi_0+\sin\alpha\sin\eta\cosh\xi_0)\\ &\qquad-\sum_{n=1}^{\infty}(A_n\sin n\eta-B_n\cos n\eta)+\sum_{n=0}^{\infty}\sum_{j=1}^{2}\left[\frac{\partial}{\partial\eta}\{a_n^{(j)}F_n^{(j)}+b_n^{(j)}G_n^{(j)}\}\right]_{\xi=\xi_0}=0\,,\\ &\left(\frac{\partial\chi}{\partial\xi}-\frac{\partial\chi^*}{\partial\xi}\right)_{\xi=\xi_0}=A_0+c(\cos\alpha\sin\eta\cosh\xi_0-\sin\alpha\cos\eta\sinh\xi_0)\\ &\qquad-\sum_{n=1}^{\infty}(A_n\cos n\eta+B_n\sin n\eta)+\sum_{n=0}^{\infty}\sum_{j=1}^{2}\left(1-\frac{2k_j}{R_m}\right)^{-1}\left[\frac{\partial}{\partial\xi}\{a_n^{(j)}F_n^{(j)}+b_n^{(j)}G_n^{(j)}\}\right]_{\xi=\xi_0}\\ &\qquad-\sum_{n=1}^{\infty}c(A_n^*\cos n\eta+B_n^*\sin n\eta)\sinh n\xi_0=0\,,\end{aligned}\right\} \tag{32}$$

$$\left.\begin{aligned}&\left(\frac{\partial\chi}{\partial\eta}-\frac{\mu^*}{\mu}\frac{\partial\chi^*}{\partial\eta}\right)_{\xi=\xi_0}=B_0+c(\cos\alpha\cos\eta\sinh\xi_0+\sin\alpha\sin\eta\cosh\xi_0)\\&\quad-\sum_{n=1}^{\infty}(A_n\sin n\eta-B_n\cos n\eta)+\sum_{n=0}^{\infty}\sum_{j=1}^{2}\left(1-\frac{2k_j}{R_m}\right)^{-1}\left[\frac{\partial}{\partial\eta}\{a_n{}^{(j)}F_n{}^{(j)}+b_n{}^{(j)}G_n{}^{(j)}\}\right]_{\xi=\xi_0}\\&\quad+\frac{\mu^*}{\mu}\sum_{n=1}^{\infty}c(A_n{}^*\sin n\eta-B_n{}^*\cos n\eta)\cosh n\xi_0=0\,.\end{aligned}\right|$$

Expanding the terms $[\partial F_n{}^{(j)}/\partial\xi]_{\xi=\xi_0}$ etc. in Fourier series:

$$\left.\begin{aligned}\left(\frac{\partial F_n{}^{(j)}}{\partial\xi}\right)_{\xi=\xi_0}&=A^{(j)}_{n0}+\sum_{m=1}^{\infty}(A^{(j)}_{nm}\cos m\eta+C^{(j)}_{nm}\sin m\eta)\,,\\\left(\frac{\partial G_n{}^{(j)}}{\partial\xi}\right)_{\xi=\xi_0}&=B^{(j)}_{n0}+\sum_{m=1}^{\infty}(B^{(j)}_{nm}\cos m\eta+D^{(j)}_{nm}\sin m\eta)\,,\\\left(\frac{\partial F_n{}^{(j)}}{\partial\eta}\right)_{\xi=\xi_0}&=E^{(j)}_{n0}+\sum_{m=1}^{\infty}(E^{(j)}_{nm}\cos m\eta+G^{(j)}_{nm}\sin m\eta)\,,\\\left(\frac{\partial G_n{}^{(j)}}{\partial\eta}\right)_{\xi=\xi_0}&=F^{(j)}_{n0}+\sum_{m=1}^{\infty}(F^{(j)}_{nm}\cos m\eta+H^{(j)}_{nm}\sin m\eta)\,,\end{aligned}\right\}\tag{33}$$

and equating to zero the coefficients of $\cos m\eta$ and $\sin m\eta$ in (32), we have

$$\left.\begin{aligned}&A_0+\sum_{n=0}^{\infty}\sum_{j=1}^{2}(a^{(j)}_nA^{(j)}_{n0}+b^{(j)}_nB^{(j)}_{n0})=0\,,\\&-A_m+\sum_{n=0}^{\infty}\sum_{j=1}^{2}(a^{(j)}_nA^{(j)}_{nm}+b^{(j)}_nB^{(j)}_{nm})=\frac{1-\sigma^2}{2(1+\sigma^2)}\sin\alpha\cdot\delta_{1m}\,,\\&-B_m+\sum_{n=0}^{\infty}\sum_{j=1}^{2}(a^{(j)}_nC^{(j)}_{nm}+b^{(j)}_nD^{(j)}_{nm})=-\frac{1}{2}\cos\alpha\cdot\delta_{1m}\,,\\&B_0+\sum_{n=0}^{\infty}\sum_{j=1}^{2}(a^{(j)}_nE^{(j)}_{n0}+b^{(j)}_nF^{(j)}_{n0})=0\,,\\&B_m+\sum_{n=0}^{\infty}\sum_{j=1}^{2}(a^{(j)}_nE^{(j)}_{nm}+b^{(j)}_nF^{(j)}_{nm})=-\frac{1-\sigma^2}{2(1+\sigma^2)}\cos\alpha\cdot\delta_{1m}\,,\\&-A_m+\sum_{n=0}^{\infty}\sum_{j=1}^{2}(a^{(j)}_nG^{(j)}_{nm}+b^{(j)}_nH^{(j)}_{nm})=-\frac{1}{2}\sin\alpha\cdot\delta_{1m}\,,\\&A_0+\sum_{n=0}^{\infty}\sum_{j=1}^{2}\left(1-\frac{2k_j}{R_m}\right)^{-1}(a^{(j)}_nA^{(j)}_{n0}+b^{(j)}_nB^{(j)}_{n0})=0\,,\\&-A_m+\sum_{n=0}^{\infty}\sum_{j=1}^{2}\left(1-\frac{2k_j}{R_m}\right)^{-1}(a^{(j)}_nA^{(j)}_{nm}+b^{(j)}_nB^{(j)}_{nm})-A_m{}^*c\sinh m\xi_0=\frac{1-\sigma^2}{2(1+\sigma^2)}\sin\alpha\cdot\delta_{1m}\,,\\&-B_m+\sum_{n=0}^{\infty}\sum_{j=1}^{2}\left(1-\frac{2k_j}{R_m}\right)^{-1}(a^{(j)}_nC^{(j)}_{nm}+b^{(j)}_nD^{(j)}_{nm})-B_m{}^*c\sinh m\xi_0=-\frac{1}{2}\cos\alpha\cdot\delta_{1m}\,,\\&B_0+\sum_{n=0}^{\infty}\sum_{j=1}^{2}\left(1-\frac{2k_j}{R_m}\right)^{-1}(a^{(j)}_nE^{(j)}_{n0}+b^{(j)}_nF^{(j)}_{n0})=0\,,\\&B_m+\sum_{n=0}^{\infty}\sum_{j=1}^{2}\left(1-\frac{2k_j}{R_m}\right)^{-1}(a^{(j)}_nE^{(j)}_{nm}+b^{(j)}_nF^{(j)}_{nm})-B_m{}^*\frac{\mu^*}{\mu}c\cosh m\xi_0=-\frac{1-\sigma^2}{2(1+\sigma^2)}\cos\alpha\cdot\delta_{1m}\,,\\&-A_m+\sum_{n=0}^{\infty}\sum_{j=1}^{2}\left(1-\frac{2k_j}{R_m}\right)^{-1}(a^{(j)}_nG^{(j)}_{nm}+b^{(j)}_nH^{(j)}_{nm})+A_m{}^*\frac{\mu^*}{\mu}c\cosh m\xi_0=-\frac{1}{2}\sin\alpha\cdot\delta_{1m}\,,\end{aligned}\right\}\tag{34}$$

where δ_{1m} equals 1 for $m=1$ and zero for $m\neq1$. Eliminating A_m's, B_m's, $A_m{}^*$'s and $B_m{}^*$'s in the above equations, we arrive at

$$\left.\begin{aligned}
&\sum_{n=0}^{\infty}\sum_{j=1}^{2}\left[a_n^{(j)}(A_{nm}^{(j)}-G_{nm}^{(j)})+b_n^{(j)}(B_{nm}^{(j)}-H_{nm}^{(j)})\right]=\frac{\sin\alpha}{1+\sigma^2}\delta_{1m}\,,\\
&\sum_{n=0}^{\infty}\sum_{j=1}^{2}\left[a_n^{(j)}(C_{nm}^{(j)}+E_{nm}^{(j)})+b_n^{(j)}(D_{nm}^{(j)}+F_{nm}^{(j)})\right]=-\frac{\cos\alpha}{1+\sigma^2}\delta_{1m}\,,\\
&\sum_{n=0}^{\infty}\sum_{j=1}^{2}\Bigg[a_n^{(j)}\left\{\left(1-\frac{2k_j}{R_m}\right)^{-1}-1\right\}\left(\frac{\mu^*}{\mu}\cosh m\xi_0A_{nm}^{(j)}+\sinh m\xi_0G_{nm}^{(j)}\right)\\
&\qquad+b_n^{(j)}\left\{\left(1-\frac{2k_j}{R_m}\right)^{-1}-1\right\}\left(\frac{\mu^*}{\mu}\cosh m\xi_0B_{nm}^{(j)}+\sinh m\xi_0H_{nm}^{(j)}\right)\Bigg]=0\,,\\
&\sum_{n=0}^{\infty}\sum_{j=1}^{2}\Bigg[a_n^{(j)}\left\{\left(1-\frac{2k_j}{R_m}\right)^{-1}-1\right\}\left(\frac{\mu^*}{\mu}\cosh m\xi_0C_{nm}^{(j)}-\sinh m\xi_0E_{nm}^{(j)}\right)\\
&\qquad+b_n^{(j)}\left\{\left(1-\frac{2k_j}{R_m}\right)^{-1}-1\right\}\left(\frac{\mu^*}{\mu}\cosh m\xi_0D_{nm}^{(j)}-\sinh m\xi_0F_{nm}^{(j)}\right)\Bigg]=0\,.
\end{aligned}\right\}\qquad(35)$$

We shall now seek for $a_n^{(j)}$'s and $b_n^{(j)}$'s for small values of k_1 and k_2. Using the relations

$$\left.\begin{aligned}
&\frac{\partial F_n}{\partial\xi}=e^{kx}\left[\mathrm{FEK}_n'(\xi)+k\frac{\partial x}{\partial\xi}\mathrm{FEK}_n(\xi)\right]\mathrm{ce}_n(\eta)\,,\\
&\frac{\partial G_n}{\partial\xi}=e^{kx}\,\mathrm{FEK}_n(\xi)\left[k\frac{\partial x}{\partial\eta}\mathrm{ce}_n(\eta)-\mathrm{ce}_n'(\eta)\right],\quad\text{etc.}\,,
\end{aligned}\right\}\qquad(36)$$

it is found that the Fourier coefficients $A_{nm}^{(j)}$'s, $B_{nm}^{(j)}$'s etc. are of the order of k^{m-2n} for $m>n$, of k^{2-m} or k^{-m} for $m=n\neq0$ and of k^{-m} for $m<n$, and especially when $m=n=0$, $A_{00}^{(j)}=F_{00}^{(j)}=O(k^0)$, $B_{00}^{(j)}=O(k^4)$ and $E_{00}^{(j)}=0$. On the other hand, if the orders of $a_n^{(j)}$'s and $b_n^{(j)}$'s are all assumed to be k^{2n-1}, it is sufficient, so far as we are concerned with the first approximation, to take only the following terms of the Fourier coefficients:

$$\left.\begin{aligned}
&A_{00}^{(j)}=-1+O(k_j^2)\,,\qquad B_{00}^{(j)}=O(k_j^4)\,,\\
&E_{00}^{(j)}=0\,,\qquad F_{00}^{(j)}=-1+O(k_j^2)\,,\\
&A_{01}^{(j)}=\frac{k_j\cos\alpha}{2(1+\sigma^2)}[\{\Omega_j(1-\sigma^2)-(1+\sigma^2)\}+O(k_j^2)]\,,\\
&B_{01}^{(j)}=\frac{k_j\sin\alpha}{2(1+\sigma^2)}(1-\sigma^2)[\Omega_j+O(k_j^2)]\,,\\
&C_{01}^{(j)}=\frac{k_j\sin\alpha}{2(1+\sigma^2)}[\{\Omega_j(1+\sigma^2)-(1-\sigma^2)\}+O(k_j^2)]\,,\\
&D_{01}^{(j)}=-\frac{k_j\cos\alpha}{2}[\Omega_j+O(k_j^2)]\,,\\
&E_{01}^{(j)}=\frac{k_j\sin\alpha}{2(1+\sigma^2)}(1-\sigma^2)[\Omega_j+O(k_j^2)]\,,\\
&F_{01}^{(j)}=-\frac{k_j\cos\alpha}{2(1+\sigma^2)}[\{\Omega_j(1-\sigma^2)+(1+\sigma^2)\}+O(k_j^2)]\,,\\
&G_{01}^{(j)}=-\frac{k_j\cos\alpha}{2}[\Omega_j+O(k_j^2)]\,,\\
&H_{01}^{(j)}=-\frac{k_j\sin\alpha}{2(1+\sigma^2)}[\{\Omega_j(1+\sigma^2)+(1-\sigma^2)\}+O(k_j^2)]\,,
\end{aligned}\right\}\qquad(37)$$

where

$$\Omega_1=-\left[\gamma+\ln\left\{\frac{k_1}{4(1+\sigma^2)}\right\}\right],\qquad\Omega_2=-\left[\gamma+\ln\left\{\frac{|k_2|}{4(1+\sigma^2)}\right\}\right]$$

and $\gamma=0.57721\cdots$ is Euler's constant.

Thus, we can determine $a_n^{(j)}$'s and $b_n^{(j)}$'s as functions of R, R_m, S, σ and α to the lowest order of k_1 and k_2, and on inserting the constants thus determined into (34), the values of the constants A_0 and B_0 can easily be obtained. Thus,

$$\left.\begin{aligned} A_0 &= \frac{-R_m\sigma^2(k_1-k_2)^2\sin 2\alpha}{k_1k_2[\{2(k_1\Omega_1-k_2\Omega_2)-R_m(\Omega_1-\Omega_2)\}^2-(k_1-k_2)^2(1+\sigma^4+2\sigma^2\cos 2\alpha)]}\,, \\ B_0 &= \frac{-R_m(k_1-k_2)[\{2(k_1\Omega_1-k_2\Omega_2)-R_m(\Omega_1-\Omega_2)\}-(k_1-k_2)(1+\sigma^2\cos 2\alpha)]}{k_1k_2[\{2(k_1\Omega_1-k_2\Omega_2)-R_m(\Omega_1-\Omega_2)\}^2-(k_1-k_2)^2(1+\sigma^4+2\sigma^2\cos 2\alpha)]}\,, \end{aligned}\right\} \tag{38}$$

which, to the first approximation, are independent of the ratio of the magnetic permeabilities μ^*/μ.

§ 4. Drag and Lift Coefficients

Next, we shall proceed to the calculation of the forces experienced by the elliptic cylinder. In the two-dimensional problem, they have been discussed in general by Yosinobu[3] and have been written in the forms:

$$D=-\frac{8\pi}{R_m}\rho\nu U_0k_1k_2B_0\,, \qquad L=-\frac{8\pi}{R_m}\rho\nu U_0k_1k_2A_0\,. \tag{39}$$

Thus, in the present problem, using the values of A_0 and B_0 as given by (38), they are given by

$$\left.\begin{aligned} D &= 8\pi\rho\nu U_0\frac{(k_1-k_2)[\{2(k_1\Omega_1-k_2\Omega_2)-R_m(\Omega_1-\Omega_2)\}-(k_1-k_2)(1+\sigma^2\cos 2\alpha)]}{\{2(k_1\Omega_1-k_2\Omega_2)-R_m(\Omega_1-\Omega_2)\}^2-(k_1-k_2)^2(1+\sigma^4+2\sigma^2\cos 2\alpha)}\,, \\ L &= 8\pi\rho\nu U_0\frac{\sigma^2(k_1-k_2)^2\sin 2\alpha}{\{2(k_1\Omega_1-k_2\Omega_2)-R_m(\Omega_1-\Omega_2)\}^2-(k_1-k_2)^2(1+\sigma^4+2\sigma^2\cos 2\alpha)}\,, \end{aligned}\right\} \tag{40}$$

and the drag and lift coefficients, defined as $C_D=D/(\frac{1}{2}\rho U_0^2L_0)$ and $C_L=L/(\frac{1}{2}\rho U_0^2L_0)$, become

$$\left.\begin{aligned} C_D &= \frac{16\pi}{R}\frac{(k_1-k_2)[\{2(k_1\Omega_1-k_2\Omega_2)-R_m(\Omega_1-\Omega_2)\}-(k_1-k_2)(1+\sigma^2\cos 2\alpha)]}{\{2(k_1\Omega_1-k_2\Omega_2)-R_m(\Omega_1-\Omega_2)\}^2-(k_1-k_2)^2(1+\sigma^4+2\sigma^2\cos 2\alpha)}\,, \\ C_L &= \frac{16\pi}{R}\frac{\sigma^2(k_1-k_2)^2\sin 2\alpha}{\{2(k_1\Omega_1-k_2\Omega_2)-R_m(\Omega_1-\Omega_2)\}^2-(k_1-k_2)^2(1+\sigma^4+2\sigma^2\cos 2\alpha)}\,, \end{aligned}\right\} \tag{41}$$

For the particular values of the parameters, the above formulae degenerate into various known results which have been obtained previously by several authors.

(I) *Case of $R_m=0$*

Since the electric conductivity of the fluid is supposed to be zero when $R_m=0$, there exists no current in the field, so that the flow field can be described just as in ordinary hydrodynamics. Putting $R_m=0$ in (16), we have $k_1=R/2$ and $k_2=0$, and the formulae (41) are reduced to

$$\left.\begin{aligned} C_D &= \frac{16\pi}{R}\frac{2\Omega_1-(1+\sigma^2\cos 2\alpha)}{4\Omega_1^2-(1+\sigma^4+2\sigma^2\cos 2\alpha)}\,, \\ C_L &= \frac{16\pi}{R}\frac{\sigma^2\sin 2\alpha}{4\Omega_1^2-(1+\sigma^4+2\sigma^2\cos 2\alpha)}\,, \end{aligned}\right\} \tag{42}$$

where $\Omega_1=-[\gamma+\ln\{R/8(1+\sigma^2)\}]$. It will readily be seen that, to the first approximation, these results are in accordance with those obtained previously by Imai[1] and Hasimoto[2].

(II) *Case of $S=0$*

When $S=0$, in other words, when the magnetic field vanishes, the flow field can also be described by ordinary hydrodynamics. Putting $S=0$ in (16), we have $k_1=R/2$ and $k_2=R_m/2$, and the formulae (41) degenerate into (42) again.

(III) *Case of $\sigma=0$*

When the thickness-ratio t is equal to unity, i.e., when $\sigma=0$, the elliptic cylinder is reduced to a circular cylinder. Putting $\sigma=0$ in (40), we have

$$\left.\begin{aligned} D &= \frac{16\pi\rho\nu U_0(k_1-k_2)}{(R_m-2k_2)(1+2\Omega_2)-(R_m-2k_1)(1+2\Omega_1)} \\ L &= 0\,, \end{aligned}\right\} \tag{43}$$

where $\Omega_j=-[\gamma+\ln(|k_j|/4)]$. These formulae coincide with those given by Yosinobu[3].

(IV) *Case of $R=R_m=0$ with finite M*

When the velocity of the fluid is very small but the magnetic field is very strong so that the Hartmann number $M=(RR_mS)^{1/2}$ remains finite, the field may be dealt with by the so-called hydromagnetic Stokes approximation. Putting $R=R_m=0$, but retaining M to be finite in (16), we have $k_1=M/2$ and $k_2=-M/2$, and the formulae (40) are reduced to

$$\left.\begin{aligned} D&=8\pi\rho\nu U_0\frac{2\Omega-(1+\sigma^2\cos 2\alpha)}{4\Omega^2-(1+\sigma^4+2\sigma^2\cos 2\alpha)}\,,\\ L&=8\pi\rho\nu U_0\frac{\sigma^2\sin 2\alpha}{4\Omega^2-(1+\sigma^4+2\sigma^2\cos 2\alpha)}\,,\end{aligned}\right\}\qquad(44)$$

where $\Omega=-[\gamma+\ln\{M/8(1+\sigma^2)\}]$. It can easily be confirmed that in the special case of $\sigma=1$, these formulae are in agreement with those obtained by Hasimoto[5] for a flat plate, who discussed a more general case in which the direction of the magnetic field is arbitrary. In the other special case of $\sigma=0$, the formula for the drag is immediately reduced to

$$D=\frac{8\pi\rho\nu U_0}{2\Omega+1}\,, \tag{45}$$

where $\Omega=-[\gamma+\ln(M/8)]$, which agrees with that for a circular cylinder as given by Yosinobu and Kakutani[6].

§ 5. Numerical Results

Detailed numerical calculations for the drag and lift coefficients have been carried out for various values of the parameters, using the formulae (41). In order to avoid confusion, however, we shall give here mainly the results for the case of $R=R_m=0.1$ for four different elliptic cylinders: $t=0$ (flat plate), 0.1, 0.5 and 1 (circular cylinder).

Table I-4. Values of C_D for $t=1.0$.

S	$R=1.0$ $R_m=1.0$	$R=1.0$ $R_m=0.1$	$R=0.1$ $R_m=1.0$	$R=0.1$ $R_m=0.1$

Table I gives the values of the drag coefficient C_D and they are plotted in Figs. 1~4. In Figs. 1, 2 and 3 the values of C_D are plotted against the pressure number S, the angle of incidence α being 0°, 45 and 90° respectively. In Fig. 4 is shown the dependency of C_D upon the angle of incidence α in the case of a flat plate. Table II and Figs. 5~6 give the value of the lift coefficient C_L for the three elliptic cylinders, C_L being evidently zero in the case of a circular cylinder. Table III and Fig. 7 give the values of the ratio C_L/C_D for the three elliptic cylinders. Fig. 5 gives the dependency of C_L upon S at the angle of incidence $\alpha=45°$ and Figs. 6~7 show the variations of C_L and C_L/C_D with the angle of incidence α,

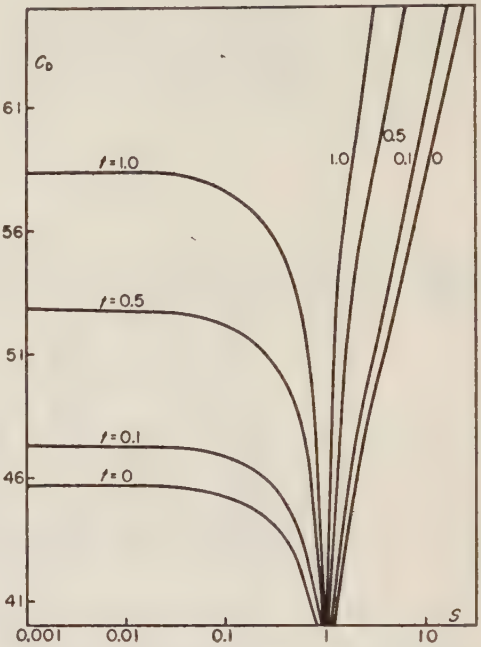

Fig. 1. Drag coefficient C_D plotted against the pressure number S, for $R=R_m=0.1$ and the angle of incidence $\alpha=0°$.

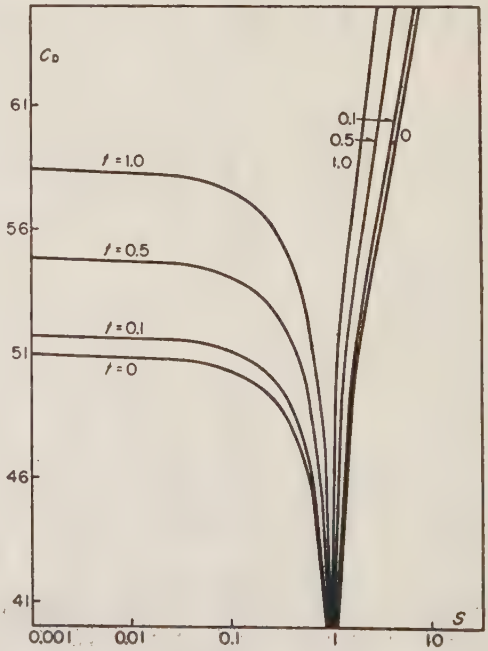

Fig. 2. Drag coefficient C_D plotted against S, for $R=R_m=0.1$ and $\alpha=45°$.

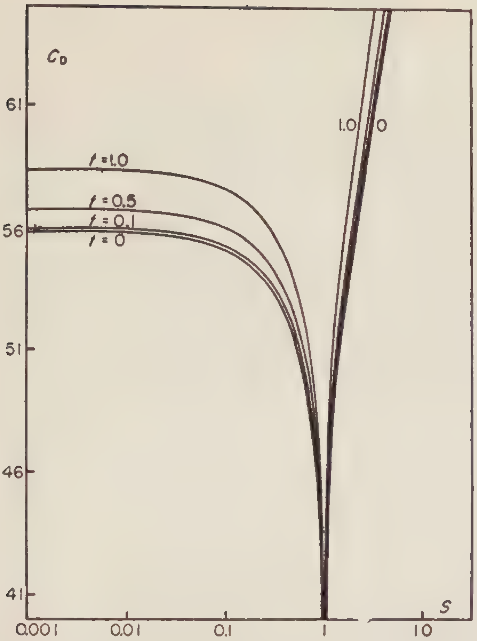

Fig. 3. Drag coefficient C_D plotted against S, for $R=R_m=0.1$ and $\alpha=90°$.

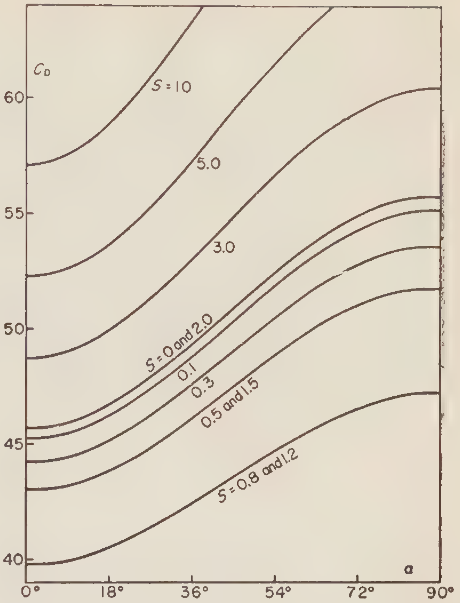

Fig. 4. Drag coefficient C_D plotted against the angle of incidence α, for $R=R_m=0.1$ in the case of flat plate ($t=0$).

Table II-1. Values of C_L for $R=0.1$, $R_m=0.1$ and $t=0$.

30	—	37.79	39.32	42.91

respectively, in the case of a flat plate.

From these tables and figures, it will be seen that the drag and lift coefficients decrease with the increase of the pressure number S when $S<1$, and the reverse is the case when $S>1$. Furthermore, it will be seen that the drag coefficient increases monotonically with the increase of either of the thickness-ratio

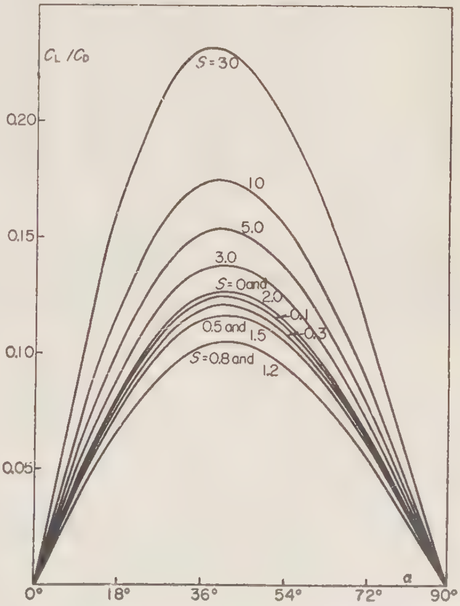

Fig. 7. Values of C_L/C_D plotted against the angle of incidence α, for $R=R_m=0.1$ in the case of flat plate ($t=0$).

or the angle of incidence of the cylinder and that the variation of the drag coefficient is very small. Whereas, the dependency of the lift coefficient on either of the thickness-ratio or the angle of incidence is remarkable.

On the other hand, the angle of incidence α_L at which the maximum lift occurs is, by (41), obtained from the equation:

$$\cos 2\alpha_L = \frac{2\sigma^2(k_1-k_2)^2}{\{\Omega_2(R_m-2k_2)-\Omega_1(R_m-2k_1)\}^2-(k_1-k_2)^2(1+\sigma^4)} . \tag{46}$$

In like manner, the angle of incidence α_R at which C_L/C_D has a maximum value is given by

$$\cos 2\alpha_R = \frac{\sigma^2(k_1-k_2)}{\{\Omega_2(R_m-2k_2)-\Omega_1(R_m-2k_1)\}-(k_1-k_2)} . \tag{47}$$

The values of α_L and α_R have also been calculated only in the case of a flat plate, and the results are shown in Tables IV~V. α_L increases towards 45° with the increase of S when $S<1$, and decreases with the increase of S when $S>1$, as is shown in Figs. 6 and 7. α_R shows a similar tendency to α_L.

Table V. Values of α_R for $t=0$ (degree)

S	$R=1.0$ $R_m=1.0$	$R=1.0$ $R_m=0.1$	$R=0.1$ $R_m=1.0$	$R=0.1$ $R_m=0.1$
0	36.42	36.42	41.40	41.40
0.001	36.43	36.42	41.41	41.41
0.01	36.45	36.43	41.41	41.41
0.1	36.69	36.51	41.48	41.46

5.0	30.04	36.61	39.40	40.65
10	16.54	35.41	37.66	40.03
30	—	31.25	33.14	38.47

As we can see from the formulae (41), $S=1$ is a singular point. This singularity is wholly due to the breakdown of the present perturbation method of solution at $S=1$, as has been discussed for a circular cylinder by Yosinobu³⁾ and for a finite flat plate by Greenspan and Carrier⁷⁾.

Molar Sound Velocity in Inorganic Melts and Solutions

By S. V. SUBRAHMANYAM AND J. BHIMASENACHAR
Physics Department, S. V. University, Tirupati, India

(Received March 27, 1961)

From an examination of the available ultrasonic and density data, in the case of eleven inorganic melts, the relation between the molar volume (M/ρ) and sound velocity, V, is found to be $MV^{2/3}/\rho=S$ where S is a constant independent of temperature. The molar sound velocity S is found to be an additive property. The contributions of different ions to the molar sound velocity of a liquid have been evaluated.

The variation, of $V^{2/3}/\rho$ with percentage weight of the solute in aqueous solutions for a number of univalent electrolytes, is found to be linear. The linear plots are extrapolated to get the value of $V^{2/3}/\rho$ for 100 percent of the solute. These values are multiplied by the respective values of the molecular weights of the solutes to give the molar sound velocity for the substance-Such extrapolated values have been found to correspond to the molar sound velocity of the substance in the liquid phase.

§ 1. Introduction

Higgs and Litovitz[1] showed that the ratio of the temperature coefficient of sound velocity (dv/dt) to the temperature coefficient of density ($d\rho/dt$) to be a constant and equal to 1.5 for a series of inorganic melts rather than 3 as in the case of organic liquids. This relationship can be written down as

$$1/V\ dV/dt=3/2\ d\rho/dt$$

where V is the sound velocity and ρ is the density. Integration and multiplication by molecular weight (M) leads to $MV^{2/3}/\rho=S$, where S is a constant independent of temperature.

The present investigation has been taken up to verify the above relation and examine whether the molar sound velocity is an additive function of the individual ions. The molten salts that have been chosen for the purpose constitute a set of inorganic liquids in which the intermolecular bonding is ionic in character. An attempt has also been made to correlate the molar sound velocity in the pure liquid with that in the aqueous solution of the substance.

§ 2. Result and Discussion

A) Molar sound velocity in molten salts

Values of S, the molar sound velocity, at different temperatures have been evaluated for eleven melts and are given in Table 1. The sound velocity data used in these calculations are taken from the work of Higgs and Litovitz[1] on lithium nitrate and Bockris and Richards[2] for the rest of the substances. The density data for the nitrates are taken from the International critical Tables[3] and for the rest of the substances from the work of Yaffe and Artsdalen[4]. In all cases, the molar sound velocity is found to be independent of temperature.

We now propose to examine whether the molar sound velocity is an additive function of the individual ions. It can be taken to be an additive function of ions, if a relation of the following type is satisfied:

$$S_{\mathrm{LiNO_3}}=S_{\mathrm{LiCl}}+S_{\mathrm{NaNO_3}}-S_{\mathrm{NaCl}}$$

Use of the average values of S's for these substances leads to $5.63=4.55+6.62-5.46$ ($=5.71$) — a clear demonstration of the additive nature of the constants. Similar tests in other cases also reveal the additive nature of molar sound velocity. It can therefore be assumed that the positive and negative ions make contributions S^+ and S^- to the total molar sound velocity S.

The contributions of different anions and cations are obtained by the following process. Assuming an arbitrary value for the nitrate ion, the contributions of Na^+, K^+ and Li^+ are calculated by subtracting this assumed value for NO_3^- from the corresponding values of S for $NaNO_3$, KNO_3 and $LINO_3$. Using these values for Na^+, K^+ and Li^+, the contributions of Cl^-, Br^- and I^- are evaluated from the S values of the corresponding halides. The

NaBr	5.25	5.32	3.40	1.92	
KBr	6.07	6.64	4.68	1.96	
NaI	5.70	6.00	3.40	2.60	2.62 (I^-)
KI	6.32	7.31	4.68	2.63	
CsCl	—	6.62	4.52	2.10	4.67 (Cs^+)
CsBr	—	6.7	4.82	1.97	

assumed value for NO_3^- is continuously adjusted until consistent values for Cl^-, Br^- and I^- are obtained. A value of 3.22 for the nitrate ion is found to give most consistent results, and the values of the contributions of different ions, arrived at on this basis, are given in Table II. The calculations are extended to the case of CsCl and CsBr leading to an average S^+ value of 4.67 for Cs.

All the substances studied in this investigation are univalent electrolytes and it will be interesting to see whether these simple relations hold good in polyvalent electrolytes also. Experimental work on these lines is in progress.

B) Molar Sound Velocity in Solutions

Investigations regarding the variation of sound velocity with concentration of a solute in one or more solvents often lead to interesting data characteristic of the solute. It is known[5] that in many organic solute-solvent systems, the plots of velocity *Vs* percentage weight are linear. In such cases the velocity for 100 percent of the solute can be evaluated by extrapolation of the graph. It has been found by the authors[6] that the extrapolated value is independent of the solvent and corresponds to the velocity in the liquid phase of the substance (near the melting point).

In the case of aqueous solutions of electrolytes, the plots of velocity *Vs* percentage weight are very often non-linear. Even in cases where it is linear, the extrapolated value is found to be very much larger than the velocity in the melt. This discrepancy is possibly due to the large difference between the temperatures at which these substances exist as liquids and the temperature at which the extrapolated value is obtained. This difficulty can be overcome by examining a property like molar sound velocity which does not vary with temperature.

It has been shown in section A that in the case of inorganic substances the molar sound velocity is given by $MV^{2/3}/\rho$. An evaluation of this constant cannot be made for an ionic solution since the significance of M becomes hazy. As an alternative the variation of $V^{2/3}/\rho$ with percentage weight of the solute is studied in the case of a number of aqueous solutions of electrolytes, using the existing data[7,8]. It is found that the plots are linear in all cases.

The linear plots are extrapolated to get the value of $V^{2/3}/\rho$ for 100 percent of the solute. These values are multiplied by the respective values of the molecular weights of the solutes to give the molar sound velocity for the substance. Such extrapolated values are shown in column 2 of Table II. The agreement between the extrapolated and experimental S values is good. This result indicates the possibility of evaluating the sound velocity in the melt from a knowledge of the variation of sound velocity and density in aqueous solutions of the substance.

The authors take this opportunity to thank the authorities of Sri Venkateswara University for all the facilities given to them.

Experimental Studies on Sonoluminescence and Ultrasonic Cavitation

By Katsuo NEGISHI

Kobayasi Institute of Physical Research, Kokubunji, Tokyo

(Received April 10, 1961)

Using a miniature spherical hydrophone made of barium titanate, the individual cavity collapse was detected as a sharp impulse (0.5 μs width) slightly after the pressure maximum of sound cycle. When may cavities collapsed simultaneously, sinusoidal sound-pressure waveform was turned into saw-tooth form. By comparing the flash of sonoluminescence with the instantaneous change of scattered light from cavitating bubbles in dark-fiield illumination, the sonoluminescence from water has been decided to occur during the final stages of the bubble collapse. The sonoluminescence from aqueous solutions of various sodium salts, organic solvents and luminol has been also examined. The luminescence of luminol has been applied to develop a new method for the visualization of ultrasonic fields.

§ 1. Introduction

It was first observed in the early 1930's by Frenzel and Schultes[1] and independently by Zimakov[2] that a weak emission of light occurred in liquids subjected to ultrasonic waves. The term 'sonoluminescence' was introduced by the formers after the method of excitation, as against electroluminescence, photoluminescence, etc. Following this discovery, many investigations on the nature and the origin of this phenomenon were carried out mainly by chemists, early observations being made mostly with dark-adapted eyes. It was revealed that the sonoluminescence is closely connected to the chemical action of ultrasonic waves and it occurs in liquids only when they are cavitated in sound fields.

In 1937, Chambers[3] studied 36 pure liquids in acoustic field of 9 kc/s and found 14 of them to luminesce. He showed that the brightness of luminescence increases as the temperature decreases, and as the product of the d pole moment and viscocity of the liquid increases. Harvey[4] distinguished sonic chemiluminescence from sonoluminescence. He considered that the sonic chemiluminescence occurs as a result of chemical reaction caused by ultrasonically activated oxygen, as shown in alkaline solution of luminol, while the sonoluminescence is not due to activated oxygen. It is, however, difficut to distinguish seriously between the two in some cases, as is to be seen later.

In recent years, quantitative measurements of weak luminescence have become rather easy by use of a high sensitive photomultiplier tube. Quantitative measurements of sonoluminescence were made by Griffing and Sette[5],[6] and by Prudhomme[7],[8] in relation to the chemical effect produced by ultrasonic cavitation and especially on the influence of the dissolved gases. They observed that the intensity of luminescence from sonically irradiated water increased with chemical yields (H_2O_2, etc.) and was enhanced by dissolving heavy rare gases like krypton and xenon. Interesting results on the spectrum of sonoluminescence were obtained by Günther *et al*[9],[10] and Srinivasan[11], who observed that the spectral distribution was a continuum resembling that of a blackbody radiating at 6,000°–10,000°K. Jarman[12] has studied the temperature dependence of luminescence from 15 pure liquids and found that the intensity of luminescence was more properly correlated with (surface tension)^2/(vapour pressure) than Chambers' correlation

There are several hypotheses on the origin of sonoluminescence, which is also connected closely to the mechanism of the chemical action of ultrasonic waves[37],[38]:

a) The electrical microdischarge theory, proposed by Frenkel[13], postulates that thin lens-shaped cavities are abruptly produced in the liquid by negative pressures due to the sound waves and electric charges of different signs appear on both walls of the cavities respectively as a result of the statistical fluctuation of charge distribution in the liquid. The electric field grows as the cavity grows into a spherical shape and then discharge takes place in spherical cavities.

b) The mechano-chemical theory, proposed by Weyl and Marboe[14),15)], assumes that light is emitted by photochemical recombination of free ions which are produced when molecules are mechanically dissociated at nascent surfaces of the growing cavities.

c) The thermo-chemical theory, described by Griffiing and Sette[6)], also attributes the emission of light to the photochemical recombination of free ions, although this theory supposes the production of ions as due to thermal dissociation in collapsing bubble.

d) The hot spot theory, originated by Noltingk and Neppiras[16),17)], proposes that sonoluminescence is merely the blackbody radiation from the gas within cavitation bubbles, which is incandesced by adiabatic compression when the bubbles collapse.

e) The triboluminescence theory, described by Chambers[3)], presumes that, when the quasi-crystalline structure of the liquid is fractured by cavitation, triboluminescence occurs as is often observed in breakdown of certain crystals.

f) The balloelectric theory, proposed by Harvey[4)], assumes the appearance of electric charges on the surface of bubbles in analogy to Lenard potentials observed on liquid drops in gases. It is stated that the potential rises as the cavity collapses because of the decrease in capacity.

There is no sufficient knowledge to decide which of the above theories on sonoluminescence is really valid. Of these theories, the discharge theory has been accepted by fairy many investigators until recent years without direct experimental evidence. Other probable theories are the hot spot theory (d) and the thermo-chemical theory (c), while the others are almost ignored at present. If one of these theories is valid, it should be expected that sonoluminescence occurs as a discrete flash of light at a definite phase of the sound cycle: *e.g.* in the discharge theory it should occur during the process of bubble growth, and in the hot spot theory at the phase of bubble collapse. In this respect, some experimental investigations have been made recently, and in fact it has been found that sonoluminescence consists of discrete flashes of light, but there are some disagreements as regards the phase relation. Wagner[18)] and Jarman[12)] have decided the phase of flash of the luminescence from water or aqueous solutions of some inorganic salts with respect to the sound-pressure cycles measured by hydrophones, and obtained results which are in favour of the discharge theory, while Gunther *et al*[19),20)] attained to an opposed result supporting the hot spot theory. Meyer and Kuttruff[21)], using high-speed photographic technique, showed that the flashes from ethylene glycol occurred during the final stage of bubble collapse, yet its phase with respect to the sound cycle (2.5 kc/s) was uncertain.

There are, moreover, many aspects of sonoluminescence and its relation to cavitation and chemical action, which are not clarified as yet. The present paper aims to clarify these points. Some applications of the sonoluminescence in visualizing the cavitation field are also presented.

§ 2. Pressure Waveform of Ultrasonic Waves Accompanying Cavitation

Prior to the observation of sonoluminescence, the phase of bubble collapse with respect to the pressure cycle of sound in aerated water was determined with the help of a miniature barium titanate hydrophone illustrated in Fig. 1. Powder of barium titanate plastered to a spherical platinum core 1.5 mm in diameter was sintered at about 1,400°C, so that the final diameter became 2 mm. This element was fixed to a porcelain tube 2 mm in diameter with molten glass and whole of the outer surface was coated with fired-on

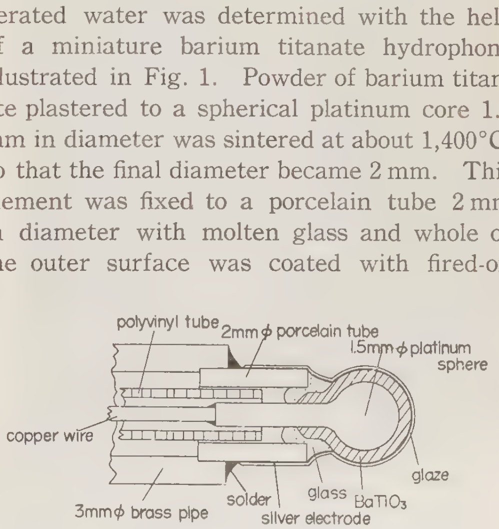

Fig. 1. Miniature barium titanate hydrophone.

silver electrode and furthermore with glaze for the mechanical protection of the silver surface. The porcelain tube was soldered to a brass tube 3 mm in diameter which served for the outer conductor. The accomplished element was polarized by DC voltage of about 500 V. This hydrophone had a electric capacitance of about 250 pF and a pressure sensitivity of about −140 dB, though not accurately calibrated.

A 24 kc/s window-type nickel transducer (radiating surface $4\times4.5\,\mathrm{cm}^2$) was used to radiate pulsed ultrasonic waves in an anechoic tank. On the back surface of the transducer, a simple accelerometer-type vibration pickup made of lead zirconate titanate was attached in order to observe the velocity waveform of the transducer after integrating the pickup singal.

Typical pressure waveforms of 0.3 ms pulses obtained at a point 1 cm in front of the center of the transducer surface are given in Fig. 2. The velocity amplitude of the transducer was about 10 cm/s. Because of the very short pulse width and the low pulse recurrence (one pulse per second), only a few cavitations were produced, so that individual shock waves caused by the collapses of cavities were observed as sharp positive impulses of about 0.5μs width. As the hydrophone used has a poor response in the frequency range above 1 Mc/s, the peak pressure of the shock waves indicated in the figures may be considerablly lower than the true value, and their width also may be broadened. The bubble collapse always occurs slightly after the pressure maximum, as is shown in the theoretical result of Noltingk and Neppiras[16].

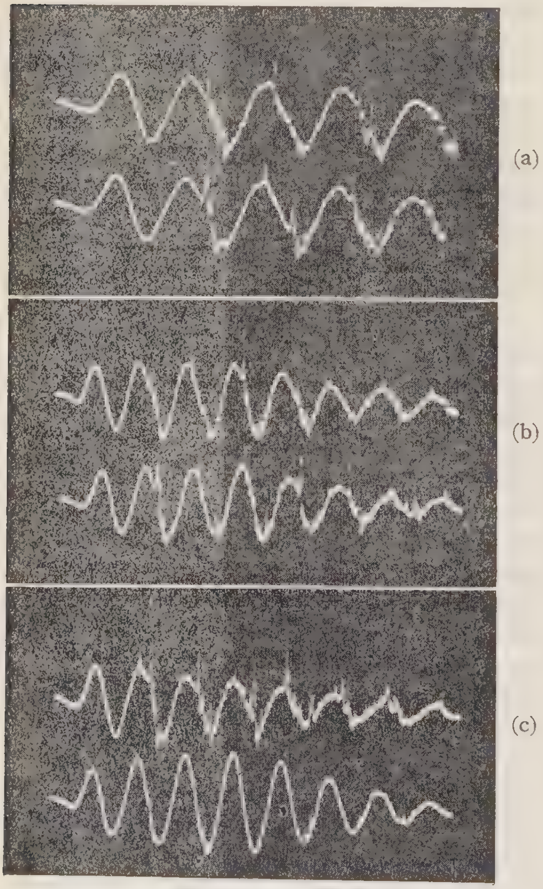

Fig. 2. Sound-pressure waveforms of 24 kc/s pulsed ultrasonic waves of 0.3 ms width in aerated water, showing shock waves caused by cavitation.

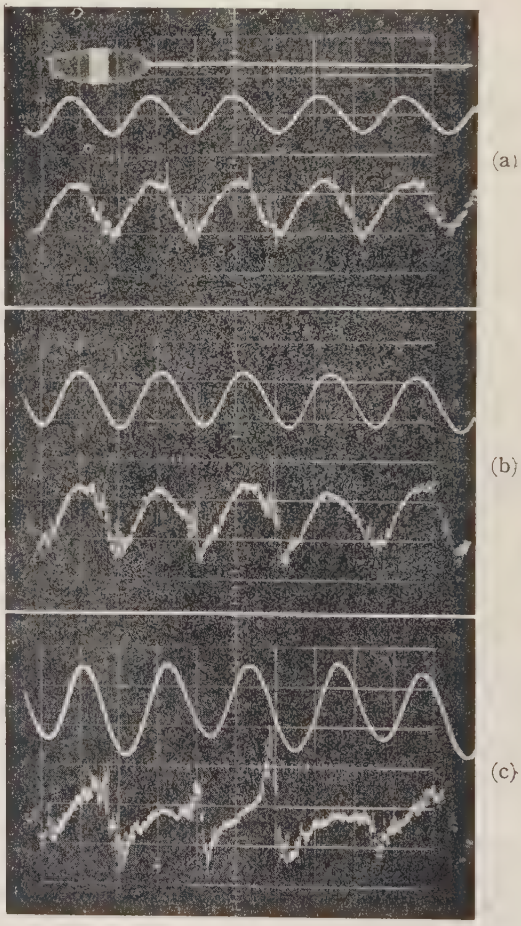

Fig. 3. Stationary parts of pressure waveforms (lower trace) and velocity waveforms (upper trace) of the transducer emitting 1.5 ms pulse, velocity amplitude being 11 cm/s in (a), 19 cm/s in (b) and 30 cm/s in (c).

The lower trace of Fig. 2 (c) is a pressure waveform obtained when cavitation is occasionally suppressed under the same condition as the upper trace. Comparing the two waveforms, it is clearly shown that the amplitude of the fundamental sound-pressure wave is attenuated by cavitation.

For longer ultrasonic pulses, say 1.5 ms width, many cavitations were simultaneously produced owing to the increasing number of cavitation nuclei created by the preceding cavitations, and consequently the pressure waveform was no longer sinusoidal, but was turned into saw-tooth form with large positive peaks. Some pressure waveforms of the stationary part of 1.5 ms pulse at a point adjacent to the transducer are shown in Fig. 3. The velocity waveform of the transducer are also shown in the same figure (upper trace), the velocity amplitude being 11 cm/s in (a), 19 cm/s in (b) and 30 cm/s in (c), respectively. It is to be concluded that the pressure peaks in comparatively long pulses or continuous waves correspond to the phase of the maxima of the bubble collapse because the pressure peak is nothing but the accumulated result of the shock waves produced by the collapsing bubbles. The generation of the subharmonic component is clearly to be seen in Fig. 3 (c). It is noticeable that the subharmonic component appears not only in the sound-pressure but also in the velocity waveform in Fig. 3 (c).

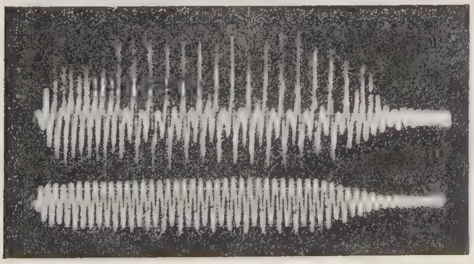

Fig. 4. Pressure waveform of 1.5 ms pulse at a point adjacent to the transducer (upper) and 5 cm in front of it (lower).

Total length oscillograms of 1.5 ms pulse are given in Fig. 4, the upper trace being the pressure waveform at a point adjacent to the transducer and the lower one at 5 cm in front of it. It requires several cycles of sound accompanying cavitation before the subharmonic component begins to appear, as is shown in Fig. 4. Subharmonics in the pressure waveform is thought to be due to the nonlinear oscillation of bubbles whose resonance frequencies are lower than the exciting frequency. As these larger bubbles are produced possibly by the accumulation of smaller ones, it may be understood that subharmonics occur after some periods of sound accompanied by cavitation. Subharmonics in pressure waves also may have a reaction on the velocity waveform of the transducer. As the cavitation region is localized near the center of the transducer surface when such short ultranic pulse is emitted, the saw-tooth waveform fades out rapidly as the distance increases from the radiating surface, and the waveform at a distance becomes similar to the velocity waveform of the transducer, as shown in the lower trace of Fig. 4.

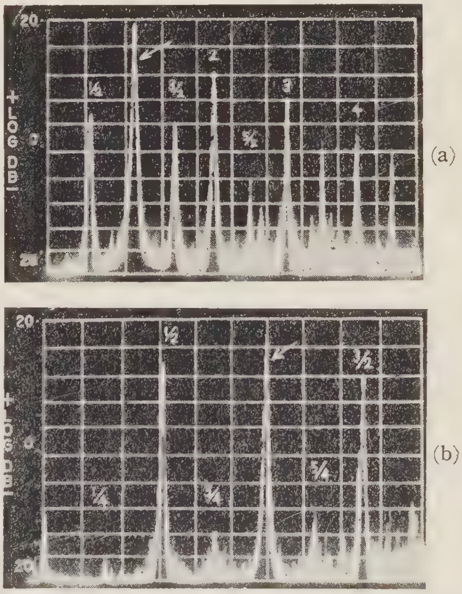

Fig. 5. Cavitation noise spectra of 24 kc/s continuous ultrasonic waves. Inscribed numbers show the spectral orders.

Cavitation noise spectra of 24 kc/s continuous ultrasonic waves are shown in Fig. 5. The fundamental frequency is indicated by the arrow and the spectral orders are also inscribed in the figure, the vertical scale being in dB. Higher harmonics and subharmonics of $n/2$ series and $n/4$ series (n=integers) are remarkable and no $n/3$ component is found. Also a continuous background noise is observed. This is presumably produced by the collapsing bubbles and especially many oscillating bubbles of various sizes in the ultrasonic field. On the other hand, at higher fundamental frequencies, *e.g.* at 500 kc/s, subharmonics of $n/2$ series and $n/3$ series were found, sometimes accompanying $n/6$ series, whereas no $n/4$ series was observed.

§ 3. Phase Relation Between Sonoluminescence and Cavitating Bubbles in Water

The phase relation between sonoluminescence and cavitating bubbles in water has been determined with respect to the sound-pressure cycles[24]. The experimental arrangement is shown in Fig. 6. A ferrite transducer resonating at 28 kc/s (radiating surface $4\times4\,cm^2$) was employed to radiate ultrasonic waves in a glass tank ($23\times45\times23\,cm^3$) filled with tap water. Experiments were also done by employing water purified by passing through ion-exchange resin, but the result was quite similar as in the case of the tap water. A full-sized image of the cavitation region before the transducer stub was projected on a screen with a small opening (2 mm in diameter) by a lens, and light from a small region at 1 cm in front of the stub center was fed to a photomultiplier tube through this opening. The photomultiplier tube used was a Du Mont type 6292 (sensitive for 300 to 600 mμ), which was connected to a regulated high voltage supply of 1,2000 V. The output voltage across a 5,000 ohm resistor connected to the anode collector of the tube was displayed after 60 dB amplification on a cathod ray oscilloscope triggered by the input voltage of the transducer. A light source was used for dark-field illumination of the cavitating bubbles from which light was scattered corresponding to the instantaneous change of bubble volume. In complete darkness, sonoluminescence was observed on the oscilloscope screen as discrete flashes once every sound cycle. When the dark-field illumination was switched on, a curve representing the instantaneous bubble volume was obtained on the oscilloscope under a reduced amplification, instead. The intensity of the scattered light from cavitating bubbles was by far the stronger than the luminescence, so that the curve of the bubble volume was not affected by the luminescence. The time constant of the apparatus was of the order of 10^{-7} sec, and the individual luminescence pulses were observed as sharp impulses of this decay time. Although both luminescence and bubble volume could not be observed at the same time, the phase relation between the two phenomena was clearly determined by this procedure, since the triggering condition of the oscilloscope was common.

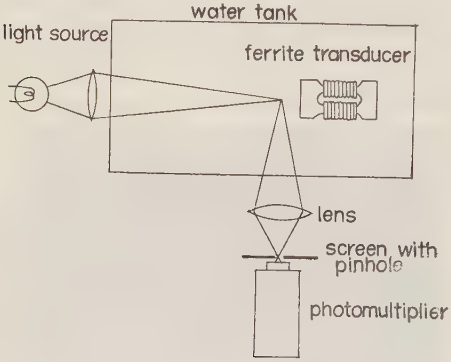

Fig. 6. Experimental arrangement

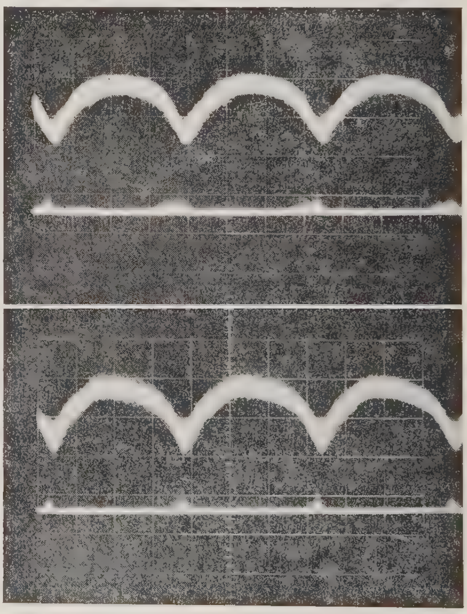

Fig. 7. Volume change of cavitating bubbles (upper trace) and sonoluminescence (lower trace) in fresh tap water (a) and in water of appreciably reduced air content (b).

Fig. 7 (a) is a double exposured oscillogram of the bubble volume and the sonoluminescence in fresh tap water (extremely supersaturated with air) showing hundreds of overlapping sweeps. The luminescence pulse begins to appear at about 1/5 period before the phase of minimum bubble volume, and goes to its maximum intensity at the minimum bubble volume, *i.e.* at the instant of complete collapse of the bubble; thereafter it rapidly fades out. In water of appreciably reduced air content, the luminescence pulses begin to appear at about 1/10 period before the bubble collapse as shown in Fig. 7 (b).

The sound-pressure waveform and change in bubble volume were observed simultaneously and are shown in Fig. 8. At the minimum of bubble volume, a remarkable positive peak was produced by superposed shock waves as mentioned in the previous section. A slight difference between the bubble volume curve of Fig. 7 and Fig. 8 is due to the fact that the output of the photomutiplier was AC-coupled to the oscilloscope in the case of Fig. 7 and DC-coupled in Fig. 8.

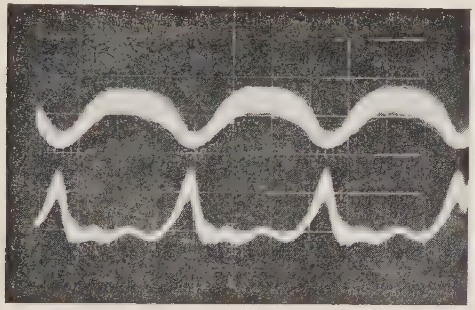

Fig. 8. Curve of bubble volume (upper) and sound-pressure waveform (lower).

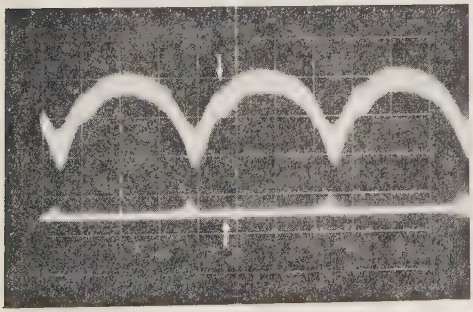

Fig. 9. Volume change of cavitating bubbles with small dips and sonoluminescence with secondary flashes (indicated by arrows).

Often, a secondary luminescence flash occurred shortly after the main flash at an appreciably high transducer input. In phase with the secondary flash, a secondary pressure peak appeared in the sound-pressure waveform, and furthermore, a small dip appeared in the curve of the bubble volume, showing that some of the bubbles rebounded and then collapsed again shortly after their first collapse, emitting a secondary flash. This is noticeable in Fig. 9.

When the transducer input was increased until subharmonic components appeared in the pressure waveform, cavitation was irregularly blown away from the stub and sonoluminescence was inhibited rather than enhanced.

§ 4. Sonoluminescence of Some Aqueous Solutions

It is known that the sonoluminescence from water is enhanced by the addition of some inorganic salts, carbon disulfide or carbon tetrachloride, whereas it is inhibited by the addition of a volatile liquid such as ether or alcohol. An examination of the effects of some additives on the sonoluminescence from water was made with the apparatus shown in Fig. 10. This arrangement fulfilled the requirement that the photomultiplier had to receive a sufficient luminous flux from a small amount of liquid. In this apparatus, the liquid needed was only 20 cc. The output current of the photomultiplier was measured by a vacuum-tube microammeter.

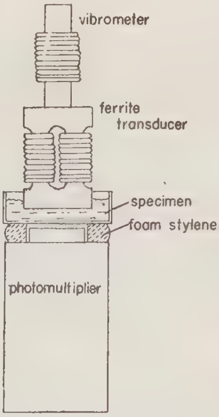

Fig. 10. Experimental apparatus.

The ferrite transducer was the same one as used in the previous experiment, but a vibrometer transducer of the same type as the main one but of smaller thickness was attached to indicate the velocity amplitude of the stub by the open-circuit voltage. The two transducers were so glued that the axes of the magnetic flux of the driving and the pickup cores at the glued surface were perpendicular to each other, thus the magnetic coupling between the two coils was negligible in practice. The vibrometer sensitivity was 1.9 V/cm/s, the calibration being made by an optical interference technique. It is to be remembered that sound-pressure amplitude of 1 atm. in water corresponds to particle velocity of 6.75 cm/s. Although the stub velocity is not directly connected to the intensity of sound in the liquid of small quantity as in this case, the stub velocity is nevertheless proportional to the pressure amplitude of sound.

As the intensity of luminescence gradually decreased with increasing temperature caused by the continuous irradiation of ultrasonic waves, the luminous flux was read as fast as possible, so that the temperature rise was below 5°C during the observation. By this procedure, readings were obtained with rather good reproducibility. Water used in this experiment was purified by passing through the ion-exchange resin.

Experimental results on the effect of the addition of various sodium salts are shown in Fig. 11 at various sound intensities. The enhancing effect of sodium chloride was not so remarkable as reported by Jarman[22] who observed that 2 N solution of sodium chloride luminesced about seven times brighter than tap water just above the cavitation threshold. This is possibly due to the difference of experimental conditions. The luminescence begins as the sound intensity attains the cavitation threshold, and the light intensity increases with increasing sound intensity. But the readings of the luminous flux are rather unstable near the cavitation threshold. 2 N solution of sodium carbonate gave brighter luminescence than the others, while the addition of sodium hydrogen carbonate considerably inhibited the sonoluminescence of water.

Effects of the addition of various organic solvents and bromine have been also examined and the results are given in Fig. 12. Most of these additives were hardly miscible with water, so that 20 cc of water was saturated by the addition of a few drops of them. Enhancing effects of carbon disulfide, bromine and methyl iodide were striking and those of carbon tetrachloride and trichloroethylene

C_6H_6	0.25	0.88	80.5	74.7	0.072	1.4

were also noticed. Bromobenzene and aniline were not so effective. It is interesting to find that substances showing the large enhancing effect have some common features, *e.g.* relatively large density, low boiling point and small solubility to water (cf. Table I). Furthermore, they give no or only very faint luminescence when subjected to ultrasonic waves in pure liquid state (*i.e.* without water). On the other hand, ethylene glycol and glycerine produce bright luminescence when subjected to ultrasonic waves, whereas the addition of small quantities of them to water does not strongly affect the sonoluminescence from water. 50% glycerine (in volume), however, luminesced with considerable brightness.

In spite of the wide variety of the intensity of sonoluminescence from these solutions, it was found that all of them luminesced at the phase of minimum bubble volume as in the case of pure water.

§ 5. Sonic Chemiluminescence of Luminol

Luminol (3-aninophthalhydrazide) in alkaline solution gives a brilliant bluish luminescence, when it is oxidized in various ways and particularly with hydrogen peroxide in the presence of activators like hemin. It is not surprising, then, to find that this solution luminesces with comparatively intense brightness, visible without dark-adaptation, when it is cavitated by ultrasonic waves. The behaviour of luminol solution when saturated with various gases has been examined in ultrasonic fields by Harvey[4] who concluded that most of light from this solution has the chemiluminescent origin. There are some other confirmations supporting his conclusion.

Results measured with the apparatus of Fig. 10 showed that luminol in neutral solution gave the same faint luminescence as observed in pure water, but the addition of sodium carbonate in this solution enhanced the lumin-

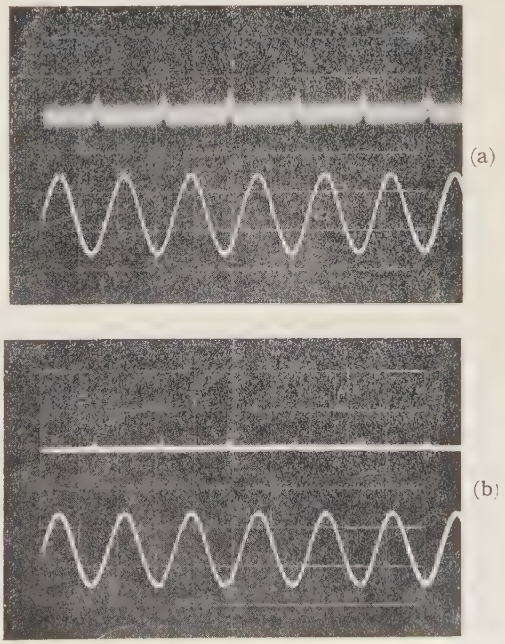

Fig. 13. Luminescence of luminol solution (a) and pure water (b) in upper trace and vibrometer output in lower trace.

escence by as much as 1,000 times. This corresponds to the fact that luminol is chemiluminescent in alkaline solution only.

The oscillographic studies on the luminescence of luminol solution also confirmed the chemiluminescent origin of the emitted light. Fig. 13 (a) shows a waveform of luminescence of luminol in the upper trace and an output voltage in the lower trace, and Fig. 13 (b) shows those of water. Just as in the case of pure water, discrete luminescence flashes occurred in luminol solution at the phase of minimum bubble volume and were somewhat higher than those of water, and in addition a continuous luminescence appeared. At higher ultrasonic intensities, this discrete flash disappeared and the continuous luminescence became predominant.

The luminescence of luminol solution arised as soon as cavitation was built up by starting the ultrasonic oscillator. When the oscillator was switched off, discrete flashes, of course, disappeared immediately after the cavitation was ceased, but a continuous afterglow remained with a decay time of about 1/20 sec. The result of simultaneous observation of the luminescence of luminol solution and the output voltage of the vibrometer is shown in Fig. 14.

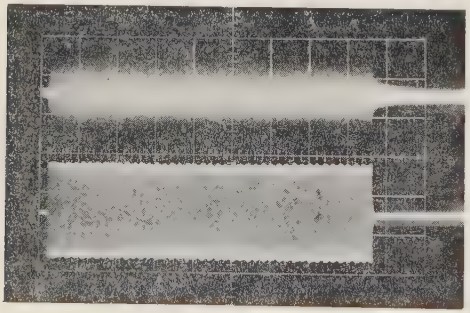

Fig. 14. Luminescence of luminol solution and vibrometer output. Sweep speed = 50 ms/div.

All of these experimental results show that most of light from luminol solution originates from the chemiluminescence of luminol caused by cavitation products, excluding discrete flashes occuring at the phase of the bubble collapse. The discrete flashes are to be attributed to the same origin as in water and aqueous solutions of salts. Presumably the flashes are mostly attributed to the presence of sodium carbonate in the solution. The brightness of luminol solution in ultrasonic fields was not improved by the addition of hemin, showing that the luminescence of luminol solution was chiefly due to the free radicals (OH and others) rather than hydrogen peroxide formed by the ultrasonic cavitation.

The intensity of luminescence from luminol solution somewhat varied with the concentration of sodium carbonate and luminol. Fig. 15 shows the luminous flux from the solution of luminol (concentration 100 mg/1) for various sodium carbonate contents, and Fig. 16 shows the luminous flux *vs.* luminol content curve for 0.1 N sodium carbonate solution. For dilute solutions of luminol (concentration below 0.1 mg/1), the intensity of luminescence decreased rapidly with the sound irradiation time. This is possibly due to the consumption of luminol. In Fig. 16, this concentration range is represented in a broken line.

The relation between ultrasonic intensity and luminous flux from luminol solution re-

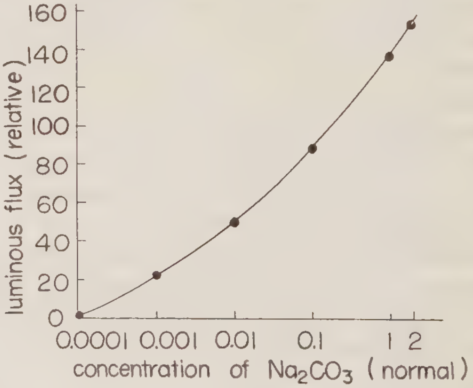

Fig. 15. Luminescence intensity *vs.* sodium carbonate concentration for luminol solution of 100 mg/l in concentration. (Vibrometer output = 40 V)

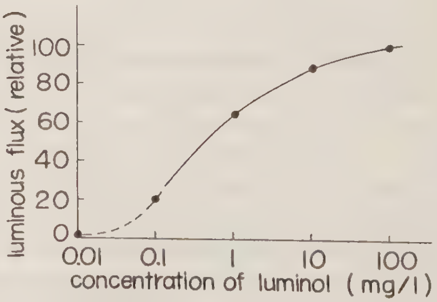

Fig. 16. Luminescence intensity *vs.* luminol content for 0.1 N sodium carbonate solution. (Vibrometer output = 40 V)

sembles that of Fig. 12 except the difference in absolute level, when it is measured with the apparatus of Fig. 10. In the different types of ultrasonic fields, however, different relations are observed as described below.

The ultrasonic intensity *vs.* luminous flux characteristics was studied for a ultrasonic frequency of 470 kc/s with the apparatus shown in Fig. 17. A glass tube 2.8 cm in diameter with a thin polyethylene membrane as the bottom was set so that the focus of a concave transducer was placed in the tube about 1 cm above the bottom. The ultrasonic field in the tube was rather uniform except near the bottom. The concave barium titanate transducer, 8 cm in diameter and 10 cm in focal length, was used by reason of its suitability in suppressing the cavitation in the coupling medium: cavitation causes the waste of ultrasonic power propagating in the medium. By the same reason, degassed water was used as the coupling medium. The luminous flux was measured in relation to the input voltage of the transducer employing a photomultiplier tube placed closely to the glass tube.

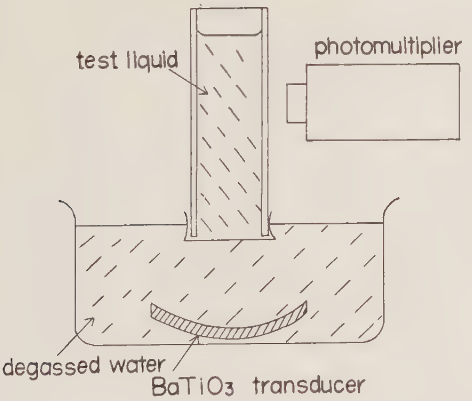

Fig. 17. Arrangement for observation of luminescence at 470 kc/s.

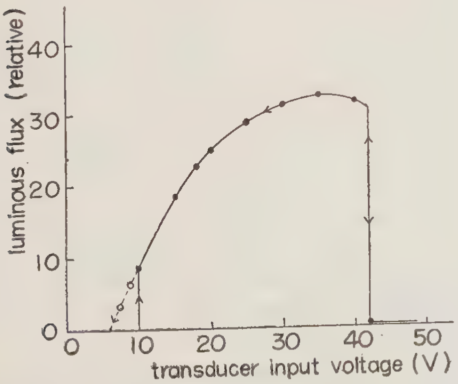

Fig. 18. Relation between ultrasonic intensity and luminescence from luminol solution at 470 kc/s.

The experimental result is shown in Fig. 18. When the input voltage attained to 10 V, the luminescence appeared abruptly, and thereafter its intensity increased with the input voltage up to 30 V. Beyond this, the luminous flux showed a tendency to saturate, but when the input voltage exceeded 42 V, the luminescence suddenly disappeared; no detectable luminescence (or only very faint luminescence) remained above 42 V. If the input voltage of the transducer was decreased from 50 V, the luminous flux varied just as in the case of increasing voltages, but the luminescence remained down to 7 V. This corresponds to the fact that cavitation once occurred has a tendency to be maintained at lower sound intensities than the threshold. The ultrasonic intensity in the glass tube at the input voltage of 42 V was estimated as 2 W/cm² from the measurement of the radiation pressure.

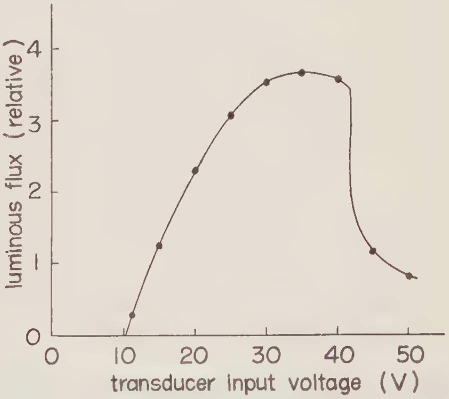

Fig. 19. Relation between ultrasonic intensity and luminescence from aqueous solution of carbon disulfide at 470 kc/s.

The abrupt decrease of luminous flux at high ultrasonic intensities was observed not only in the luminol solution, but also in every sonoluminescent liquids. As an example, the experimental result on the aqueous solution of carbon disulfide is shown in Fig. 19.

It is known that the optimum sound intensity exists for the chemical action of ultrasonic waves, *e.g.* the production of nitrous acid in aerated water, the liberation of iodine from the aqueous solution of sodium iodide, the reduction of potassium permanganate, etc.[25][26]. Although the complete explanation of these phenomena is not yet given, it seems that these phenomena are directly connected with the nature of cavitation. The maximum of chemical yield is observed in experimental arrangements which are essentially the same as Fig. 17. On the other hand, it is reported that in stationary wave system, both chemical yields and luminescence do not decrease at higher ultrasonic intensities, but only saturate[27]. Further discussions will be made in the later section.

§ 6. Discussions on the origin of sonoluminescence

Although no conclusive evidence supporting one of the above-mentioned theories on the origin of sonoluminescence has been discovered as yet, there are many respects in which some of the theories are inadequate. The electrical microdischarge theory proposed by Frenkel[13] now appears to be inadmissible because of the phase relation of sonoluminescence (cf. Table II): according to his account, the discharge should take place through the low-pressure gas in the expanding cavities, whereas sonoluminescence proved to occur during the final stages of the cavity collapse. Furthermore, his assumption of lens-shaped cavity formation has no experimental evidence, and if realized, it may be only in completely degassed water, whereas sonoluminescence occurs only in engassed liquids. The discharge theory cannot be supported also by the fact that no line or band spectra of the dissolved gases have been observed in the spectra of sonoluminescence. The triboluminescence theory and the mechano-chemical theory also seem to be implausible because of the phase relation of sonoluminescence (cf. Table II) and of the assumptions involved in these theories. The balloelectric theory, though consistent as regards the phase relation, also seems implausible. While it is known that the balloelectric charge is highly dependent on the conductivity of the liquids, the sonoluminescence is rather unaltered or enhanced in electrolytic salt solutions as above stated (cf. § 4).

Table II. Moment of flash of sonoluminescence as expected from various theories on its origin

Moment of flash / Theory	Cavity growth	Cavity collapse
(a) microdischarge	○	
(b) mechano-chemical	○	
(c) thermo-chemical		○
(d) hot shot		○
(e) triboluminescence	○	
(f) balloelectric		○

Now it appears to be credible that sonoluminescence is basically thermal in origin. Noltingk and Neppiras[16,17] showed theoretically that a cavity collapses so fast that the gas within it is adiabatically compressed and its temperature increases up to 10,000°K. Such a fast collapse of cavity is accompanied with a shock wave in the liquid phase, as detected by a hydrophone as shown in Fig. 2. These shock waves have also been observed by Bohn[23] and Günther *et al.*[20] The continuous spectra of sonoluminescence observed by Srinivasan[11] and Günther *et al.*[9][10] resemble that of a blackbody radiating between 6,000°K and 11,000°K. (Also the line spectra were observed together with the continuum in aqueous solutions of inorganic salts[10][39]; *e.g.* Na-D-line is observed in NaCl-solution). This is, of course, not a conclusive evidence of the hot spot theory: as indicated by Jarman[22], the spectra of certain chemiluminescence, particularly bioluminescence, also resemble that of the blackbody radiation. However, it seems that no fact directly contradicts to the hypothesis of the thermal origin of sonoluminescence. The phase relation of sonoluminescence decided conclusively by the present work is a strong support of this hypothesis: sonoluminescence does occur during the final stages of the cavity collapse. Probably, a cavity expands and collapses emitting a single flash of light, and a cavity, which expands to a larger size, collapses at a later phase of the pressure cycle accompanying a higher temperature rise and thus a brighter luminescent flash. Therefore, Fig. 7 suggests that cavities successively collapse in order of their expanded sizes emitting flashers of increasing intensity, till finally, the cavities of larger sizes cannot collapse, causing the disappearance of luminescence.

The sonoluminescence from water is quenched if the cavity contains too much water vapour. For the pressure inside the cavity to increase, the molecules of gas and vapour have to strike the collapsing cavity wall and then to rebound. When the molecules of water vapour strike the wall of the liquid water, a large portion of them might be adsorbed on the wall, causing a smaller increase of the pressure and then the quenching of sonoluminescence. The absorption of energy by the dissociation of water molecules also causes the reduction of temperature within the collapsing cavities. The appreciable increase of sonoluminescence from water by the addition of some inorganic salts is possibly due to the vapour-pressure lowering. The quenching effect of sodium hydrogen carbonate is thought to be due to the liberation of carbon dioxide which is known to be a substance quenching the sonoluminescence of water.

Liquids which are highly volatile and immiscible with water, like carbon disulfide, have small affinities with water. Therefore, in the aqueous solution of such a liquid, the pressure inside the collapsing cavities could increase without the adsorption of vapour molecules. Furthermore, the blackbody radiation from the incandesced gas and vapour within the cavities might be enhanced by the presence of solid carbon liberated from the vapour molecules. The analogy between sonoluminescence and luminescence in a shock tube has been indicated by Jarman[22)], and Fairbain and Gaydon[35)] has noticed dusty carbon liberated from carbon disulfide or carbon tetrachloride in the shock tube after shock waves had propagated several times in it. Noltingk and Neppiras[16)] also showed that the temperature inside the collapsing cavity increases in propotion to $(\gamma-1)$, where γ is the ratio of the specific heats. However, γ-values of such vapours shown in Table I are not higher than that of air ($\gamma=1.40$) or water ($\gamma=1.33$) except carbon disulfide. This may suggest that sonoluminescence is not simply a blackbody radiation but also some ionic processes (or dissociation of neutral molecules) as observed in high current density arcs[36)] are to be taken into consideration. In the visible region, high current density arcs through rare gases show high luminous efficiencies particularly in krypton and xenon. This is also true both in sonoluminescence and luminescence in shock tubes.

There is another possible explanation for the enhancing effect of organic impurities: colloidal particles of these hydrophobic organic liquids suspending in water may act as cavitation nuclei causing the occurrence of cavitation to increase.

In summarizing, it is concluded that sonoluminescence is basically thermal in origin: the high temperature occurs in the cavitation bubbles as a result of the adiabatic compression of bubbles when they collapse. The hot spot theory is plausible, though also the thermochemical mechanism is not excluded. Further investigations are desirable to clarify the more detailed mechanism of sonoluminescence and sonic chemiluminescence: accurate observations of spectral lines and bands, particularly in the ultraviolet part will be of some use.

§ 7. Application of luminol to visualization of ultrasonic fields

Many methods of the visualization of ultrasonic fields are known such as optical, chemical, mechanical and electrical methods[28)]. The optical method utilizing the diffraction of light by ultrasonic waves is often used because the image formation is well analysed theoretically and beautiful photographs are obtainable[29)]. Some limitations, however, exist in this method: the applicable frequencies are ordinarily above 0.5 Mc/s and only the images viewed along the direction parallel to the wave fronts are obtained, and furthermore, a special optical apparatus is required. The chemical method, using sonosensitive compounds, are applicable to visualize the intensity distribution on arbitrary section of ultrasonic fields. Reported sonosensitive compounds are thermo-

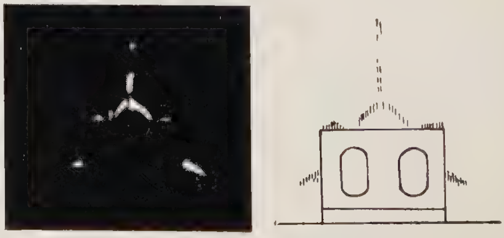

Fig. 26. Ultrasonic cavitation field (left) of a 50 kc/s ferrite transducer (right).

sensitive coloured compounds like mercury silver iodide (Ernst and Hoffmann[30]), thermosensitive phosphors (Schreiber *et al.*[31]), Pétermann[32]), Ernst *et al.*[30]), photographic paper in dilute developer (Torikai and Negishi[33]), starch plate in iodine solution (Bennett[34]), etc. In these methods, however, there exist some disadvantages related to the insertion of sonosensitive screens or plates in ultrasonic fields. In mechanical[40]) and electrical methods[41]), particular image converters are required for the visualization of ultrasonic fields.

A new chemical method of the visualization of ultrasonic fields has been developed here as an application of the sonic chemiluminescence of luminol. In this method—the luminol method, it is possible to observe the three-dimensional structure of the ultrasonic field without giving any disturbance to it. The luminescence from luminol solution is considered to be an instantaneous measure of the oxidation action of ultrasonic waves, so that the observed luminous structure shows, exactly speaking, not the intensity distribution of the ultrasonic fields, but rather the instantaneous distribution of ultrasonic oxidation. Further advantages of this method are that no special optical or other apparatus is required, and that the application of this method is not limited by the shape of the liquid container. The luminol method is thought to be an only adequate method whereby internal fields of vessels like flask can be visualized.

Some disadvantages, however, exist in this method: the luminescence from luminol in ultrasonic fields is so weak that the observation must be made in a dark room, and this method becomes useless for ultrasonic fields in which no cavitation occurs. Then, the applicable ultrasonic frequencies are limited practically up to 5 Mc/s.

There is no critical concentration of luminol or sodium carbonate; for example, 0.2 g of luminol and 5 g of sodium carbonate in 1,000 cc water is of use. If a barium titanate transducer is immersed directly in this solution without electric insulation, it is short-circuited by the electric conduction of the solution, and then its electro-acoustic efficiency is much decreased. Even in such a case, if the frequency of the transducer is higher than 400 kc/s, this method is applicable by reducing the concentration of sodium carbonate until considerable ultrasonic power can be radiated from the transducer. When a lower frequency barium titanate transducer is used, it must be electrically insulated because its impedance becomes higher than the leakage resistance of the solution. Practically, it is desirable to maintain the temperature of luminol solution below 25°C, as the luminescence from luminol decreases with increasing temperature.

Many photographs of ultrasonic fields were taken in a dark room, using a camera with F:2.4 lens and Fuji SSS films (ASA 200). The appropriate exposure time was two minutes or so. Some examples of ultrasonographs taken by the luminol method are shown in Fig. 20 to Fig. 26.

Fig. 20 shows 30 cc test tubes irradiated from the bottom by 500 kc/s ultrasonic waves. The ultrasonic field in the tube never becomes uniform.

Fig. 21 shows a flat-bottomed flask (100 cc) irradiated by 500 kc/s ultrasonic waves. When the ultrasonic waves are irradiated perpendicularly to the bottom, only a small part of the incident ultrasonic power penetrates through it (left photograph). At an appropriate incident angle, however, the bottom becomes more transparent and a larger amount of the ultrasonic power penetrates into the flask (right photograph). At higher ultrasonic intensities, the luminescence from the flask disappears. In experiments on the ultrasonic treatments of liquids, careful attentions must be paid to such phenomena. Some disagreements reported in experimental results of ultrasonic treatment are thought to originate at least partly from these phenomena.

Fig. 22 shows a ultrasonic fountain induced by a 500 kc/s barium titanate transducer (5 cm in diameter) placed on the bottom of 1 liter beaker.

Fig. 23 shows an internal field of a 400 kc/s cylindrical barium titanate transducer (9 cm in inner diameter, 2.6 cm in height). Beautiful concentric circles of stationary wave pattern are noticed.

Fig. 24 shows a interference pattern of 500 kc/s ultrasonic waves in a circular glass tank (24 cm in diameter). The ultrasonic waves, radiated from both faces of the transducer as indicated by arrows, are reflected by the tank wall and then interfere with each other.

Fig. 25 shows ultrasonic fields of a concave barium titanate transducer (470 kc/s, 8 cm in diameter, 10 cm in focal length) at various input voltages. At 20 V, only the focal region luminesces. As the input voltoges are increased, the luminous region spreads towards the transducer, and at 65 V, the whole region of the converging sound beam between the transducer and the focus luminesces but no luminescence is found at the focal region. At 75 V, all luminescence suddenly disappears except at the fringe of the sound field. This shows that the oxidation by ultrasonic waves is suppressed when the ultrasonic intensity is too high. In spite of the difference in sound intensities at various points in the sound field, the luminescence disappears simultaneously not only in the case of the concave transducer (Fig. 25), but also in experiments in the flask and the test tube. This suggests that cavitation occurs somewhat co-operatively at least in high frequency ultrasonic waves.

Fig. 26 shows a cavitation field of 50 kc/s ferrite transducer. The cavitation field in this case looks entirely different as compared with those at high frequencies, the luminous region being mainly restricted on the radiating surface of the transducer and on the axis of the sound beam.

§ 8. Summary

Shock waves caused by the ultrasonic cavitation were detected in water by a miniature spherical hydrophone made of barium titanate. When a few cavitations were produced, the bubble collapse occurred slightly after the pressure maximum of the sound-pressure cycle as shown theoretically by Noltingk and Neppiras. When many cavitations were simultaneously produced, large positive peaks of saw-tooth form appeared in the pressure waveform owing to the superposition of many shock waves. By observing the scattered light from the cavitating bubbles in dark-field illumination, these large peaks were confirmed to occur at the phase of minimum bubble volume.

In this very phase, *i.e.* at the instant of complete collapse of the bubbles, the sonoluminescence from water did occur as discrete flashes of light. The sonoluminescence from aqueous solutions of some sodium salts and some organic liquids were also studied. The addition of heavy, volatile and immiscible organic liquids as carbon disulfide or methyl iodide enhanced the sonoluminescence from water. The luminescence from the alkaline solution of luminol in ultrasonic fields was found to consist of discrete flashes and superposed continuous light. The latter disappeared with a decay time of about 1/20 sec when the ultrasonic waves were turned off. The intensities of both the sonoluminescence from water (or aqueous solutions) and the sonic chemiluminescence of luminol showed peculiar dependence on ultrasonic intensity. The luminescence increased with increasing sound intensity at first, but decreased (or nearly vanished) rather suddenly at a high sound intensity.

The discussion on the origin of sonoluminescence were made and it is concluded that sonoluminescence is basically thermal in origin: the high temperature occurs in the cavitation bubbles as a result of the adiabatic compression of bubbles when they collapse.

As an application of luminescence from luminol solution, a new method for the visualization of ultrasonic fields was developed. This method has the advantage of applicability to the three-dimensional case without giving any disturbance to the fields. Moreover, the application of this method is not limited by the shape of the liquid container.

Experimental Evidence for Frank's Theorem on Dislocations by X-ray Diffraction Micrography

By Mitsuru YOSHIMASTU

Rigaku Denki Co. Ltd., Hajima, Akijima, Tokyo

(Received March 3, 1961)

In X-ray diffraction micrographs of a silicon single crystal, some nodes where three dislocation lines meet were observed. The Burgers vectors of these dislocations were determined, except of their sense, from the change in intensity contrast with different reflecting lattice planes. Frank's theorem, corresponding to Kirchhoff's law for electric current, was experimentally confirmed.

§1. Introduction

It is well known as Frank's theorem[1], corresponding to Kirchhoff's law of electric current, that the sum of the Burgers vectors of dislocations meeting at a node must vanish if each dislocation is considered to go into the node. However, so far as the author knows, it seems that this theorem have not been experimentally confirmed till quite recently. Fujita et al have confirmed the theorem for the graphite crystal by using the moirè pattern of electron micrographs[2].

Although many dislocation lines were almost always observed in the X-ray diffraction micrographs of silicon single crystals obtained by Lang's method, any node has not been observed where several dislocation lines meet. The specimens used previously were cut parallel or vertical to the growth axis and were thin. The probability for a node to be found in the interior of the specimen is considered to be small. It is expected that the chance observing the node is increased if a specimen plate is cut parallel to a plane in which dislocations exist. It is considered that such a situation is realized in the {111} planes oblique to the growth axis. In the X-ray diffraction micrographs of such a specimen, we have observed some points at each of which three dislocation lines meet. From the change in intensity contrast with different reflecting lattice planes, we determined the Burgers vectors of these dislocations and tried to confirm Frank's theorem.

§ 2. Experimental

A specimen of thin plate was prepared from a twinned silicon crystal. The specimen was polished with the carborundum of ♯1600 and etched with the CP-4 solution. The thickness of specimen was 0.65 mm.. The orientation of specimen is shown with a pole figure in Fig. 1.

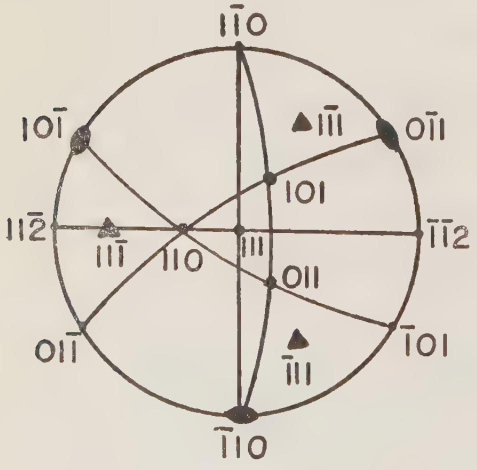

Fig. 1. The pole figure of the specimen. X-ray diffraction photographs are obtained by diffraction from the lattice planes of poles marked by ▲ and ●. The three round great circles show the trace of planes which belong to the pole $[\bar{1}\bar{1}1]$, $[\bar{1}11]$ and $[11\bar{1}]$.

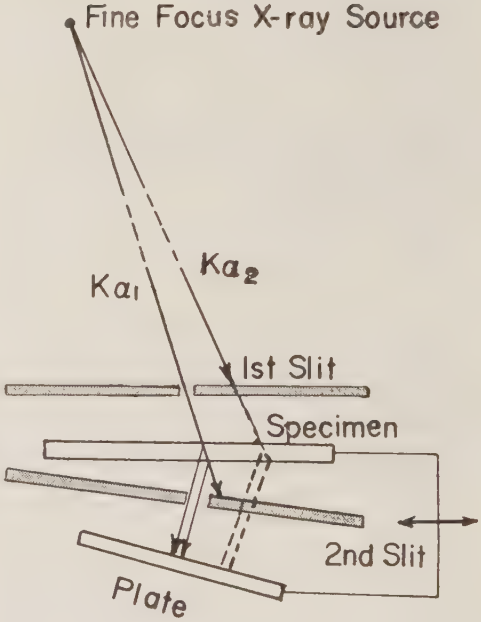
Experimental arrangement is essentially the same as that of Lang[3] except technical details, the schematic diagram being shown in Fig. 2. A fine focus X-ray source of apparent size $40\mu\times30\mu$ is used. The distance from the specimen to the source is about 200 mm., the one from the specimen to the plate, 15～20 mm.. To take a photograph from a wide area of the crystal, the crystal and the plate are moved right and left at the same time by a combination of a gear and a synchronous motor. Deflection of the crystal orientation during translation is within 2 second angular range. The X-ray tube with Ag target was operated with 50 kilo constant voltage and 1 mA.



ig. 2. Schematic diagram of experimental arrangement. The pathes of $K\alpha_1$ and $K\alpha_2$ radiations which are emitted from a point source and diffracted from a lattice plane in the crystal are drawn. The difference in the direction of $K\alpha_1$ and $K\alpha_2$ is exaggerated.

In order to obtain diffraction images with a high resolution, X-rays which contribute to the images must be limited to the $K\alpha_1$ radiation. This can be made possible by using a collimating system with a small angular spread $\Delta\theta < \dfrac{\Delta\lambda}{2d\cos\theta}$, where $\Delta\lambda = \lambda_{k\alpha_2} - \lambda_{k\alpha_1}$, d, lattice spacing and θ, the Bragg angle. In this case, a fine adjustment of the crystal is necessary for realizing the Bragg reflection. Practically, the difficulty of the fine adjustment was avoided in the following way. The slit was at first widely opened. In this case, however, the $K\alpha_2$ as well as $K\alpha_1$ radiations are diffracted from a same lattice plane but at different regions in the crystal, the former resulting in the poor resolution. Next, the width of the first slit was made narrower to cut off the $K\alpha_2$ radiation contributing to the diffraction image.

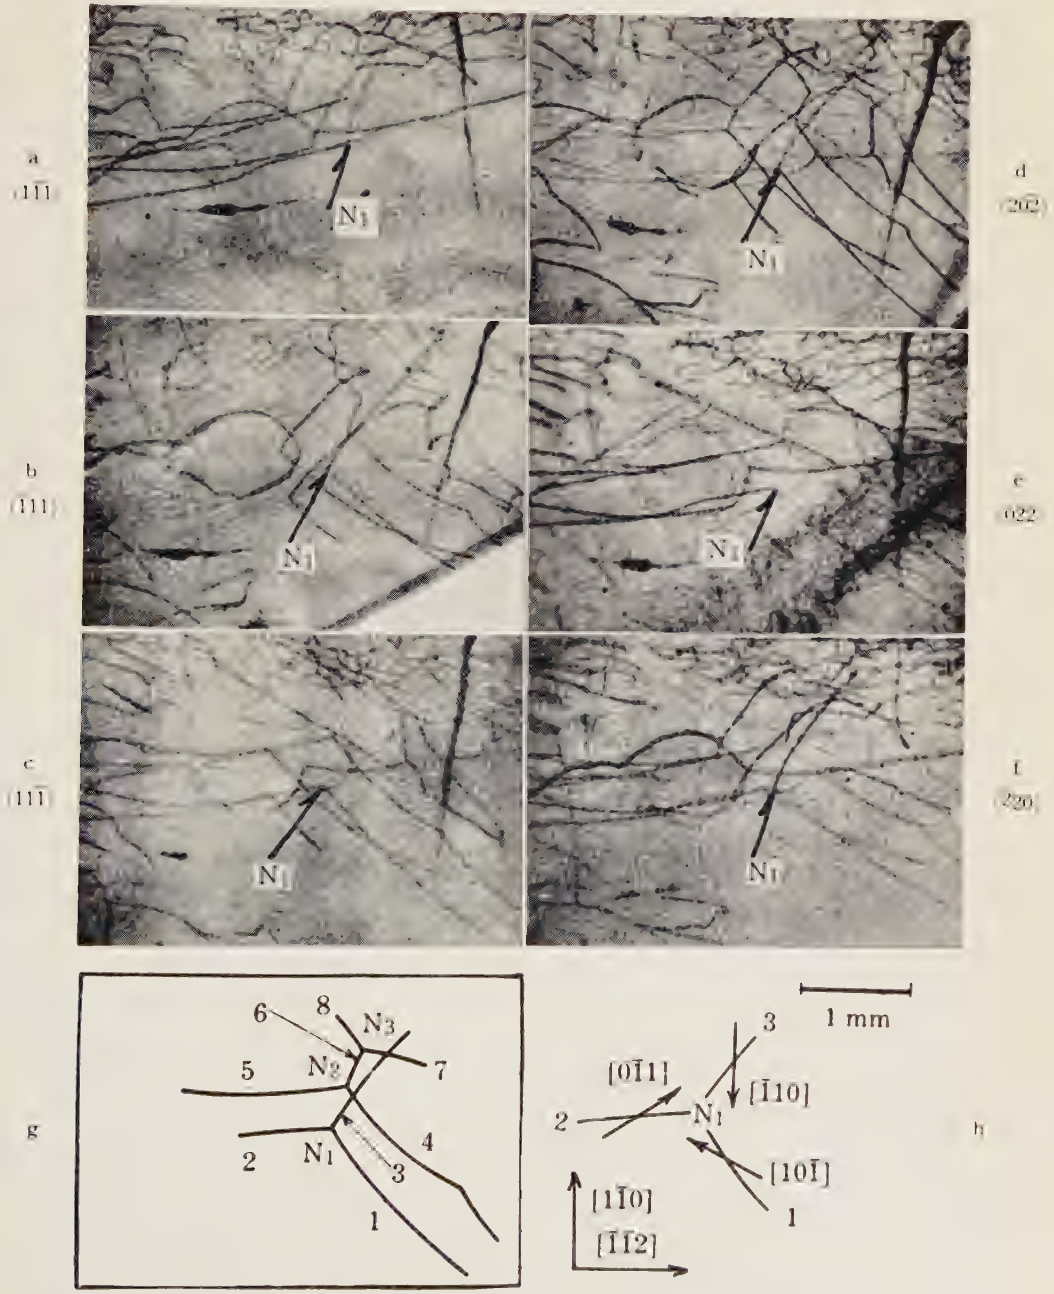


Fig. 3. X-ray diffraction micrographs taken with various reflecting planes. (g) is a schematic drawing of dislocation lines meeting at nodes, being sketched from (d). (h) shows the Burgers vectors of dislocation lines meeting at a node N_1.

§ 3. Results and discussions

X-ray diffraction photographs from the same region of specimen were obtained for various reflecting lattice planes, as shown in Fig. 3. In them some nodes at which three dislocation lines meet are observed. Three sets are shown schematically in Fig. 3 (g).

The Burgers vectors of dislocation lines meeting a node were determined on the basis of following two facts. (i) The intensity contrast due to dislocation lines is considered to be maximum when the Burgers vector is parallel to the normal of reflecting lattice plane; we would call this the maximum condition. (ii) The intensity contrast vanishes when the Burgers vector is vertical to the normal of reflecting lattice plane (the zero condition), although the dependency with the intermediate angle between the Burgers vector and the normal might not be monotonous. The direction of Burgers vector in silicon crystals is usually considered to be parallel to one of ⟨110⟩ directions. Therefore, a dislocation with a certain Burgers vector should represent the highest contrast for one of {220} reflections, for example the (220) reflection, and no intensity contrast should occur for reflection from planes parallel to the [110] direction.

It is practically convenient to examine at first the zero condition for {111} reflections. There are three directions of ⟨110⟩ parallel to one of {111} planes. When a dislocation image is found to vanish for one of {111} planes, for instance, (111), the Burgers vector must be one of three ⟨110⟩ directions parallel to (111). If another one of {111} reflections, for instance, the $(11\bar{1})$ reflection do not reveal the dislocation image, the Burgers vector is determined to be parallel to the intersecting line of the above two planes, the $[1\bar{1}0]$ direction. On the contrary, if the $(11\bar{1})$ reflection reveals the dislocation image, the possibility of the $[1\bar{1}0]$ direction is denied. However, it is not always possible to examine the zero condition for all {111} reflections. In this case, ambiguity is left among a few directions. This ambiguity is removed by examining the maximum condition mentioned above for some appropriate planes of {110}.

Let us notice dislocation lines meeting a node N_1 shown in Fig. 3 (g) and first determine the Burgers vector of the dislocation 1. The dislocation image disappears for the $(1\bar{1}1)$ reflection, Fig. 3 (a), among experimentally observable {111} reflections. This means that the Burgers vector must exist in the $(1\bar{1}1)$ plane according to the zero condition. From the pole figure of the specimen, Fig. 1, it is known that three $[10\bar{1}]$, [110] and [011] directions are parallel to the $(1\bar{1}1)$ plane. On the other hand, the diffraction photographs obtained from the $(\bar{1}11)$ plane and the $(11\bar{1})$ plane clearly show the dislocation image of 1, as seen in Fig. 3 (b) and Fig. 3 (c) respectively. The $(\bar{1}11)$ plane is parallel to [110], and the $(11\bar{1})$ plane is parallel to [011]. Thus, the possibility of the [110] or the [011] directions have been denied, and the $[10\bar{1}]$ direction is left as only one possibility for the Burgers vector. This could not be experimentally comfirmed by the reflection from the (111) plane containing the $[10\bar{1}]$ direction. However, it can be confirmed by the maximnm condition. Fig. 3 (d), (e) and (f) show the experimentally observable {220} diffraction photographs. The $(20\bar{2})$ diffraction photograph obtained from the $(10\bar{1})$ plane vertical to the $[10\bar{1}]$ direction, Fig. 3 (d), shows the highest intensity contrast for the dislocation 1 among them. Accordingly, the Burgers vector of the dislocation 1 is concluded to be parallel to the $[10\bar{1}]$ direction.

In the same way, the Burgers vector of the dislocation 2 and 3 are determined to be parallel to the $[0\bar{1}1]$ and the $[\bar{1}10]$ directions respectively. These three directions are on the same plane (111).

It is to be noticed here that the sense of the Burgers vector cannot be determined from the intensity contrast in the X-ray diffraction micrography. The sense of the Burgers vector of each dislocation has two possibilities. If the sense is taken in such a way as shown in Fig. 3 (h), the sum of the Burgers vectors of above three dislocations vanishes. This fact is no more than Frank's theorem. At least, under a suitable condition mentioned above, Frank's theorem can be experimentally confirmed by a X-ray diffraction micrography only assuming the sense of the Burgers vector.

By the similar procedures, the Burgers vectors of other dislocation lines 4, 5, 6, 7, and 8 in Fig. 3(g) are concluded to be parallel to the directions $[10\bar{1}]$, $[0\bar{1}1]$, $[\bar{1}10]$, $[0\bar{1}1]$, and $[10\bar{1}]$ respectively. Of course, it is apparent that the Burgers vectors of these dislocations satisfy Frank's theorem at each node N_2 and N_3 when the sense of these Burgers vectors is appropriately chosen as in the previous case.

Antiferromagnetism of MnHg

By Yasuaki NAKAGAWA and Tomiei HORI

Department of Physics and Chemistry,
Gakushuin University, Mejiro
Tokyo

(Received February 27, 1961)

The existence of an intermetallic compound of Mn and Hg with an equiatomic composition, MnHg, has been confirmed by Lihl[1] and de Wet[2], as having the simple B2 (CsCl) type of structure. The latter author has also measured the magnetic susceptibility at 90, 195° and 295°K, and suggested that it is probably antiferromagnetic at low temperatures. Since the atomic arrangements in MnHg are similar to those in MnAu[3] and MnPd[4], the detailed studies on the antiferromagnetism may be interesting in view of the theory of magnetism of metals.

In the present note, the experimental investigations are reported on the magnetic susceptibility, the electrical resistivity, and the crystal structure in the temperature range from 90 to 360°K. The specimens used were prepared as follows: pure Hg and the powders of electrolytic Mn were mixed at the desired proportion, sealed in an evacuated quartz tube, heated to 400°C, and then held at this temperature for 35 hours. It was confirmed by the X-ray diffraction patterns that the products consisted of only MnHg.

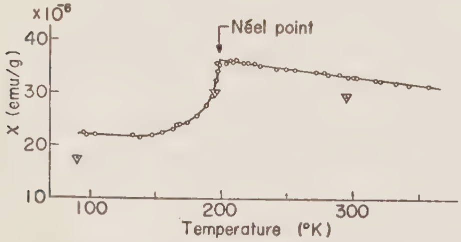

Fig. 1. Magnetic susceptibility, χ, of MnHg. (▽: de Wet[2])

The magnetic susceptibility was measured by Faraday's method. It is independent of magnetic fields up to 12 koe, and the temperature dependence is shown in Fig. 1, in which the values obtained by de Wet[2] are also plotted. The Néel point may be 198°K at which the susceptibility has a maximum value. Above the Néel temperature, however, the susceptibility cannot be satisfactorily expressed by the Curie-Weiss law, i.e. the effective Bohr magneton number derived from the experimental curve is unreasonably large.

The electrical resistivity was determined by means of the measurements of the torque exerted on the small specimen by a 50 cps rotating magnetic field. The apparatus is similar to that reported by Braunbeck.[5] The absolute values of the resistivity were obtained by comparing with the torque exerted on a standard specimen of copper, though the results were not so accurate. The temperature dependence of the resistivity exhibits an anomaly at the Néel point, as shown in Fig. 2.

It was proved by the X-ray diffraction method* that MnHg was not transformed from cubic to tetragonal structure at low temperatures, in contrast to MnAu and MnPd. The lattice constants determined from the (110) lines are also shown in Fig. 2.

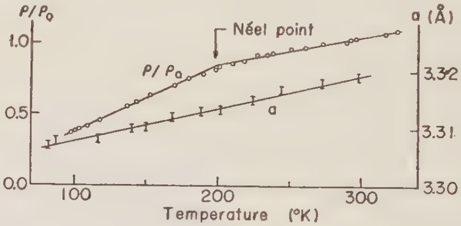

Fig. 2. Electrical resistivity, ρ, and lattice constant, a, of MnHg. Resistivity at 0°C, ρ_0, is about $5\times10^{-5}\,\Omega$ cm. Crystal structure is of the CsCl type.

It may be concluded from the above experiments that MnHg is antiferromagnetic at the temperatures below 198°K.

On the Faraday Effect in Many-Valley Semiconductors

By Louis Gold

Radiation Laboratory and the Department of Nuclear Engineering University Michigan, Ann Arbor

(Received April 10, 1961)

In developing the complete classical electrodynamics for free carriers in many-valley semiconductors, a new relation for the Faraday rotation has been deduced which reveals the imprecise nature of earlier formulae. Since there is active research continuing in such materials as n-germanium1), it appears appropriate to make immediately available a basic relation which properly describes the phenomenon.

The general formula, including collisional damping, will be left for a fuller description. In the infrared region where collisions may be ignored in the usual manner, the index of refraction μ may be written in the form

$$\mu^2=1-\frac{2x^2}{[\ ]_3\mp\sqrt{[\ ]_3{}^2-4([\ ]_1[\ ]_2-[\ ]_4)}} \tag{1}$$

where the abbreviations denote

$$[\ ]_i=a_{ii}+\frac{a_{i3}{}^2}{x^2-a_{33}} \qquad \text{for } i=1,\,2$$

$$[\ ]_3=a_{11}+a_{22}+\frac{a_{13}{}^2+a_{23}{}^2}{x^2-a_{33}}$$

$$[\ ]_4=\frac{w_c{}^2}{\omega^2}+\left(a_{12}+\frac{a_{13}a_{23}}{x^2-a_{33}}\right)^2 \tag{2}$$

and

$$x^2=\frac{3N_0q^2/m_2}{\omega^2}\,, \qquad \omega_c=\frac{3qB}{m_2}$$

The basic physical quantities that enter are: ω the impressed frequency, N_0 the carrier density in each valley, q the electronic charge and m_2 the transverse mass.

The a_{jk} relate to the transformed mass tensor in the frame of reference where the magnetic field $\vec{B}$ is along the z-axis which also corresponds to the direction of wave propagation. The components in the cubic reference frame

$$\overleftrightarrow{m}_{\text{cubic}}=\frac{1}{3}m_2(a_{jk}) \tag{3}$$

where

$$a_{11}=a_{22}=a_{33}=K+2$$
$$a_{jk}=a_{kj}=S_i(K-1)\,,$$
$$i\neq j\neq k\neq i\,, \qquad K=m_1/m_2 \tag{3a}$$

transform via

$$a_{jk}=\frac{\partial x_j}{\partial x_{j'}}\cdot\frac{\partial x_k}{\partial x_{k'}}a_{j'k'} \tag{4}$$

Specification of the separate contributions to the rotation for the four sets of energy surfaces derives from selection of the S_i having values ±1 as described elsewhere2). If the chemical potential changes at high magnetic field producing a redistribution of electrons, then each valley must be accordingly weighted (allowance also being made for N_0 changes in x2).)

It may be seen that the familiar Appleton-Hartree relation obtains from (1) if the scalar mass limit is imposed. Thus in the usual way, the choice of sign specifies either the ordinary or extraordinary circularly polarized component of the wave. Prior relations, such as that of Stephen and Lidiard3), bear little resemblance to (1) and do not reduce to the Appleton-Hartree formula for an isotropic mass medium.

Finally, a resonance behavior may be expected in the Faraday rotation since for the extraordinaay component large changes occur when

$$\omega^2=\frac{1}{2}\,\omega_p{}^2\,\frac{A_1\pm\sqrt{A_1{}^2+(\omega_c{}^2/\omega_p{}^2)A_2}}{A_2}\,,$$

$$\omega_p{}^2=\frac{3N_0q^2}{m^2} \tag{5}$$

wherein

$$A_1=a_{12}{}^2-a_{11}a_{22}-\frac{\omega_c{}^2}{\omega_p{}^2}a_{33}$$

$$A_2=a_{11}a_{23}{}^2+a_{22}a_{13}{}^2+a_{33}a_{12}{}^2-(a_{11}a_{22}a_{33}+2a_{12}a_{13}a_{23}) \tag{5a}$$

Precisely these critical frequencies (resonances) were derived earlier4) in an effort to comprehend how magnetoplasma effects may influence cyclotron resonance determinations; it was pointed out then that new peaks would appear in the intermediate region where $\omega_c/\omega_p \sim 1$, the regime $\omega_p \ll \omega_c \sim \omega_p$, however, corresponding to "pure" cyclotron resonance.

Passage Effect in the Electron Spin Resonance of Fe-Doped Silicon

By Takeo IGO
Electrical Communication Laboratory
Musashino-shi, Tokyo

(Received May 15, 1961)

Recently Weger[1] investigated the effect of passage upon the ESR signal of an inhomogeneously broadend line. He studied shape and amplitude of the signal under various passage conditions theoretically and checked the theoretical predictions experimentally.

It is reported here that a passage effect was observed in the ESR of Fe-doped silicon[2],[3] and the relaxation time, T_1, was estimated from the passage conditions.

In Fig. 1 is shown the dispersion signal in-phase with respect to the modulation obtained at pumped helium temperature (~2°K) with a p-type sample of silicon into which Fe was diffused at 1100°C for about an hour. The signal is obtained by superimposing a modulation field at a frequency of 70 cps on the static magnetic field and then detecting the real part of the rf susceptibility which varies at this frequency using a phase sensitive detector.

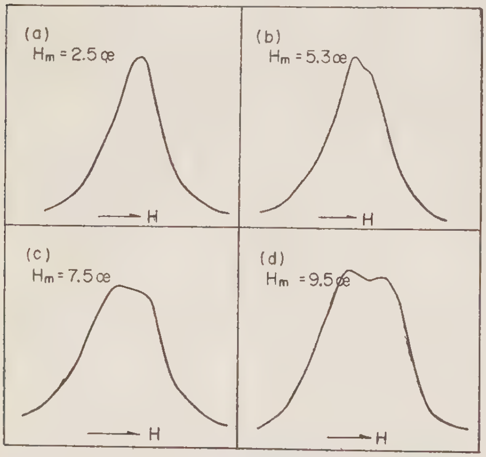

Fig. 1. In-phase dispersion signal in Fe-doped silicon as a function of magnetic field for several values of H_m. The static magnetic field is parallel to [$\bar{1}$01] direction. $T \approx 2$°K.

It is clear from Fig. 1 that the signal in-phase with respect to the modulation behaves unusually when the modulating field intensity, H_m, increases. When H_m is small, it has a typical line shape for an adiabatic rapid passage line, with a g-value of 2.07 independent of the crystal orientation and a half-width of about 10 oersteds. When H_m is increased, the line shape changes as shown in the figures (b), (c) and (d). At intermediate H_m-values, the top of the line is flattened, and then the saddle appears at large H_m-values. The in-quadrature signal, however, showed no such an unusual behavior. These behaviors of signals, according to Weger,[1] can be expected for an inhomogeneously broadend line with T_1-short compared with, or of the same order as, the modulation period. When H_m is small, all the spin packets covered by H_m are traversed (adiabatically) rapidly and an "absorption-type" signal is observed. As H_m is large enough, however, the adiabatic condition is violated over a portion of the modulation cycle. Then a "dispersion-derivative-type" signal arises from the non-adiabatically traversed spin packets. Since this "dispersion-derivative-type" signal is in-phase with respect to the modulation, it does not mix in the in-quadrature signal, but it mixes in the in-phase signal, yielding the observed results.

Occurence of such a passage effect depends on the ratio $H_1/\omega_m H_m T_1$. If we increase the rf field intensity, H_1, the unusual behavior should occur at at a larger value of H_m. This was verified experimentally. This and the fact that the DPPH marker signal was quite normal exclude the possibility that our observation is due to an instrumental effect. (Because the phase-setting was discrete, the phase was not exactly set to in-phase or in-quadrature position. The positions was determined by maximizing or minimizing the marker signal.)

The conditions under which the above passage effect occurs are (assuming $T_2 = T_1$):

$$(H_1/\omega_m H_m) < T_1 , \qquad \omega_m T_1 \ll 1 ,$$

$$\gamma H_1 T_1 \gg 1 , \qquad \gamma H_1^2 \gtrless (dH/dt) .$$

We can estimate T_1 from these conditions. In our estimation T_1 is of the order of 10^{-4} sec. T_1 is also determined directly from the saturation measurement. Preliminary saturation measurements gave a value of the same order as the above as T_1.

It is a pleasure to thank Mr. T. Asakawa for preparing the samples. I wish to express my thanks to Dr. T. Shindo and Dr. E. Yamaka for their interest in this work.

Logarithmic Growth of the Cesium Antimonide Films on Antimony

By Kiyoshi MIYAKE

*Electrical Communication Laboratory, Nippon Telegraph and Telephone Public Corporation, Tokyo, Japan**

(Received January 23, 1961)

The reaction of cesium vapor with antimony film is a kind of reaction in which an electro-positive gas, namely, cesium vapor makes contact with antimony film which behaves as an electro-negative metal, followed by the formation of cesium antimonide. The compound has a very high resistivity, and has been suggested to be CsSb.[1),2)] The present note deals with experimental determination of the growth rate of this compound film.

Antimony was evaporated in a cylindrical glass envelope on to a square glass plate. A U-shaped trap for cesium vapor and a tube containing metallic cesium were connected to the one end of the glass envelope. The evaporation was carried out at room temperature in a vacuum better than 3×10^{-8} mm Hg, the rate being 0.01-0.002 mg per cm^2 per min.[3)] The film thickness ranged from 250 to 1100 A. Such films are known to be crystallized.[4)] The original resistance of the film was calculated from the dimensions (4×10 mm) and the electrical resistivity in bulk. The resistance between two leads attached on the opposite edges of the glass plate was measured prior to the reaction.

The resistivity of CsSb grown on the surface of antimony is about 10^7 times that of antimony in bulk.[1),2)] Hence it may be assumed that the resistance of the film is, at least in the early stage of the reaction, equal to that of the unaffected antimony film. If the compound layer is homogeneous, the thickness of the layer should be proportional to that of the antimony layer consumed by the reaction. We assume, for the time, that these are identical, although an increase in thickness of the film during the formation of cesium antimonide has been reported.[5)] Thus, the thickness of the growing layer can be determined from the measurement of electrical resistance.

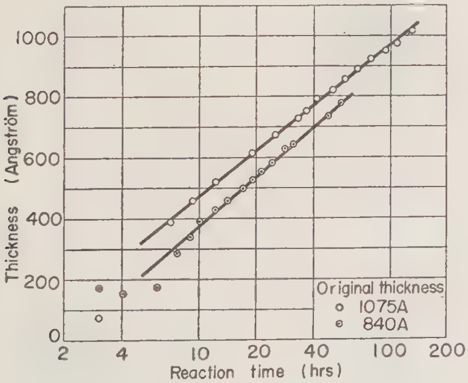

Fig. 1. Thickness of the CsSb layer grown on antimony films *vs.* the reaction time.

The measurement was carried out at room temperature in complete darkness and under conditions in which the rate of supply of the cesium vapor was higher than the formation rate of the compound. Fig. 1 shows the thickness of the compound layer grown on antimony film *vs.* the logarithm of time. As is seen in the figure, the relation between the thickness x, in A, and time t, in hours, is given by

$$x=k\log(t/c+1)\,, \tag{1}$$

where, k and c are constants. Usually, there is an induction period for the reaction, which is slightly longer than c. For one specimen and for $t\gg c$, the relation between x and t is well represented by Eq. (1). However, the values of k and c differ for different samples. The former ranged between 310 and 520 A, and the latter between 1.1 and 3.2 hrs. For thin films ($x<300$ A) and for the induction period the observed points are scattered.

Eq. (1) no longer holds when the thickness of the unaffected antimony layer is reduced to less than about 50 A, and a comparatively long time is required for the whole layer to be changed into the compound. Therefore, the formation process of the compound in this stage is considered to be different from that in the early stage. The variations in k and c for different samples may be due to the difference in microscopic surface conditions and in crystalline structure of the films.[6)]

Electron Distribution in $KMnF_3$, $KFeF_3$, $KCoF_3$ and $KNiF_3$

By Atsushi OKAZAKI and Yasutaka SUEMUNE
Department of Physics, Faculty of Science, Kyusyu University, Fukuoka, Japan

(Received March 4, 1961)

The structures of $KMnF_3$, $KFeF_3$, $KCoF_3$ and $KNiF_3$ are of the cubic perovskite type at room temperature[1], while that of $KCuF_3$ shows the Jahn-Teller distortion.[2] The electron distributions in the former four compounds are determined by an X-ray analysis. The experimental and analytical details are similar to those in the case of $KCuF_3$ [2]. For these compounds the [001] projections of the electron distribution obtained by the F_0 synthesis are shown in Fig. 1, where F_0 means the observed structure factor. In all the cases the electron distributions around F^- ions are elongated in the direction perpendicular to the 3*d* metal-fluorine-3*d* metal bonds. This elongation may be attributed either to anisotropic temperature effects or to the fact that the centre of F^- ion occupies such positions as being distributed with uniform probability along a circle. The analysis is now being undertaken.

A Note on the Magnetoresistance of PbTe at High Magnetic Fields

By Eizaburo YAMADA and Kisaburo SHOGENJI
Hitachi Central Research Laboratory,
Kokubunji, Tokyo

(Received March 27, 1961)

At high magnetic fields the magnetoresistance of crystals is known to show an oscillatory behavior as a function of H. This phenomenon is due to the quantization of the electron orbits, and the degeneracy of the electrons is necessary for its appearance. PbTe crystal is favorable for investigation of this phenomenon, since its electrons have a large mobility and are degenerate at low temperatures. Recently an experiment has been carried out by Kanai *et al.*[1]. We comment here theoretically on this phenomenon.

When a high magnetic field ($\omega_c\tau \gg 1$), whose direction is chosen as z-axis, is applied to a crystal and the electrons of the crystal are degenerate, the conductivity tensor due to an energy ellipsoid with anisotropic effective mass is expressed as[2]

$$\sigma=\left|\begin{array}{ccc} \frac{\alpha_{xx}}{\alpha_1}\frac{Se^2}{m\omega_0{}^2\tau} & -\frac{ne^2}{m\omega_0}+\frac{\alpha_{xy}}{\alpha_1}\frac{Se^2}{m\omega_0{}^2\tau} & \frac{\alpha_2}{\alpha_1}\frac{ne^2}{m\omega_0}+\frac{\alpha_{xz}}{\alpha_1}\frac{Se^2}{m\omega_0{}^2\tau} \\ \frac{ne^2}{m\omega_0}+\frac{\alpha_{xy}}{\alpha_1}\frac{Se^2}{m\omega_0{}^2\tau} & \frac{\alpha_{yy}}{\alpha_1}\frac{Se^2}{m\omega_0{}^2\tau} & -\frac{\alpha_3}{\alpha_1}\frac{ne^2}{m\omega_0}+\frac{\alpha_{yz}}{\alpha_1}\frac{Se^2}{m\omega_0{}^2\tau} \\ -\frac{\alpha_2}{\alpha_1}\frac{ne^2}{m\omega_0}+\frac{\alpha_{xz}}{\alpha_1}\frac{Se^2}{m\omega_0{}^2\tau} & \frac{\alpha_3}{\alpha_1}\frac{ne^2}{m\omega_0}+\frac{\alpha_{yz}}{\alpha_1}\frac{Se^2}{m\omega_0{}^2\tau} & \frac{\det\alpha}{\alpha_1}\frac{Se^2\tau}{m} \end{array}\right|, \qquad (1)$$

$$\omega_0=\frac{eH}{mc}, \qquad \omega_c{}^2=\alpha_1\omega_0{}^2, \qquad \alpha_1=\alpha_{xx}\alpha_{yy}-\alpha_{xy}{}^2 \qquad \text{etc.},$$

where α_{ij}'s are dimensionless constants which represent relative inclination of H to the principal axes of the ellipsoid. S and τ are the density of states and the relaxation time respectively. Both are functions of the Fermi level ζ and show a periodic variation with $1/H$.

PbTe has a cubic symmetry and its electronic band structure is expressed by <111> 8 or 4 valley model.[3),4)] When H is applied in the [100], [111] or [110] direction of PbTe, non-vanishing elements of conductivity tensor of the crystal are: σ_{xx}, σ_{yy}, σ_{zz} and the anti-symmetric part $\sigma_{xy}=-\sigma_{yx}$. These are obtained by summing up the elements of Eq. (1) for all the valleys. The elements of the resistivity tensor become as

$$\left.\begin{array}{ll} \rho_{xx}=\sigma_{xx}/(\sigma_{xx}\sigma_{yy}+\sigma_{xy}{}^2)\,, & \rho_{zz}=1/\sigma_{zz}\,, \\ \rho_{xy}=\sigma_{xy}/(\sigma_{xx}\sigma_{yy}+\sigma_{xy}{}^2)\simeq 1/\sigma_{xy}\,. & \end{array}\right\} \qquad (2)$$

From Eqs. (1) and (2) ρ_{xx} is known to be proportional to $S\tau^{-1}$, ρ_{zz} to $(S\tau)^{-1}$, whereas ρ_{xy} independent of S and τ. Thus ρ_{xx} and ρ_{zz} show an oscillation, but ρ_{xy} does not.

In spite of the above discussion, the Hall coefficient of Bi shows an oscillation[5)]. The reason, we think, is as follows. In Bi $p \simeq n$, so the leading term of σ_{xy} becomes small, and the oscillation is due to higher order terms of H^{-1} which are neglected in the above.

The period of oscillation is determined by the cyclotron mass $m_c=\alpha_1{}^{-1/2}m$, which is a function of the relative direction of H with respect to the ellipsoid. The variation of ρ_{xx} and ρ_{zz} is generally superposition of the oscillations having different periods, each of which has its origin in one of the valleys. The periods of PbTe are shown in Table for several directions of H.

Table. The periods of oscillation due to each valley. $\Delta(1/H)$ in $e\hbar/m_\perp c\zeta$. $r=m_\perp/m_{/\!/}$.

Valley \ Direction of H	[001]	[111]	[110]
[111], $[\bar{1}\bar{1}\bar{1}]$	$\sqrt{\frac{r}{3}(1+2r)}$	1	$\sqrt{\frac{r}{3}(2+r)}$
$[\bar{1}11]$, $[1\bar{1}\bar{1}]$	$\sqrt{\frac{r}{3}(1+2r)}$	$\sqrt{\frac{r}{9}(1+8r)}$	r

Optical Constants of LiF in the Extreme Ultraviolet

By Riso Kato

Department of Physics, Faculty of Science, Kyoto University

(Received April 26, 1961)

Reflection and absorption spectra of LiF single crystal were reported in a previous work[1]. Detailed analyses and discussions could not be made, however, because the previous data contained fairly large errors. Data were refined by improving the reflectometer and by careful treatment of specimen surface. Fig. 1 shows the reflection and absorption spectra refined in the present work.

LiF becomes transparent below 11.8 ev and the reflection from the back surface of specimen contributes to the reflectivity in the region. Consequently the observed reflection spectrum shows the minimum and maximum near the tail of fundamental absorption as seen in Fig. 1. The previous data were disturbed by the hydrolysis of crystal surface, because LiF was found to be easily hydrolysed slightly above room temperature in air to give a broad absorption ranging from 12 to 8 ev. The values of relectivity in the transparent region were corrected by the theory of multiple reflection and the phase associated with the reflection characteristic was computed by using Kramers-Kronig relation to get the optical constants from the reflectivity. Corrected values of reflectivity fitted very well with those calculated from known refractive indices in the near ultraviolet. Reflectivities in the region above 13.2 ev contain rather large errors as shown in Fig. 1 and were adjusted so as to give zero absorption in the transparent region in the course of phase computation. The full line in Fig. 1 shows the reflection spectrum, corrected in the above way, used for phase computation.

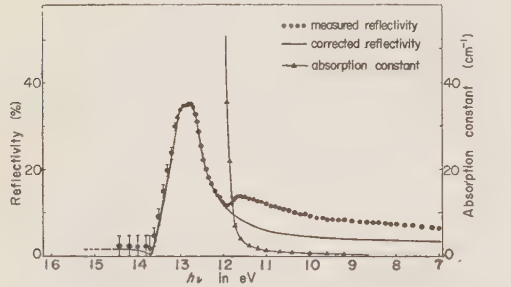

Fig. 1. Reflection and absorption spectra of LiF single crystal measured at room temperature.

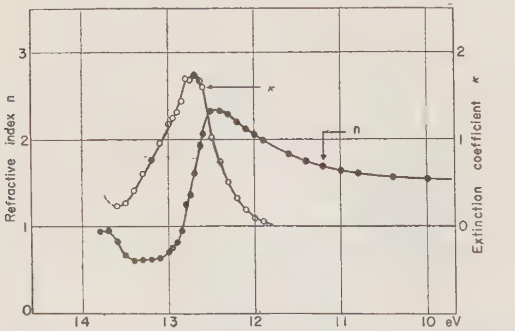

Fig. 2. Refractive index and extinction coefficicnt of LiF *versus* photon energy.

Variations of the refractive index and extinction coefficient *versus* photon energy calculated from the phase and reflectivity are plotted in Fig. 2. The absolute value of absorption constant ($K=4\pi\kappa/\lambda$) and the peak position of the first exciton band at room temperature were obtained as follows: $K_{\max}=2.2\times10^6\ \mathrm{cm}^{-1}$ and $h\nu=12.7\pm0.1$ ev.

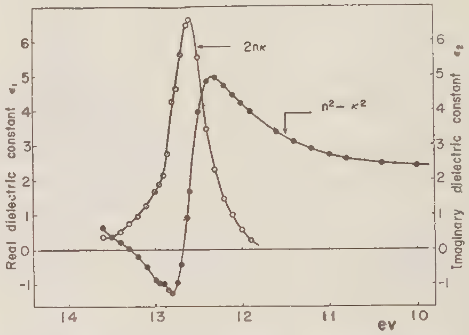

Fig. 3. Real and imaginary parts of dielectric constant of LiF *versus* photon energy.

Real and imaginary parts of dielectric constant ($\varepsilon_1=n^2-\kappa^2$, $\varepsilon_2=2n\kappa$) are plotted in Fig. 3 and the oscillator strength of the present band is obtained from the following formula

$$2n\kappa=\sum_i \frac{\omega_p^2 f_i \omega\beta_i}{(\omega_i^2-\omega^2)^2+\beta_i^2\omega^2},$$

assuming that only $i=0$ term is effective in the region. Constants in the formula $\hbar\omega_0=12.6\pm0.1$ ev, $\hbar\beta_0=0.42\pm0.02$ ev are obtained from Fig. 3 and $\omega_p^2=4\pi Ne^2/m$. The obtained value is 0.069 ± 0.005/electron or 0.42 ± 0.03/ion, which is in good agreement with the theoretical value on NaCl calculated by Dexter[2] on the basis of excitation model.

Details of the experiment and analyses as well as the effect of hydrolysis will be reported in a near future.

Temporary Bleaching of Color Centers in KCl Crystal

By Masamitsu HIRAI, Mikihiko IKEZAWA
and Masayasu UETA

*Department of Physics, Faculty of Science,
Tohoku University, Sendai.*

(Received May 4, 1961)

Alkali halide crystals colored additively or by X-ray irradiation exhibit several electron captured centers called *F*, *M*, *R* and *N*. Among these centers only *F* has been clarified by Pick[1] to have the property to trap one more electron and convert to *F′* center at low temperature. Concerning other complex centers, there may be possibilities of electron trappings to form *M′*, *N′* etc. on the analogy of *F*→*F′*. However, there are no detailed experiments showing such facts so far we know. It will be due to the thermal unstability of the trapped electrons. The short life trapping states of electron will be observed by the temporary absorption changes of complex centers under the simultaneous illumination of F-light which produces free electrons. Ingenious techniques of temporary bleaching were first adopted by Lambe and Compton[2] and successively by Compton and Klick[3] in NaCl.

A KCl crystal additively colored and containing *F* centers with a concentration of 2.7×10^{16}/cc was cleaved to a piece of $6\times7\times10\,\text{mm}^3$. The crystal was illuminated by F-light at room temperature so as to produce *M*, *N* and *R* centers as shown in Fig. 1 curve (a). The crystal was cooled down to 90°K and was illuminated by a intense dc incandescent lamp filtered to produce *F* band light. The absorption change of the crystal in the region between 400 mμ and 1100 mμ was measured with a chopped light of 8 cps to avoid the error due to the scattered illuminating F-light. Absorption measurements were performed along the direction perpendicular to the illuminating F-light. Curve (b) in Fig. 1 shows the temporary change of the transmission of the crystal thus measured. The ordinate indicates the increase of transmission expressed by arbitrary unit.

As seen from the figure, with the decrease of *F* band, *M* and *N* bands also decrease. The transmission-decrease in the whole region between 500 mμ and 750 mμ is considered to be due to the formation of *F′* band.

Curves (F), (M) and (N) in Fig. 2 show the rates of transmission-increases with time in *F*, *M* and *N* bands, respectively. In the case of *F* band, transmission increases gradually after the start of F-light illumination and it decreases a bit after the illumination is turned off. However, if the crystal is illuminated with red light covering *F′* absorption band region, the transmission of *F* band returns to the initial value. In cases of *M* and *N* bands, after the F-light is turned off, transmissions return to the value before the illumination. Moreover, in the case of *M* band, the decay of the transmission is slower than that in *N* band.

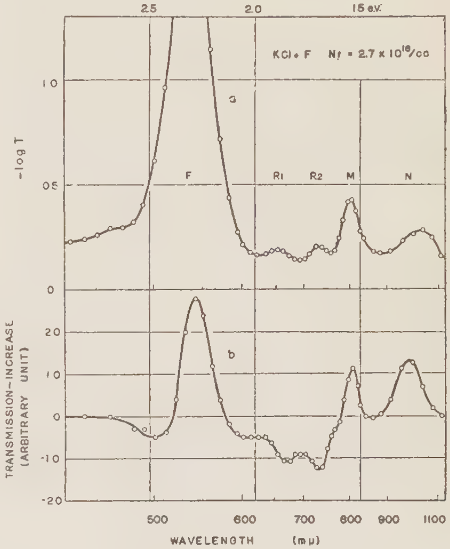

Fig. 1. a: The absorption curve of the crystal containing *F*, *M*, *R* and *N* centers at 90°K.
b: The temporary increases of the transmission of the crystal illuminated with *F*-light at 90°K.

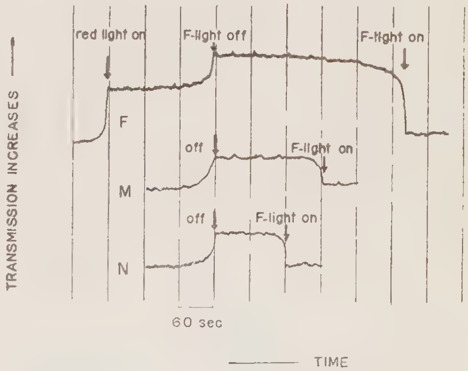

Fig. 2. The transmission changes with time in *F*, *M* and *N* bands.

These facts may show that electrons released from *F* centers are trapped temporarily by *M* and *N* centers forming *M′* and *N′*-type centers and cause decreases of *M* and *N* bands. The *M′* and *N′*-type centers are quite unstable at 90°K and *N′* center is more unstable than *M′*.

The detailed studies of color centers by the temporary bleaching have beeing carried out in KCl crystals in various stages of center formation.

Magnetic Annealing Effect in Cobalt

Takashi SAMBONGI and Tadayasu MITUI

Department of Physics, Faculty of Science,
Hokkaido University

(Received May 1, 1961)

Recently, Takahashi and Kōno1) observed that a ferromagnetic anisotropy is induced in Co when annealed in magnetic field. In this effect the allotropic transformation of Co at 417°C2) seems to play an important rôle. The present study was made for the purpose of making clear the origin of this anisotropy induced by magnetic annealing.

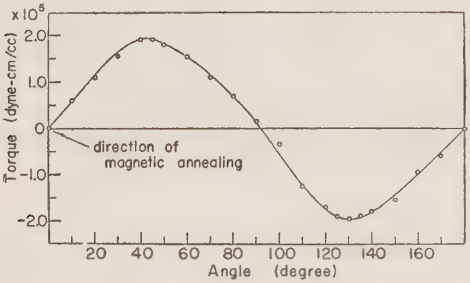

Fig. 1. Torque curve measured at room temperature.

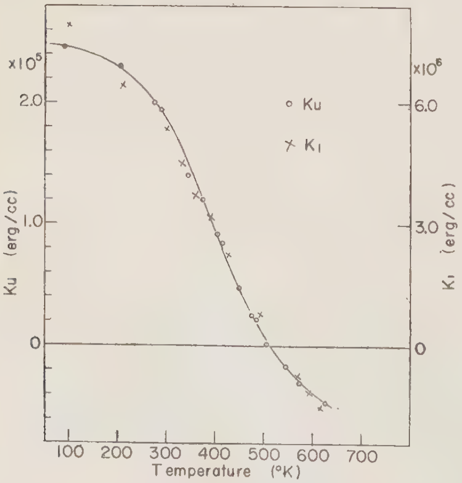

Fig. 2. Temperature dependence of the induced anisotropy, compared with the crystal anisotropy energy measured by Sucksmith and Thompson.

Several polycrystalline specimens were prepared from Co metal of ca. 99.3% purity. After melted in vacuo and annealed at 1000°C, they were machined into disc shape of ca. 15 mm in diameter and ca. 1 mm in thickness. The specimens were annealed at 600°C for 2 hours, and then cooled with cooling rate about 5°/min, in an applied magnetic field of about 8 KOe from above the transformation temperature. Torque curves were measured in effective magnetic field of about 10 KOe by an air-bearing torque magnetometer at room temperature.

An example of them is shown in Fig. 1, which shows a uniaxial anisotropy with the direction of easy magnetization perpendicular to that of magnetic field applied on cooling.

The temperature dependence of the induced anisotropy energy K_u was measured over the temperature range from 90°K to 700°K, compared with the crystal anisotropy energy K_1 measured by Sucksmith and Thompson3) as shown in Fig. 2.

From this result one can deduce the origin of the induced anisotropy. As well known, on the transformation of Co, one of the 4 sets of the {111} plane of f. c. c. phase is conserved parallel to the (00·1) plane of h. c. p. phase, so there are possibilities that one f. c. c. grain is transformed into at most 4 h. c. p. grains of different orientation. When applied magnetic field, each grain will transform preferentially so that the f. c. c. (111) plane of the least angle to the direction of magnetic field should be parallel to the h. c. p. (00·1) plane. So the orientation of h. c. p. grains is no longer completely random and a uniaxial anisotropy is observed with the direction of easy magnetization perpendicular to that of magnetic annealing when measured below 250°C.

In this mechanism the magnetic field may play some rôle only in the process of developing the stacking faults, nuclei of h. c. p. phase4), which lie in the f. c. c. (111) plane with the least angle to the direction of magnetic field.

We propose that contribution of crystal anisotropy energy to the mechanism of this effect may be more important than that of magnetoelastic energy in the dynamics of the allotropic transformation of Co.

The detail will soon be published in this journal.

Mössbauer Effect of the Intermetallic Compound UFe_2

By Shigehiro Komura, Nobuhiko Kunitomi,
Poh-Kun Tseng, Naomoto Shikazono
and Hidekuni Takekoshi
*Jepan Atomic Energy Research Institute,
Tokai-mura, Ibaraki-ken*

(Received May 23, 1961)

In the previous note[1] the intermetallic compound UFe_2 has been found to be ferromagnetic with Curie temperature at 195°K. The magnetic moment associated with this ferromagnetism has also been determined to be 1.13 Bohr magnetons per molecule of UFe_2, magnetic moment contributions of each constituent atoms, uranium and iron, are still left to be clarified.

In our present investigation the hyperfine field at the position of Fe^{57} nuclei in UFe_2 has been measured by means of Mössbauer effect. The transmission through the powdered UFe_2 sample of 14.4 kev gamma-ray emitted from Co^{57} incorporated in silicon has been observed at liquid nitrogen temperature as a function of the velocity of gamma-ray source. The UFe_2 sample used for the present experiment is the same one as that prepared in the magnetic measurement[1].

The absorption lines for UFe_2, stainless steel and metallic iron at room temperature as well as that for UFe_2 at liquid nitrogen temperature have been measured for comparison as shown in Fig. 1. The spread of six absorption lines observed for metallic iron at room temperature which are shown schematically in the Fig. 1c) corresponds to the hyperfine field of 330 koe[2] and are taken to be the standard of hyperfine field. One of six absorption lines for metallic iron illustrated in the Fig. 1c) gives the linewidth of the both natural and instrumental origin which is independent of the hyperfine field.

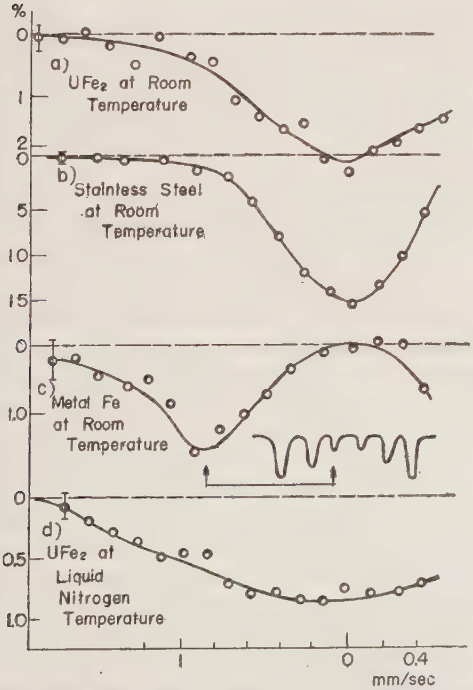

Fig. 1. Absorption spectra obtained with Fe^{57} in UFe_2 and with some other samples as references.

The estimated value for the hyperfine field at the position of Fe^{57} nuclei in UFe_2 at room temperature has been determined from the observed linewidth of Fig. 1a) to be 20 ± 8 keo which is slightly larger than that for stainless steel at room temperature shown in Fig. 1b). The value for the hyperfine field at the position of Fe^{57} nuclei in UFe_2 at liquid nitrogen temperature has also been found from Fig. 1d) to be 65 ± 8 koe which may be compared consistently with the value for the magnetic moment of 1.13 Bohr magnetons per molecule of UFe_2.

The absorption pattern for UFe_2 at liquid nitro-temperature does not resolve into six lines but spreads broadly. Contrary to the expectation from the fact that the intensity of the two outer-most absorption lines is three times larger than that of two central lines in usual Mössbauer experiment of Fe^{57}, the both ends of the pattern decrease gradually with the velocity of the gamma-ray source. This indicates that the hyperfine field of Fe^{57} in UFe_2 may take the fluctuating values below 65 koe. The reason for this is still uncertain because of the possible oxidation of the UFe_2 sample during Mössbauer experiment and the insufficient resolution of the measurement.

The investigation of neutron diffraction for UFe_2 which are now being carried out in our laboratory may clarify the magnetic moment of each constituent atoms in UFe_2 and the origin of the fluctuating hyperfine field further.

The present authors are indebted to Mr. Y. Hamaguchi for his valuable discussions.

On Radiations from Plasma in a Static Magnetic Field

By Kenji Mitani and Hiroshi Kubo
Yoshida College, Kyoto University

(Received March 3, 1961)

Gross[1] and Bernstein gave a dispersion relation for plasma oscillation in a static magnetic field. Kato[3] observed the above oscillations in a weak magnetic field. Here it is reported that the radiation which seems to be associated with their theory have been found. Measurements were carried out, by use of a 3 cm microwave radiometer[4], on extraordinary waves radiated from the plasma perpendicularly to the applied magnetic field.

Fig. 1 shows the resonance curves obtained. In each curve, a minor peak appears on each side of the main peak, which, for various reasons, can be considered to be the cyclotron radiation, and will be called C-type peak. Of minor peaks, one on the left-hand side of the mine peak will be called P_1-type peak and the other P_2-type peak. The magnetic field intensity of P_1-type peak is weaker than that of C-type, while the magnetic field intensity of P_2-type is stronger than that of C-type.

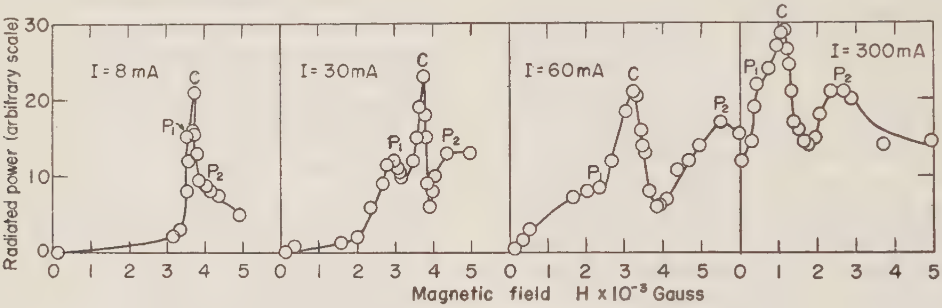

Fig. 1. Resonance curves for various discharge currents.

In Fig. 2, the square of the normalised magnetic strength giving the maximum intensity γ^2 is plotted against the normalised number density of electron η, where γ is defined as the ratio of the cyclotron frequency ω_c to the microwave frequency ω, and η the ratio of the square of the plasma frequency $\omega_p{}^2=4\pi e^2N/m$ to ω^2, in which e, m and N are the charge, mass and number density of electron. N's are the values measured by the probe method in the absence of magnetic field, and then reduced to the case in the presence of magnetic field. In this figure, the crosses (×) show the experimental values for C-type, the solid circles (●) for P_1-type and the open circles (○) for P_2-type; and the solid curve C is obtained from the theoretical relation $\gamma^2=1-\eta$ for cyclotron resonance, where the collision is neglected because its effect is not significant.

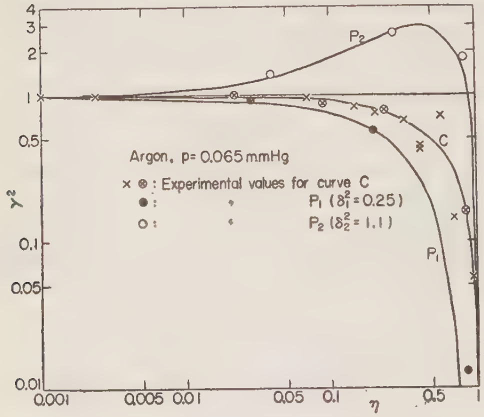

Fig. 2. Dispersion relations for C-, P_1- and P_2-type radiation. The points ●, ○ and ⊗ correspond respectively to the experimental peak values P_1's, P_2's and C's in Fig. 1.

Now the P-type radiation (the radiation at P-type peak) will be compared with the theoretical results by Gross, who gave a dispersion relation for plasma oscillation in a static magnetic field:

$$1-\eta=\tfrac{1}{2}(\gamma^2+\delta^2)\pm\tfrac{1}{2}[(\gamma^2-\delta^2)^2+4\eta\gamma^2]^{1/2}\ ,$$

where δ is ck/ω, in which c is the light velocity and k the wave number in plasma; δ is also expressed by λ/λ_p, in which λ and λ_p are wavelengths in free space and in plasma. Furthermore in the above equation, the positive sign is adapted for $\delta^2<1$ and the negative for $1<\delta^2$. The solid curves P_1 and P_2 were calculated from the above equation for $\delta^2=0.25$ and $\delta^2=1.1$ respectively. These curves agree well with the experimental results. From these values of δ^2, the wavelength of P_1-type and P_2-type peaks are calculated to be about 6 cm and 3 cm in plasma, these values being harmonic in the ratio of 2:1.

Furthermore, it is found in our experiment that, when the P-type radiations exist, the power of cyclotron radiation were several decibels above the level of black body radiation.

In conclusion, it seems most reasonable to relate the P-type radiation with Gross's expression. The authors greatefully acknowledge their indebtedness to Professor S. Kojima at University of Education for his encouragement and helpful discussion. The authors' thanks are also due to Professor I. Takahashi at Kyoto University for his kind suggestion and discussion.

Magnetic Annealing of Cobalt

By C. D. GRAHAM, JR.

General Electric Research Laboratory
Schenectady, New York

(Received March 8, 1961)

Takahashi and Kōno have reported very large negative values of the uniaxial magnetic annealing anisotropy K_u in cobalt, and have suggested that this anisotropy is associated with the cubic-to-hexagonal phase change which occurs near 400°C.[1] This note presents a more detailed mechanism for the magnetic annealing, and describes an experiment which confirms the proposed mechanism.

Face-centered-cubic cobalt transforms martensitically to hexagonal cobalt in such a way that the [0001] direction of a hexagonal grain is parallel to a <111> direction of its parent cubic grain.[2] Since there are four <111> directions in a cubic grain, there are four possible orientations for a hexagonal grain within each cubic grain; normally, all four orientations should occur with equal probability. However, in the presence of a saturating magnetic field there will be an energy difference of (K_1+K_2) between hexagonal grains with [0001] axes parallel and perpendicular to the applied field. Here K_1 and K_2 are the first and second crystal anisotropy constants of hexagonal cobalt, at the transformation temperature. At 400°C, according to the data of Sucksmith and Thompson,[3] this energy difference amounts to about 1.6×10^6 erg/cm³, and acts to favor hexagonal grains with [0001] axes perpendicular to the applied field $[(K_1+K_2)<0]$. Thus the presence of a strong field during the transformation should tend to produce a fiber texture in a polycrystalline cobalt sample, with [0001] directions approximately perpendicular to the field applied during cooling. This fiber texture is froxen into the material at all lower temperatures and causes the observed uniaxial anisotropy.

Just below the transformation temperature, the induced uniaxial anisotropy K_u will be positive; that is, the easy direction will be parallel to the field applied during cooling. At about 300°C, the crystal anisotropy (K_1+K_2) goes through zero and becomes positive for lower temperatures; the induced anisotropy K_u must also go through zero at this temperature, since the induced anisotropy results only from the presence of a crystallographic texture in the material. Below 300°C, K_u must therefore be negative, meaning that the easy axis is perpendicular to the field applied during cooling. For all temperatures below the transformation, the temperature dependence of K_u should be the same as that of the crystal anisotropy (K_1+K_2), except that K_u will be negative when (K_1+K_2) is positive, and vice versa.

To test this hypothesis, an untextured polycrystalline cobalt disk, 12.5 mm in diameter by 0.125 mm thick, was cooled in a hydrogen atmosphere from about 900°C to room temperature with a field of 3000 Oe applied along a diameter. A torque curve measured at 10,000 Oe after this treatment showed the presence of a uniaxial induced anisotropy with $K_u=-200{,}000$ erg/cm³, which is about three times larger than the value given by Takahashi and Kōno. This uniaxial anisotropy was then determined as a function of temperature from room temperature up to 325°C, by immersing the sample in a heated silicone oil bath while measuring the torque curves. The results are shown in Fig. 1, along with the values of (K_1+K_2) taken from Sucksmith and Thompson. Both curves go through zero just below 300°C and both are nearly linear with temperature, thus confirming the prediction of the model. The curve of K_u vs. temperature was retraced exactly on returning to room temperature, indicating that no permanent structural changes

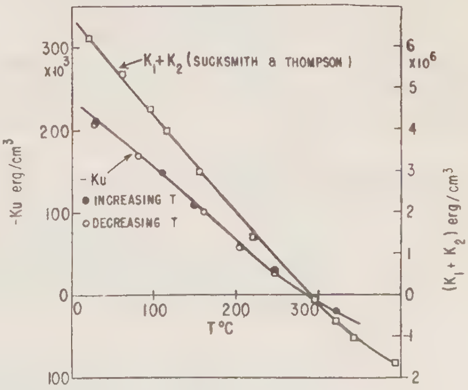

Fig. 1. Induced anisotropy K_u and magnetocrystalline anisotropy (K_1+K_2) vs. temperature.

had occurred on heating.

The measured anisontropy of 200,000 erg/cm^3 at room temperature is about 6% of the value predicted by this model if an initially untextured cubic material is transformed completely to hexagonal cobalt with the maximum possible fiber texture. The predicted torque curves for the induced anisotropy are not exactly of the form $-K_u \sin 2\theta$, largely because of the influence of the K_2 term; the measured torque curves appear to be quite accurately $\sin 2\theta$ in form. The difference is presumably due to smearing out of the ideal texture assumed in the calculation.

I am grateful to J. D. Livingston and J. M. Lommel for helpful discussions of the problem.

Drift Mobility of Photo-Injected Electrons in Hexane-Silicone Mixture

By Pyon-un CHONG and Yoshio INUISHI

College of Engineering, Osaka University, Osaka, Japan

(Received May 9, 1961)

As was reported previously[1) 2)], drift mobility μ of photo-injected electrons in n-Hexane and in Benzene has following characteristics.

(1) They do not show any field dependency upto 0.5 MV/cm being 1×10^{-3} cm^2/sec. V for Hexane and 0.45×10^{-3} cm^2/sec. V for Benzene at 20°C.

These magnitude are much smaller than the value for perfect free electrons in inert liquids[3)].

(2) With decreasing viscosity due to increasing temperature, drift mobility μ increases following a kind of Stokes type law

$$\mu = \mathrm{k}\cdot\eta^{-n} \qquad (1)$$

n is 2 for n-Hexane and 1.5 for Benzene.

From these experimental facts the migration of either attached negative ions or polaron-like electrons following injection of electrons from cathode was speculated to be the mechanism of the conduction in pure liquid.

To clarify these points further, several experiments[4)] have been continued by us with the same apparatus which was described in our previous papers.[1) 2)]

In this paper the mobility of photo-injected electrons in n-Hexane-Silicone oil mixture will be mentioned. The Silicone oil used has mean molecular weight 1200 and viscosity 6×10^{-2} poise at 20°C.

By mixing n-Hexane and the Silicone at various proportion, it has been possible to vary the viscosity of the mixture for a wide range. Fig. 1 shows the dependence of the drift mobility of photo-injected carrier on the viscosity of the mixture. Although mobility decreases with increasing viscosity, it is not possible to cover all range by simple Stokes law (1) with constant n.

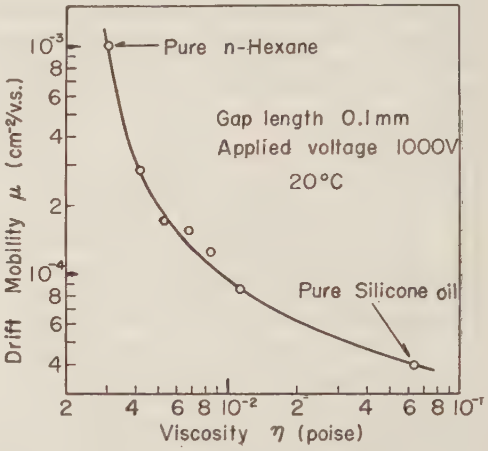

Fig. 1. The relation between μ and η in n-Hexane Silicone oil mixture.

For larger Silicone content n is almost equal to 1 and Stokes type law (1) seems to be valid. These situations may be possibly due to larger electron attachment cross section in Silicone and negative ion migration produced by attachment. On the contrary, the mobility in pure Hexane seems to be abnormally higher than the value obtained from extrapolation of the mixture value. Measurement in n-Hexane vapour shows little attachment. Accordingly we may speculate the migration of polaron in pure Hexane. Initial steep decrease of the mobility with increasing Silicone might be related to the attachment due to Silicone or impurities in Silicone.

Magnetic Domain Observation of $BaFe_{12}O_{19}$ by Faraday Effect

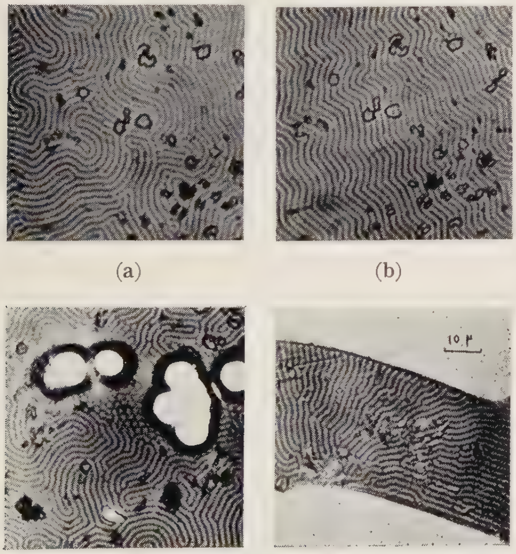
By Hiroshi KOJIMA and Kimiyoshi GOTO

The Research Institute for Scientific Measurements, Tohoku University, Sendai, Japan

(Received March 14, 1961)

Magnetic domain of $BaFe_{12}O_{19}$ after magnetizing at various field was observed by Faraday effect. Small single crystals have been prepared by the similar method as Brixner1). That is, 1.67 g Fe_2O_3 with 55 g $BaCl_2$ in an alumina crucible was heated at 1250°C for 4 hr in O_2 stream and cooled at the rate of 5°C/hr to room temperature, then the mixture was washed with hot HCl solution. After magnetic separation black magnetic crystals about 2–3 mm in diameter were obtained and their X-ray powder pattern was in agreement with ASTM File Card 7-276. From these crystals, thin platelets 1–10μ in thickness were selected under microscope and fixed on an ordinary coverglass of 0.15 mm thick with Cemedine.

Domain structure on c-plane was observed by a polarising microscope. The colour of transparent platelets for tungsten lamp were dark red to yellowish orange according to their thickness, so that the contrast of the domain can be increased with red or orange filter. After applying various fields domain structure was observed at elevated temperature up to 250°C without magnetic field. Fig. 1 shows the domain structures of the platelets, 6.0μ thick and the following results were obtained from these investigations:



(a) (b)

(c) (d)

Fig. 1. Domain patterns of $BaFe_{12}O_{19}$.
(a) demagnetized state,
(b) after applying 8190 Oe parallel to c-axis,
(c) ‘trapped’ cylindrical domain near holes,
(d) nucleation center after applying 5760 Oe.
Magnification is same for all photographs.

(1) Labyrinth pattern was observed for demagnetized crystal, ((a)).

(2) Comparatively parallel domain was observed after magnetized at high field ((b)), and the critical field from which, opening of the hysteresis loop occurs, was about 6000 Oe and rather high comparing with the results of Kooy and Enz2). After decreasing the field from the region between 2440 Oe and 5760 Oe, the specimen may take the mentioned both kinds of patterns at random case by case.

(3) Cylindrical domain, which is stable only at higher field as reported by Kooy, was often ‘trapped’ near crystal imperfection, i.e. hole, edge or sometimes even in the middle of plane surface, ((c)).

(4) Parallel domain usually spreads from a nucleation center but some crystals have no center at all. These domains were essentially straight but slightly waved and the period became larger when the applyed field was increased.

(5) Saturation field became naturally much higher, if the field was applyed perpendicular to c-axis. In this case, after magnetizing just below saturation, ‘crushed’ labyrinth along the direction of applyed field was observed, which shows that the domain wall parallel to the field is more stable than the perpendicular one.

(6) Domain could hardly observed at 250°C due to the decrease of contrast but increase of domain width could be clearly followed up to about 200°C.

(7) Calculated thickness3) of the platelets from the domain width was reasonable comparing with the value measured by microscope but the increasing rate of domain width during heating was fairly larger than the theoretically expected one.

Details will be published in the near future.

The Growth of Zinc Sulphide Single Crystals from Flux

By Yo MITA

Research Laboratory, Nippon Electric Company, Kawasaki, Japan

(Received April 24, 1961)

As zinc sulphide is a material that evaporates at the temperature far below the melting point, normal solidifying crystallization technique fails. The single crystals of it are generally obtained by evaporation or vapour-reaction method. The growth from solutions has not been reported so far except hydrothermal synthesis[1] because of the difficulty in obtaining fluxes or solvents that are suitable for this purpose. On the other hand it is well known in the case of phosphor firing that the addition of a few percent of flux, such as alkali halides, promotes the crystallization of phosphor particles. However, the size of the obtained crystals is extremely small and rarely exceeds ten microns.

Attempts have been made to grow single crystals of zinc sulphide with considerable size, using sodium chloride as solvent flux. The schematic figure of the furnace used in the experiments is illustrated in Fig. 1. The growing apparatus is composed of double quarts tubes, the inner of which contains about 100 grams of sodium chloride as flux and ten grams of luminescent pure zinc sulphide powder as starting materials. The outer tube is at first sealed and evacuated at 200°C for a few hours for dehumidification. Then it is warmed up to about 1070°C in the atmosphere of dried nitrogen, where it is held at least ten hours. The system is subsequently cooled at the rate of 10~20 deg/hr above the transition point at 1040°C and then cooled with much faster rate. The crystals are grown as the result of spontaneous nucleation and subsequent growth in the flux or on the surface of the ZnS powder. Most crystals are needle-like with maximum size about 10 mm in length and 0.2 mm in diameter. However, if the system has been warmed up above 1100°C, no needle-like crystals can be obtained, owing presumably to the abrupt change in crystal habit.

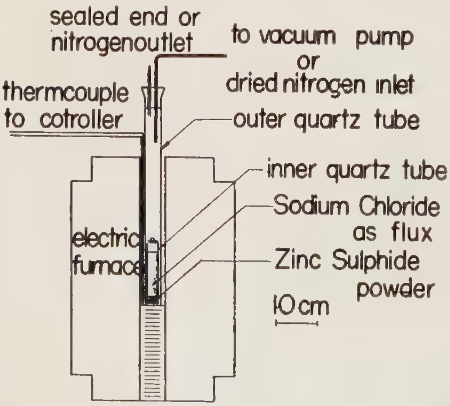

Fig. 1. Cross section of the furnace and growing devices.

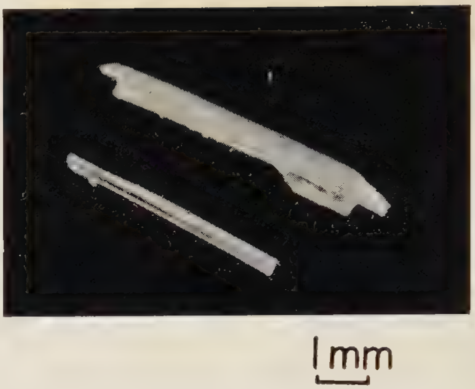

Photo. 1. Single crystals of zinc sulphide.

The X-ray and polarising microscope examinations indicate that the structure of these crystals is mainly wurtzite type, and that their long axis coincides with crystallographic *c*-axis. Mixed structure is found, however, in the crystals that have been slowly cooled beyond the transition point.

Spectroscopic analysis shows the presence of sodium of the amount from 0.05% to 0.5%. It also detects the traces of Fe, Cu, and Si which are supposed to have come from flux.

The crystals show very weak luminescence of yellow-green when irradiated with 3650Å UV light. The emission colour, however, changes to blue-white with increasing exciting light intensity. The phosphorescence is always yellow-green in both cases.

The yellow-green emission seems presumably due to accidental impurities. Another emission of blue-white, may be attributed to host crystals activated with chlorine.

The author would express his sincere gratitude to Dr. Osamu Harashima, who has guided and encouraged him, and to Mr. Ichizo Uchida for his continuous support and valuable discussions.

Effect of Neutron Irradiation on Carrier Lifetime in Si

By Kenji MATSUURA and Yoshio INUISHI
Faculty of Engineering, Osaka University

(Received May, 9, 1961)

The effect of neutron irradiation on the carrier lifetime τ in silicon and its annealing process were observed.

Single crystal specimens of N-type Si were irradiated with thermal neutrons in No. 16 hole of Japan Research Reactor No. 1. After a dose of 1.1×10^{15} nvt, the decay in photo-conductivity at room temperature with X_e light pulse (1 μS) excitation was observed by microwave absorption method.[1) 2)] As shown in Fig. 1, the decay curve shows fast recombination decay component (τ_r) and slow thermal release component (τ_t) without D. C. bias light shining, but the longer decay time component disappeared under strong external bias light illumination. Accordingly shallow trapping centers (which were not found before irradiation) must have been introduced in Si by neutron irradiation. These shallow trap formation was not found in case of γ-irradiation. By measuring temperature dependence of slow decay time constant τ_t, energy levels of these shallow traps were found to locate at 0.17 ev above the valence band (or below the conduction band) for 40 Ω cm, Sb-doped pulled Si, whereas 0.11 ev in 20 Ω cm floating zoned N-type Si.

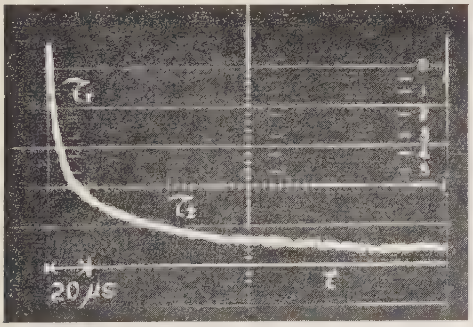

Fig. 1.

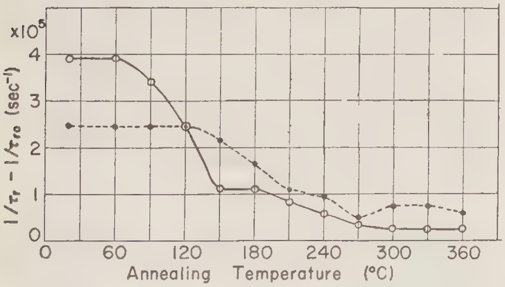
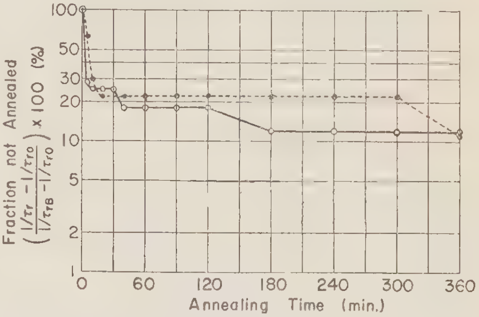


Floating zoned N type Si: Solid line —○—
(τ_{r0}=21 μS. resistivity before irrad.=20 Ω·cm)
Pulled N type Si (Sb doped): Dotted line ---●---
(τ_{r0}=40 μS. resistivity before irrad.=40 Ω·cm)

Fig. 2. Isochronal annealing of two different kind N type Si, following 1.1×10^{15} nvt neutron irradiation. Annealing time of these crystals is ten minutes at each temperature. (τ_{r0} is the recombination lifetime before neutron irradiation.)



Annealing Temperature=250°C
Floating zoned N type Si: Solid line —○—
(τ_{r0}=15 μS, resistivity before irrad=20 Ω·cm)
Pulled N type Si: Dotted line ---●---
(τ_{r0}=14 μS, resistivity before irrad=40 Ω·cm)

Fig. 3. Isothermal annealing curves of a pulled N-type Si and a floating zoned N-type Si following 1.1×10^{15} nvt neutron irradiation. (τ_{r0} and τ_{rB} are the recombination lifetimes before and jus tafter neutron irradiation, respectively)

The isochronal and isothermal annealing curves of recombination lifetime τ_r are shown in Fig. 2 and Fig. 3 respectively. The annealing curves seem to consist of 2 steps as shown in Fig. 2 and Fig. 3. The activation energy for pulled Si seems to be a little larger than that for floating-zoned Si, and the lifetime is more deeply damaged in the latter than in the former at the same nvt. The abnormal peak in annealing curve which was found in pulled Si in the case of γ-irradiation[2)], was not found in this case.

The relation between lifetime damage and A-center formation is being investigated.

Ferromagnetism of the Intermetallic Compound UFe_2

By Shigehiro KOMURA, Nobuhiko KUNITOMI,
Yoshikazu HAMAGUCHI and Masanobu SAKAMOTO
Japan Atomic Energy Research Institute,
Tokai-mura, Ibaraki-ken

(Received May 23, 1961)

The intermetallic compound UFe_2 has been known to be ferromagnetic[1], but no detailed observation of the magnetic properties of UFe_2 has been reported. In this study the magnetic properties of UFe_2 has been investigated for the temperature range from 300°K down to 100°K and it has been found that UFe_2 really shows an evidence of ferromagnetism with Curie temperature at 195°K.

The materials used for the sample were 99.9% metallic uranium and 99.9% electrolytic iron. The quantities of materials according to the formula UFe_2 were melted together in vacuum with an induction furnace in a crucible of sintered alumina. The materials were held at 1300°C for an hour, then cast into a graphite vessel and cooled down naturally to room temperature. The sample has been proved to be stoichiometric within 1% by chemical analysis and no extra lines other than UFe_2 have been observed in X-ray diffraction patterns.

The temperature variation of magnetization of UFe_2 under various magnetic fields up to 6.5 koe has been measured over the temperature range from 225°K to 104°K and replotted isothermally as a function of field as given in Fig. 1. By extrapolating the plots to zero field at each temperature by means of the least square method using the formula

$$J(H, T)=J(O, T)+aH-b/H^2\ ,$$

the temperature dependence of the spontaneous magnetization of UFe_2 has been obtained as shown in Fig. 2. The Curie temperature of 195°K and the spontaneous magnetization at absolute zero of 18.0 emu/g and hence the effective Bohr magneton number of 1.13 per molecule of UFe_2 have been determined from Fig. 2.

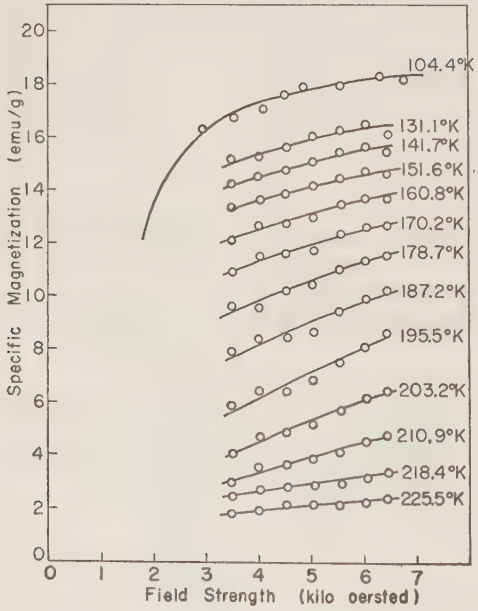

Fig. 1. Magnetization curves of UFe_2 at various temperatures.

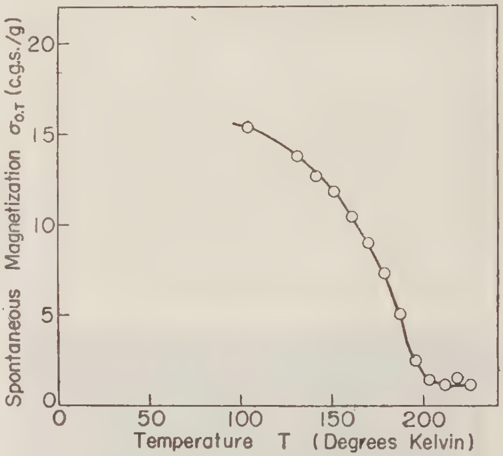

Fig. 2. Spontaneous magnetization vs. temperature curve of UFe_2.

It is interesting to compare the present result with that for the antiferromagnetic UMn_2[2] which shows lambda type anomaly of susceptibility at 260°K with a small parasitic ferromagnetism below 230°K. As UMn_2 and UFe_2 are isostructural, the study of the ternary alloys of these three elements may reveal some interesting information concerning the electronic structure and are now in progress in our laboratory.

The authors express their thanks to Mr. H. Watanabe for the sample preparation and to Mr. H. Motohashi for-X-ray analysis.

Oscillations in a Plasma in a Weak Magnetic Field

By Shoji KOJIMA, Eiichi KAWASAKI* and Kiyoe KATO

Tokyo University of Education, Otsuka, Tokyo

(Received April 8, 1961)

One of the authors (K. K.) reported the plasma type oscillations in a bounded plasma in a weak external magnetic field[1]. Here similar experiments are performed at somewhat different conditions, and standing waves between electrodes are observed. These happen when either the discharge tube has the cathode of a good electron emission or the pressure of the tube is sufficiently low.

The discharge tubes were filled with mercury vapour. When the pressure of the tube was about 10^{-4} mm Hg, the oscillations were detected by a super-regenerative detector adjusted to the frequency of 714 Mc. A result is reproduced as a function of discharge current I_p and of magnetic field strength H in Fig. 1. The intensities of oscillations I_n which were measured simultaneously on a oscilloscope are also shown in the same figure. It is found from these results that the oscillations have large dependence on the discharge current, but small on the magnetic field except for quenching at $f_d = n \cdot f_c$, where f_d is the frequency of the detector and f_c the electron cyclotron frequency. Such oscillations were investigated in detail in the region from 250 gauss to 450 gauss when the pressure was 8×10^{-4} mm Hg and it was observed that they have the fine structure as shown in Fig. 2. Then, the existence of the standing waves between electrodes was verified and numbers of half-waves were measured by a movable probe. The obtained number is indicated at the corresponding oscillation in the same figure. The fine structure seems to be originated from change o the number.

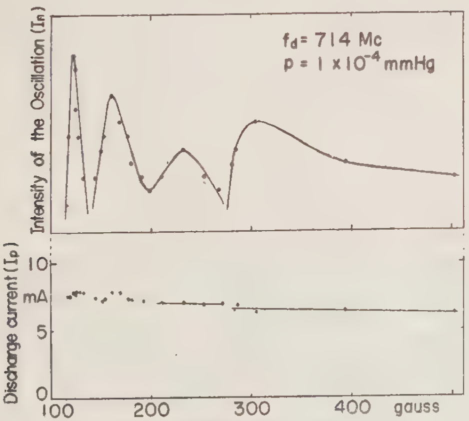

Fig. 1. Plots of discharge current *vs.* external magnetic field strength for the oscillations of constant frequency, and change of intensity of of the oscillation.

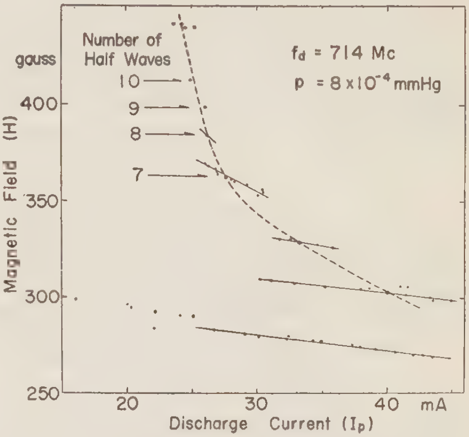

Fig. 2. Plots showing relation of magnetic field strength and discharge currents which generate the oscillations of 714 Mc.

In the previous experiments, only the weak electron beam could be obtained because of the higher pressure and of the poor electron emission of the cathode, and by it the local oscillation was excited mainly. Such local oscillations were observed without external magnetic field by Merrill and Webb[2], Kojima et al.[3] and Mahaffey[4]. In the previous paper, it was reported that the local oscillation propagates predominantly in a direction perpendicular to the magnetic field, which was applied parallel to the discharge current. Now that the pressure is low and the tubes have cathodes of a excellent electron emission characteristic in the present experiment, the strong electron beam can be obtained. This strong electron beam excites the plasma oscillation along its path. This phenomenon was verified with a external electron beam by Boyd et al.[5] and Kharchenko et al.[6]. The standing waves between electrodes are formed by the beam when the plasma frequency is adequate against the distance between electrodes. Such standing waves will grow up to the perfect ones of Looney-Brown type[7] in the suitable uniform plasma. Hence they propagate in a direction parallel to the magnetic field and are almost indepent of its strength.

ESR Spectra of Irradiated Polyvinylalcohol and Its Related Compounds

By Seiji OGAWA*

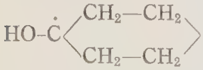
Japanese Association for Radiation Research on Polymers, Tokyo

(Received April 18, 1961)

ESR Spectrum of γ-irradiated polyvinylalcohol (PVA) is of a superposition of two types of patterns which are easily separated at suitable conditions. One of them is a triplet pattern spaced by 35 gauss and the other is a diffuse singlet which has longer life at room temperature but more rapidly decays near the second order transition temperature than the former.

As in the cases of other various organic solids, the reasonable interpretation of those spectra has not been well established. The obscurity in the interpretation of ESR spectra of organic free radicals trapped in solid state may partially be caused by the fact that the two protons of β-methylene group bonded to the central carbon atom where the unpaired electron is localized do not always contribute equally to the hyperfine structure of ESR spectrum[1].

Characteristic ESR spectrum of irradiated cyclohexanediol-1, 4 is triple triplet (Fig. 1-a). As the interpretation of the spectrum the following considerations may be reasonable: In the free readical



$\mathrm{HO}\text{-}\dot{\mathrm{C}}\langle{}^{\mathrm{CH_2-CH_2}}_{\mathrm{CH_2-CH_2}}\rangle\mathrm{CHOH}$

the two axially bonded protons of the two β-CH_2 groups contribute to the hyperfine structure with splitting 37 gauss and the two equatorially bonded protons with 11 gauss. These splittings are reasonable values, satisfying

$$\Delta H=40\cos^2\theta\,,\qquad \theta_e-\theta_a=120^\circ\,.$$

Here θ denotes the rotation angle between the C–H bond and a p-orbit of the unpaired electron around the C–C bond.[1)-3)]

In the case of messo-pentanediol-2, 4, which resembles to PVA in chemical structure, a double quartet spectrum (Fig. 1-b) is obtained at room temperature and the spectrum changes to the one as shown in Fig. 2-c when cooled to or below 110° K. This change is reversible. This indicates that the rotation of the CH_3 group bonded to the central carbon atom of the free radical is not free enough at low temperature. The chemical structure of the corresponding free radical may be considered as

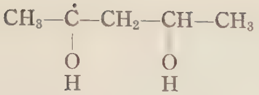
---

* On leave from Dai Nippon Spinning Company, Ltd.



$$\mathrm{CH_3{-}\underset{\underset{H}{O}}{\dot{C}}{-}CH_2{-}\underset{\underset{H}{O}}{CH}{-}CH_3}$$

One proton of the CH_2 group is to lie on the nodal plane of the p-orbit of the unpaired electron and the free radical could take such a steric configuration if the original hydrogen bonds in the crystal reserved almost completely.

In the case of PVA the triplet pattern may be interpreted similarly as pentanediol-2, 4. The free radical which corresponds to the triplet pattern is known to be trapped almost in crystalline parts of irradiated PVA and the triplet pattern of orientated PVA fibre, thermally elongated by the ratio of drawing, 10, does not display the orientation dependence which is expected for α-H. The splitting of 35 gauss is also too large for α-H. (Fig. 2-a, b, c) So it seems reasonable to consider that the free radical does not contain α-H and the structure is $\mathrm{\sim CH_2{-}\underset{OH}{\dot{C}}{-}CH_2\sim}$. It can be said safely that the identification of free radicals in solid state is difficult for a system without some regularity in the steric configuration of β-H.

The author would like to express his thanks to Dr. E. Nagai for his offering pentanediol-2, 4.

Emission Spectra of Potassium Bromide-Thallium Phosphors

By Tokumichi TAMAI and Eiichi MATSUI

Department of Physics, Faculty of Science, Kyoto University

(Received April 26, 1961)

Emission spectra of potassium bromide-thallium phosphors have been studied at liquid nitrogen, dry ice plus alcohol, and room temperatures. Single crystals were the same ones whose absorption spectra have been reported[1]. Monochromatic excitation was provided by a quartz prism spectrometer with a high pressure xenon are lamp; the intensity of emission was measured at right angles to the crystal by an RCA 1P28 photomultiplier after dispersion of the emission in a Beckman type monochromator. Spectral sensitivity of the photomultiplier was taken from the data in the RCA tube handbook.

Emission spectra of the potassium bromide-thallium phosphors have been reported by several authors[2]. The present authors have obtained results slightly different from previous investigators at A and C bands and also found the emission excited at B band. Fig. 1 shows emission spectra at three different temperatures. Emission curves excited at A, B and C bands were the same. The emission curve at room temperature shows a single broad flat-topped peak centered at 350 mμ. The curve at liquid nitrogen temperature consists of two well-resolved bands at 317 mμ and 365 mμ. Both bands show approximately Gaussian shape. Further discussion with detailed measurements will be reported in a near future.

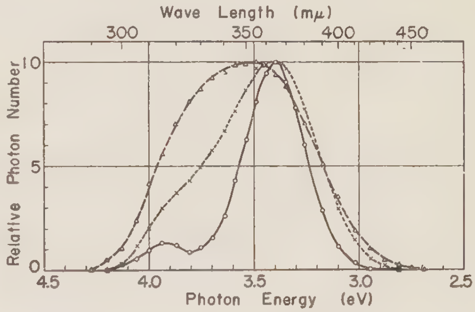

Fig. 1. Emission spectra of potassium bromide-thallium phosphor.
Measurements; ○: at liquid nitrogen temperature, ×: at dry ice plus alcohol temperature, △: at room temperature.

The authors would like to exprees their gratitude to Prof. Y. Uchida for his kind guidance and continual interest in the work.

Tetragonal Distortion in Copper Manganite-Chromite System

By Syôhei MIYAHARA, Kiyoshi MURAMORI
and Naoki TOKUDA

Department of Physics, Faculty of Science, Hokkaido University, Sappro, Japan

(Received May 11, 1961)

According to Dunitz and Orgel[1] cupric and manganese ions in spinel crystals give rise to crystal distortions of a type of $c/a<1$ and $c/a>1$ for occupations of tetrahedral and octahedral sites respectively. $CuCr_2O_4$ in which cupric ions are placed in tetrahedral sites, has been confirmed experimentally to be a tetragonal structure with $c/a<1$[2]. In $CuMn_2O_4$ where cupric and manganese ions are placed in tetrahedral and octahedral sites respectively, directions of distortions by both ions in tetrahedral and octahedral sites are opposite and therefore these distortions will be partly compensated. In order to investigate the crystal structure in such a situation as in $CuMn_2O_4$, copper manganite-chromite system have been studied.

Specimens are prepared from powders of CuO, Cr_2O_3 and Mn_3O_4 which are made by calcining each salts. The mixtures are fired for three days in air at 800°C. Both specimens cooled slowly from 800°C to room temperature at the rate of 15°C/h and quenched in water have been measured with a X-ray diffractometer.

Lattice parameters of the system at the room temperature are shown Fig. 1. The system has a cubic structure in the range $0\leqq a\leqq 1.0$ and a tetragonal structure with $c/a<1$ in the range $1.0<a\leqq 2.0$ where a cubic structure coexists except $a=2.0$. In the cubic region lattice parameters of specimens depend on a heat treatment and the degree of the dependence decrease with the increasing of the chromium concentration. Therefore it will be caused by manganese ions distorted oppositely to cupric ions. In the two phase region, increasing the chromium composition the intensity of the tetragonal phase decreases continuously and disappears at a $a=2.0$. On the other hand the intensity of the cubic phase decreases continuously with the decreasing of the chromium concentration and disappears at $a=1.0$.

As is shown in Fig. 1 increasing chromium concentration the lattice parameter of the cubic structure in the two phase region deviates gradually from cube root of the unit cell volume of the tetragonal structure.

As is shown in Fig. 2, the tetragonality is gradually decreased by the substitution of the manganese ions for the chromium ions, it will be however seen that the tetragonality remains even near the specimen where the tetragonality phase disappears.

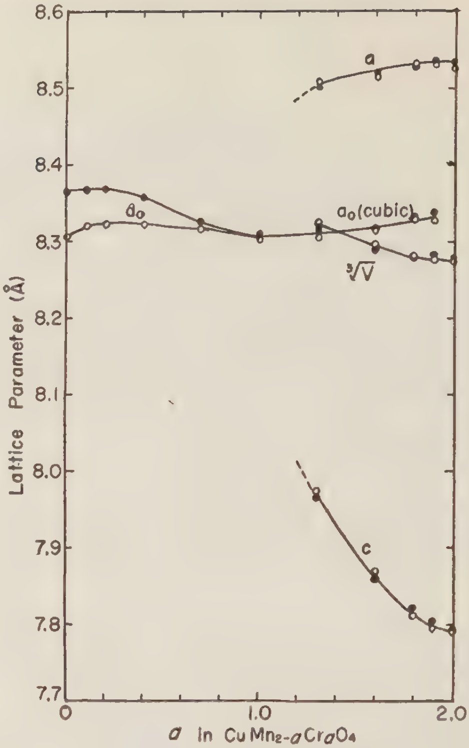

Fig. 1. The lattice parameter versus chromium concentration a.
○: specimen cooled slowly.
●: specimen quenched in water.

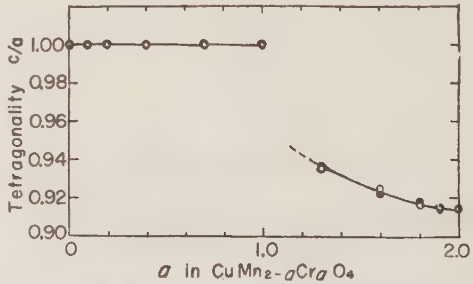

Fig. 2. The tetragonality versus chromium concentration a.
○: specimen cooled slowly.
●: specimen quenched in water.

It is noticed that in the cubic rigion the lattice parameter and the diffraction line width of the specimen depend on a heat treatment of the specimen, while in the two phase region, they do not depend on it and even of the intensities of the both structures do not.

The Second Excited State of Sn^{120}

By Mitsuhiro KAWAMURA, Atsushi AOKI
Department of Physics, Kyoto Prefectural University, Kyoto
and Hidetsugu IKEGAMI
Institute for Nuclear Study, University of Tokyo, Tokyo

(Received April 26, 1961)

The directional correlation and the polarization-direction correlation of the 1.03 Mev–1.17 Mev gamma-gamma cascade in Sn^{120} have been measured. It is found that the spin and the parity of the second excited state of Sn^{120} is 4 and even, respectively.

§1. Introduction

McGinnis[1)] proposed the decay scheme of Sb^{120m} having a half-life of 5.8-day, on the basis of the measurements of the spectrum of gamma ray and that of conversion electron. One of the present authors[2)] (H. I.) revised recently the decay scheme of Sb^{120m}, as shown in Fig. 1.

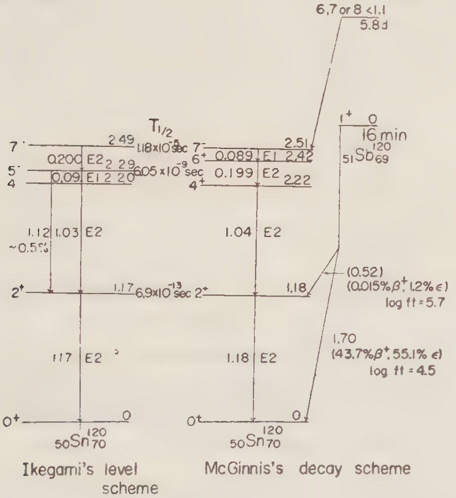

Fig. 1. Revised level scheme of Sn^{120} by Ikegami confirmed partly by present work. Decay scheme of Sb^{120m} proposed by McGinnis is also shown.

For the medium weight even-even nuclei to which Sn^{120} belongs, several nuclear models[3)–5)] are used to explain the level spacings, the spins and the parities of the excited states as well as the transition probabilities. The second excited state of Sn^{120} is rather considered as the vibrational state than as the rotational state from the ratio of the energy of the second excited state to that of the first excited state. According to the quadrupole vibrational model of the even-even nuclei with spherical equilibrium shape, this level is expected as the degenerated two-phonon state having the level assignment of either 4^+, 2^+ or 0^+. Moreover, in the case of the spin value 2 of the second excited state, the transition to the first excited state from the second excited state, is characterized by the predominant E2 transition in Scharff-Goldhaber and Weneser's free vibrational model[3)], while by the predominant M1 transition in Shapiro's prediction[6)]. Therefore, in order to resolve the ambiguity of the level assignment and the character of the gamma ray, it is very interesting that the directional correlation and the polarization-direction correlation measurements of the 1.03 Mev–1.17 Mev gamma-gamma cascade in Sn^{120} are performed.

§2. Source preparation and Gamma Ray Spectra

1) *Source preparation*

The 5.8-day Sb^{120m} was prepared by the irradiation of natural tin metal containing a fractional chemical impurity of about 1.7×10^{-5} with an internal beam of 12–14 Mev proton in a 64 inch cyclotron at the Institute for Nuclear Study, University of Tokyo, leading to the reaction Sn(p, n)Sb. Irradiated tin was dissolved in aqua regia, then converted into 8N hydrochloric acid solution and extracted with isopropyl-ether repeatedly. The organic layer was washed with 3N hydrochloric acid and the solvent was evaporated off in the presence of 3N hydrochloric acid containing a small amount of hydro-oxylamine hydrochloride. This residual acid solution was used as the source for the measurement of gamma ray spectrum and the directional correlation experiment. In the measurement of the polarization-direction correlation experiment, the source was electro-deposited onto the thin copper foil and made into a small ball and stuffed in a vinylchloride container whose wall thickness was about 1 mm and its volume 1 mm$\phi \times$2 mm.

2) Gamma ray spectra

The single gamma ray spectra were measured with a 20-channel pulse-height analyzer, as shown by curve A in Fig. 2.

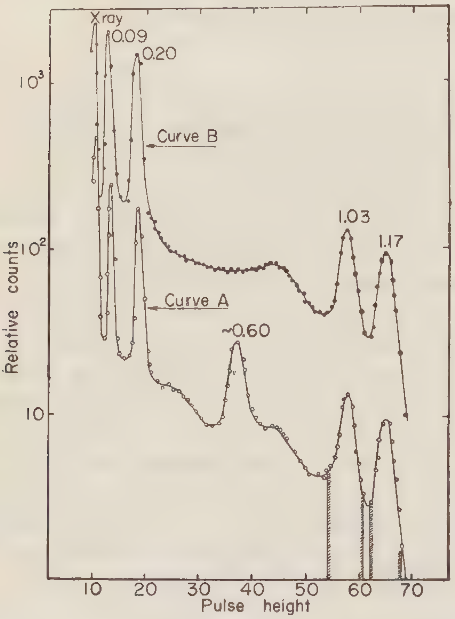

Fig. 2. Gamma ray spectra of Sb^{120m}. Curves A and B give the spectra obtained from natural and enriched tin, respectively. The shaded portions represent the windows of the pulse-height analyzers in the measurement of the directional correlation.

The peaks corresponding to the 0.09, 0.20, 1.03 and 1.17 Mev decay with a half-life of about 6-day, but the peak appearing at about 0.6 Mev decays with a half-life of about 3-day. The latter peak was considered reasonably as the composed peak of the cascade gamma rays[7)] of Te^{122} following the decay of Sb^{122} arising from the reaction $Sn^{122}(p, n)Sb^{122}$. In Fig. 2, curve B was obtained from 98% enriched Sn^{120} whose chemical form was SnO_2. The peak corresponding to about 0.6 Mev disappears completely.

§ 3. Directional Correlation Measurement

The source material was prepared in the form of $SbCl_3$ in HCl solution and filled in a 5 mm in diameter and 5 mm long Lucite case whose wall-thickness was 2.0 mm. The attenuation of the correlation coefficient due to the quadrupole interaction in the intermediate state in the liquid form is considered to be negligibly small, as the mean life of the first excited state of Sn^{120} is very short which is measured as 1.0×10^{-12} sec from the Coulomb excitation experiment[8)]. A gamma ray goniometer at the Institute for Nuclear Study was used. The Dumont 6292 and RCA 6342 photomultiplier tubes mounted with NaI(Tl) crystals of $1^3/_4$ in. $\phi \times 2$ in. were used as detectors. The distance between the source and the front face of each crystal was 7 cm. The coincidence circuit was operated at a resolving time $2\tau = 4 \times 10^{-7}$ sec and the windows of the pulse-height analyzers were set on the shaded portions in Fig. 2. The measurement was carried out at direction angles of 90°, 112.5°, 135°, 157.5° and 180°. The accidental coincidence counts amounted to 1–7% of total conicidence counts. The experimental result and the most fitted curve are shown in Fig. 3.

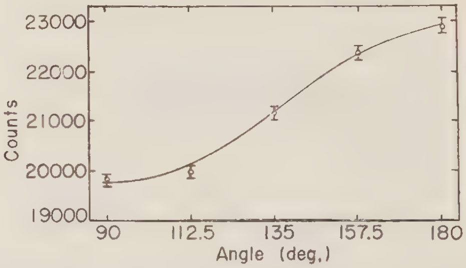

Fig. 3. Directional correlation of the 1.03 Mev–1.17 Mev gamma-gamma cascade. The solid curved represents the least-squares fit of the experimental data.

The measured coefficients take the following values:

$$A_2' = +0.0984 \pm 0.0013 ,$$
$$A_4' = +0.0094 \pm 0.0005 .$$

In order to obtain the true coefficients, the attenuation factors due to the angular resolution were measured by the use of Lawson and Frauenfelder's method[9)]. The gamma rays from Co^{60} coming through the collimator, were detected so as to count only the photopeaks. The measured angular resolution curves are shown in Fig. 4.

The attenuation factor Q_λ is expressed as follows, using the angular resolution curve $f(\theta)$:

$$Q_\lambda=(J_\lambda/J_0)^2\ ,$$

where $J_\lambda=\int f(\theta)P_\lambda(\cos\theta)|\sin\theta|d\theta$. The attenuation factors obtained experimentally are

$$Q_2=0.926\ ,$$
$$Q_4=0.773\ .$$

Using these values, the corrected coefficients A_λ are determined as follows:

$$A_2=+0.106\pm0.002\ ,$$
$$A_4=+0.012\pm0.001\ .$$

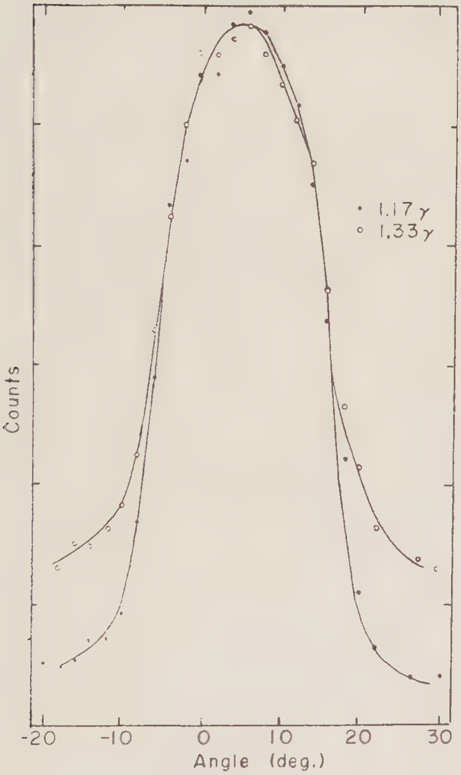

Fig. 4. Angular resolution curves measured at a distance of 7 cm for the 1.33 Mev and 1.17 Mev gamma ray from Co^{60} source.

§ 4. Polarization-Direction Correlation Measurement

The gamma ray polarimeter reported previously[10)] was used for the measurement of the polarization-direction correlation of the 1.03 Mev–1.17 Mev gamma-gamma cascade. Its photograph is shown in Fig. 5.

In this apparatus, the crystals for the direction and the side counters were both NaI(Tl) of $1^1/_2$ in. in diameter and 1 in. thick, and the scattering phosphor was a plastic scintillator of 4 cm in diameter and 4.5 cm long which was composed of polystyrene, *p* terphenyl (1%), POPOP (0.03%) and zincstearate (0.03%). The distance between the source and the front face of the crystal for the direction counter and that of the scattering phosphor were both 5 cm. The crystal for the side counter was placed at such a position that the distance between the front face of its crystal and the center axis of the scattering phosphor was 5 cm and the mean scattering angle at which the scattering events were detected was about 80°. The asymmetry ratio of the gamma ray polarimeter in the arrangement mentioned above was estimated as $R=2.12$ for 1 Mev gamma ray[11)]. The electronic circuit was the same one used in the measurement[10)] of Cd^{114}. To eliminate the false coincidence count, the pulse-height analyzers in the side counter channel and the scattering phosphor channel were adjusted to stop out the pulses corresponding to the energy less than 320 Kev and 250 Kev, respectively. The pulse-height analyzer in the direction counter channel was adjusted so as to count only the gamma ray higher than 430 Kev. By these adjustment of the electronic circuit, the contribution from the

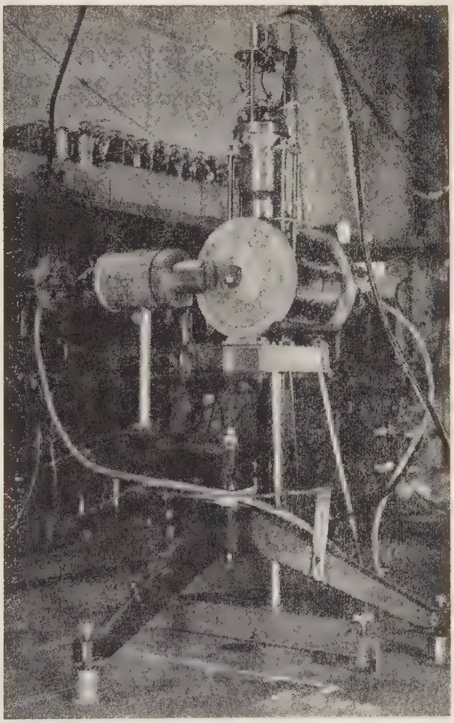

Fig. 5. Photograph of the gamma ray polarimeter.

gamma-gamma cascade[1),2)] containing either 0.09 Mev or 0.20 Mev gamma ray was removed completely.

Nevertheless, as the source was made from natural tin, the contribution from the 0.69 Mev –0.56 Mev gamma-gamma cascade in Te^{122} might be contained. But it was ascertained that its contribution was less than 1% of that from the 1.03 Mev–1.17 Mev gamma-gamma cascade on the seventh day after bombardment, so that the analysis of data was not affected at all by this contribution. Under the above-mentioned experimental condition, the measurement was carried out at a direction angle of 90° and the polarization of either 1.03 Mev or 1.17 Mev gamma ray was detected. The measured asymmetry are shown in Table I with the one in the case of Ti^{46} gamma-gamma cascade in which the gamma ray energy is almost the same as the present ones.

Table I. Measured asymmetry in the measurement of the polarization-direction correlation.

Nucleus	Cascade	$N_{\parallel}/N_{\perp}$ (90°)
Sn^{120}	1.03 Mev–1.17 Mev	0.92±0.03
Ti^{46}	0.89 Mev–1.12 Mev	0.92±0.02

§ 5. Result and Discussion

The measured directional correlation pattern agrees well with the one expected for the decay sequence of 2(D+Q)2(Q)0 ($\delta=-0.18$) as well as 4(Q)2(Q)0, so that we cannot accept the alternative.

The averaged polarization-direction correlation function[12)] can be expressed as follows:

for 4(E2)2(E2)0

$$\langle W(\theta,\varphi)\rangle_{AV}=1+0.1020P_2(\cos\theta)+0.0091P_4(\cos\theta)+[-0.0510P_2^2(\cos\theta)+0.0008P_4^2(\cos\theta)]\cos 2\varphi$$

and for 2(M1+E2)2(E2)0, where $\delta=-0.18$

$$\langle W(\theta,\varphi)\rangle_{AV}=1+0.1121P_2(\cos\theta)+0.0102P_4(\cos\theta)+[-0.1025P_2^2(\cos\theta)+0.0009P_4^2(\cos\theta)]\cos 2\varphi$$

and the p-value[13)] which is defined as the ratio of $\langle W(90°,90°)\rangle_{AV}$ to $\langle W(90°,0°)\rangle_{AV}$, takes the following values:

for 4(E2)2(E2)0 $p=1.40$,
and for 2(M1+E2)2(E2)0,
where $\delta=-0.18$ $p=1.99$.

Therefore, it is possible to exclude sharply the alternative, by means of the polarization-direction measurement. The asymmetry obtained in the polarization-direction correlation measurement agrees very well with the measured one for the gamma-gamma cascade in Ti^{46} which has the well-established decay sequence of 4(E2)2(E2)0 and its gamma ray energies are almost the same as that in Sn^{120} detected in the present experiment. As the asymmetry is expected to be 0.81 for the decay sequence of 2(M1+E2)2(E2)0 ($\delta=-0.18$), this decay sequence should not be accepted. Consequently, it is concluded that the spin and the parity of the second excited state is 4 and even, respectively and the transition from the second excited state to the first excited one is pure electric quadrupole transition.

This result is consistent with that obtained from the internal conversion measurement of 1.03 Mev gamma ray by several authors[1)].

Since the degeneracy of the second excited state is a consequence of the harmonic oscillator approximation in the surface vibrational model, it is expected that the degeneracy will be removed by higher order term in the nuclear energy[14)]. The level assignment of 16 min Sb^{120} is considered[1)] as 1^+, on the basis of the information of the transition to the ground and the first excited states of Sn^{120}, so that the transition from the 1^+ level of Sb^{120} to the second 2^+ level of Sn^{120}, if it exist, could be detected. In order to realize this possibility, 16 min Sb^{120} was produced by the bombardment of 98% enriched Sn^{120} by 7–8 Mev proton or the irradiation of natural Sb by the fast neutron which is emmitted in the bombardment of 24 Mev deuteron on graphite target, and the gamma ray spectra were measured carefully.

However, the evidence of the existence of second 2^+ level was not obtained.

From these experimental results, the 2.20 Mev level may by regarded as a two quasi-particle excitation level $(h_{11/2})^2$ in Kisslinger and Sorensen's model[15)] on the single closed shell nuclei.

However, as the absence of the second 2^+

level may be caused by the strong degeneracy of the triplet, the possibility of a two phonon vibrational level still remains.

Acknowledgement

The authors wish to express their hearty gratitude to Prof. T. Hayashi of Kyoto Prefectural University for his valuable discussions and to Dr. K. Saito of Institute for Nuclear Study of University of Tokyo for his co-operation in chemical separations.

They are also indebted to the cyclotron crew of the Institute for Nuclear Study for the operation of the machine.

and Zyun-itiro MATUMOTO

Nuclear Physics Division, Japan Atomic Energy Research Institute
Tokai-mura, Ibaraki-ken

(Received May 4, 1961)

The proton and neutron separation energies and the β-decay energies are estimated for most of the nuclei that have been dis- covered or will be discovered in near future. In this estimation four semi-empirical rules for the proton and neutron separation energies are used in addition to the available experimental data. These rules are also used to eliminate the wrong data and to correct the wrong interpretations of the experimental results. The "best" values thus obtained are tabulated. Explanations are given for some of the data which are eliminated or need large adjustments.

§1. Introduction

It is needless to say that the nuclear (ground-state) binding energies, or equivalently the nuclear masses, are very important quantities for nuclear physics. A great many data have been acquired till now, and a quick view of them may be obtained in the recent papers of Everling et al.[1] In spite of these efforts, however, the overall situation is still not satisfactory. If one looks into the data, one will be confused by many irregularities that are theoretically inexplicable. Most of these irregularities seem to be false ones being due to incorrect or insufficient experiments.

The elimination of such false data has been facilitated by the use of mass formulas and nuclear systematics, in particular the β-decay energy systematics[2,3]. These have been also useful to estimate the binding energies for which no or only poor experimental data are available.

In this paper we advance this kind of study. By making use of a systematics which is explained in the next section, we try to eliminate the false data and estimate the " best " values as accurately as possible.

§ 2. Systematics for the Proton and Neutron Separation Energies

There are many kinds of systematics concerned with the nuclear binding energies. The systematics we use in this paper is that for the separation energies of the last protons or neutrons. We denote the proton and neutron separation energies of the nucleus with Z protons and N neutrons as $S_p(Z, N)$ and $S_n(Z, N)$ respectively. Our systematics consists of the following four rules.

1. $S_p(Z, \text{even-}N)$ for a fixed Z value increases smoothly (almost linearly) with N.
2. $S_n(\text{even-}Z, N)$ for a fixed N value increases smoothly (almost linearly) with Z.
3. $S_p(\text{odd-}Z, \text{odd-}N)$ is larger, and $S_p(\text{even-}Z, \text{odd-}N)$ is smaller than the values inferred from the smooth curves of the rule 1. Similarly, $S_n(\text{odd-}Z, \text{odd-}N)$ is larger, and $S_n(\text{odd-}Z, \text{even-}N)$ is smaller than the values inferred from the smooth curves of the rule 2.
4. $S_p(Z, N+1)$ is not much smaller than $S_p(Z, N)$, and $S_n(Z+1, N)$ is not much smaller than $S_n(Z, N)$.

Although the legitimacy of the above rules should be tested by the experimental data, we shall give some theoretical bases for them in the following.

The non-smoothness of the nuclear properties as functions of Z and N seems to be caused mainly by the Pauli exclusion principle. For example, there should be no magic number if there were no exclusion principle. If one plots $S_p(Z, N)$ as a function of Z, big discontinuities occur at the proton magic numbers. The β-decay energy systematics[2,3] has the same kind of discontinuities. These discontinuities are inconvenient to estimate the unmeasured quantities and also to examine the reliabilities of the experimental data. On the other hand, if one plots $S_p(Z, N)$ for a fixed Z value as a function of N as is used in the rule 1, the last proton which is our central object is always the same Z-th proton. Therefore, we can expect that the effect of the exclusion principle is mostly avoided in this kind of plots and a smooth function is obtained. The same argument holds for the rule 2.

Sometimes, however, the addition of neutrons or protons causes so marked change to the nuclear properties that the above-mentioned smoothness is broken. We have found three cases in which the rules 1 and 2 do not hold well. First, a discontinuity occurs when the point, $Z=N$, is passed through. This discontinuity is probably due to the symmetry energy between the protons and the neutrons which includes a part proportional to $|N-Z|$[4]. Second, discontinuities may occur for the plots of the rule 1 when N passes through a magic number, and for the plots of the rule 2 when Z passes through a magic number. This kind of discontinuity is much smaller than the discontinuity of $S_p(Z, N)$ as a function of Z which occurs when Z passes through a magic number. Third, discontinuities may occur when the nuclei change their shapes markedly. A typical example is that for the neutron numbers changing from 88 to 90.

When the spin-parities of the low-lying states of the odd-mass nuclei are known, we can modify the rules 1 and 2 slightly. To do so, we deal with the proton and neutron separation energies from (or to) the lowest states with particular spin-parities instead of those from (or to) the ground states. For example, we consider the energies which are necessary for removing the last protons from the lowest $5/2^+$ states of the Sb isotopes. The modified rule 1 is that these energies increase smoothly with N. We can also deal with the energies which are necessary for removing the last protons from the lowest $7/2^+$ states of the Sb isotopes. They increase smoothly with N, too. These modified rules are expected to hold somewhat better than the original ones.

In the above arguments the reason why N must be even for the rule 1 and Z must be even for the rule 2 is not stated. It will be easily seen that no odd-odd nucleus is concerned with the rules 1 and 2. Suppose a proton is added to the nucleus with even-Z protons and odd-N neutrons. If there were no directional coupling between the added proton and the original nucleus, the binding energy of the added proton would take a value which is close to that obtained from the interpolation of the plots of the rule 1, and the ground state of the final odd-odd nucleus would be a degenerate state with several spin values. Actually, however, there is some directional coupling, and the degenerate state splits into single-spin states. Among these states, our object is the ground state which has the largest binding energy. The binding energy of this ground state will be larger than that of the above-mentioned degenerate state; and accordingly, the proton separation energy of the odd-odd nucleus will be larger than that obtained from the interpolation of the plots of the rule 1. The rest of the rule 3 is explained in the same way. This rule was first discovered by Way[5], and de-Shalit[6] gave an explanation from the standpoint of the shell model.

We can refine the rule 3 in the following way. We arrange the nuclei and the proton and neutron separation energies as Fig. 1.

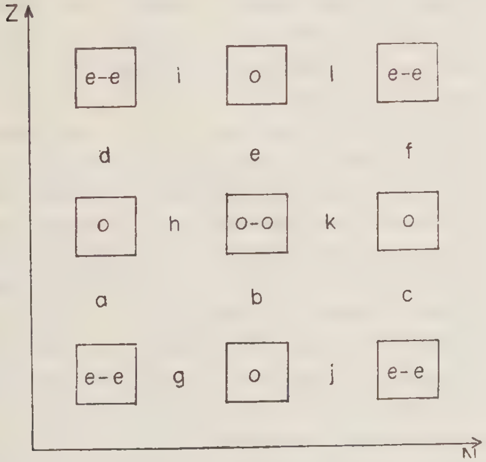

Fig. 1. Arrangement of nuclei. "e-e", "o-o" and "o" mean the even-even, odd-odd, and odd-mass nuclei respectively. The letters between the nuclei stand for the proton and neutron separation energies.

The refined rule 3 is

$$(2b-a-c)-(2e-d-f)$$
$$=(2h-g-i)-(2k-j-l)>0.$$

It follows from this inequality that the distance between the mass surfaces of the odd-odd and odd-mass nuclei is smaller than that between the odd-mass and even-even ones. There is no definite exception to the refined rule 3, while there are a few exceptions to the original rule 3.

The rule 4 is almost purely empirical. However, the following reasoning, though the possibility of its justification in near future is doubtful, may be helpful to understand it. $S_p(Z, N+1)$ may be divided into $S_p(Z, N)$ and the interaction energy between the Z-th proton and the $N+1$-th neutron. Probably, there are both attractive and repulsive parts in the interaction between a proton and a neutron. In forming the ground state of the $(Z, N+1)$ nucleus the Z-th proton and the $N+1$-th neutron take such configurations that the attractive part is in the most use and the repulsive part in the least use. Thus, the net interaction between the Z-th proton and the $N+1$-th neutron is attractive (at least, not strongly repulsive); and consequently, $S_p(Z, N+1) \gtrsim S_p(Z, N)$.

Actually, there are cases in which $S_p(Z, N)$'s are slightly larger than $S_p(Z, N+1)$'s. The rule 4 is stated in a somewhat vague way taking account of this situation.

§ 3. Estimation and Tabulation of S_p, S_n, Q_β

As is mentioned in § 1, our systematics explained in § 2 is not clearly seen when the raw data are plotted with preliminarily estimated S_p and S_n values. We use every kind of data concerned with the ground-state binding energies. They include the reaction Q-values, the α- and β-decay Q-values, and the mass values. Next, we adjust the data within the errors so as to fit the systematics. The errors of the mass-spectroscopic data are taken to be three times those given in the literatures. For the other kinds of data the errors in the literatures are adopted in this stage. For the data without errors the authors' judgments are used. At the same time we improve the estimations of the S_p and S_n values. It should be noted that these adjustments and improvements are not very simple since many quantities are mutually correlated. For example, $a+h=b+g$

in Fig. 1. Although this procedure greatly improves the fit of the systematics, there still remain some deviations. Looking into the data which cause these deviations we usually find doubtful points in the experiments or in the interpretations of the experimental results. Then, we either eliminate these data or give different interpretations to them. After re-improving the estimations of the S_p and S_n values we get the final results. *The important thing to be mentioned is that a good fit of the data to our systematics is attained without adjusting the well-established experimental data.*

To collect the experimental data we mainly use the compilations of the nuclear data[7,…,12]. Most of the data which appeared after these compilations had published are also included, but some of them may have escaped from the authors' attention. Some of the new data which do not differ from the old ones significantly are neglected, since the inclusion of them does not seem to be so urgent as it necessitates tremendous labor. Most of the references of the new data can be found in the blue "Recent References" sheets of Nuclear Data Sheets[7]. Therefore, the references of the new data are given only when they are not found in the above sheets[13,…,54]. For many nuclei with mass numbers $A \leq 70$, the binding energies are very precisely known. For these nuclei the values in Reference 1 are used with very few changes. As is seen from the argument in § 2 our systematics is not very effective to estimate the binding energies of the relatively few nuclei with $Z > N$. In such cases we use the systematics of the Coulomb energy differences between the mirror nuclei.

The "best" values of the proton and neutron separation energies and the β-decay Q-values (Q^- for β^--decay and Q_ε for electron capture decay), which are the results of the above final adjustments, are tabulated in Table I. The value which is obtained directly from experiment is marked the asterisk, *. Some kinds of averages of the experimental data also belong to this class. For $A \leq 70$ the results of the least squares method[1] are classified here. The value which is obtained from the experimental value after adjustment within the error is marked the dagger, †. The experimental data with much poorer accuracies than those of the adopted values (calculated or estimated values) are excluded from the above two classes even though they coincide. The mark, ♯, is attached to the value which is obtained from the experimental value after adjustment beyond the error. The value without any mark and without parentheses is calculated from the experimental data, either adjusted or unadjusted. The value in parentheses is the estimated value. Even though a value may be calculated from the experimental data, it is put in parentheses if some of the experimental data need so much adjustments as to nullify the original data.

The above marks are not sufficient to indicate all the locations and adjustments of the experimental data. The locations of the experimental Q-values of the α-decays and some of the reactions are not seen in Table I. For the mass-spectroscopic measurements such doublet values that are connected *only* with S_p, S_n, or Q_β are marked, but all others are not. For example, the existence of the mass difference measurement of $\mathrm{Gd}^{155}-\mathrm{Gd}^{154}$ is indicated by the mark on $S_n(\mathrm{Gd}^{155})$, but no mark is attached to $S_p(\mathrm{Ba}^{134})$ though the masses of ${}_{56}\mathrm{Ba}^{134}$ and ${}_{55}\mathrm{Cs}^{133}$ themselves have been measured. It seems better to indicate the existence of the mass measurement and the adjustment of its value in the table of masses which may be published elsewhere. Of course, the data which have no corresponding marks are also used to get the "calculated" values in Table I. For some of these data which need large adjustments discussions are given in § 4 in the same way as the data with marks.

We do not go deep into the estimation of the uncertainties of the values in Table I because it is complicated too much. We simply divide the whole values into five classes according to their uncertainties. These classes are shown in Table II, in which the "uncertainty" should be taken as the maximum of possible errors. The values in the first class have sufficient precisions for our systematics and for most other purposes. Since it is not our aim to discuss the accuracy of a few keV, the values are given only to two places of decimals in MeV units. If one wants more accuracy, one should consult References 1, 7, etc. The estimated values and the values adjusted beyond the errors cannot be precise

Table I. The "best" values of the proton separation energies (S_p), the neutron separation energies (S_n), the β^--decay Q-values (Q^-), and the electron capture Q-values (Q_ε). The values are in MeV units. For notation see Table II.

Example	*Comment*
$1.2_3{}^*$	The asterisk, *, means a measured, unadjusted value.
$1.2_3{}^\dagger$	The dagger, †, means a value which is obtained from the experimental value after adjustment within the error.
$1.2_3{}^\sharp$	The mark, ♯, means a value which is obtained from the experimental value after adjustment beyond the error.
1.2_3	A value without any mark is a calculated value.
(1.2_3)	A value in parentheses is an estimated value.

Example	*Uncertainty*	
1.23^*, $1.23^\dagger$, 1.23	$0<$	≤ 0.04
$1.2_3{}^*$, $1.2_3{}^\dagger$, $1.2_3{}^\sharp$, 1.2_3, (1.2_3)	$0.04<$	≤ 0.25
$\sim 1.2_3{}^*$, $\sim 1.2_3{}^\dagger$, $\sim 1.2_3{}^\sharp$, $\sim 1.2_3$, $(\sim 1.2_3)$	$0.25<$	≤ 0.50
$\sim 1.2^*$, $\sim 1.2^\dagger$, $\sim 1.2^\sharp$, ~ 1.2, (~ 1.2)	$0.50<$	≤ 1.0
$\sim 1._2{}^*$, $\sim 1._2{}^\dagger$, $\sim 1._2{}^\sharp$, $\sim 1._2$, $(\sim 1._2)$	$1.0<$	

enough to belong to this class. The uncertainties of the estimated values are estimated fairly conservatively. The probability that the estimated range does not include the real value is perhaps a few percent at most. Such uncertainties of the well-estimated values are about 0.2 MeV, and these values belong to the second class.

By the authors' judgment some data are assigned larger errors than those given in the literatures, and are classified into the lower grades. Typical ones are the mass-spectroscopic data, for which three times the errors in the literatures are assigned.

The values in Table I are also shown in graphical form in Figs. 2 to 5 in order to see how our systematics holds. Furthermore, Fig. 6 in which some of the S_p(odd-Z, N)'s calculated from Reference 1 are plotted will show how the plots look without any adjustment.

§ 4. Discussions of Particular Data

In this section we discuss the data which need large adjustments or re-interpretations. The data which cause some deviations from our systematics are also discussed even though they are not adjusted appreciably.

Discussions are given in the order of increasing atomic numbers. The mass-spectroscopic data are discussed in the last.

Na^{20}, Q_ε. The value, 15.3 MeV, obtained from the Ne^{20}(p, n) threshold[55] is too large. The systematics of the Coulomb energy differences suggests $Q_\varepsilon \sim 14.0$ MeV, and this value is also supported by the rule 3. The observed threshold may be due to the excited states of Na^{20}.

Co^{57}, Q_ε. There are two experimental values, 0.57 ± 0.03 MeV obtained from the measurement of the internal bremsstrahlung[56], and 0.837 ± 0.003 MeV obtained from the Fe^{57}(p, n) threshold[20]. The rule 3 is consistent only with the latter value. The observation of a higher energy γ-ray[57] also supports the latter value.

Zn^{72}, Q^-. The reported weak $\sim$1.6 MeV β^--ray[58] is certainly not due to this nucleus.

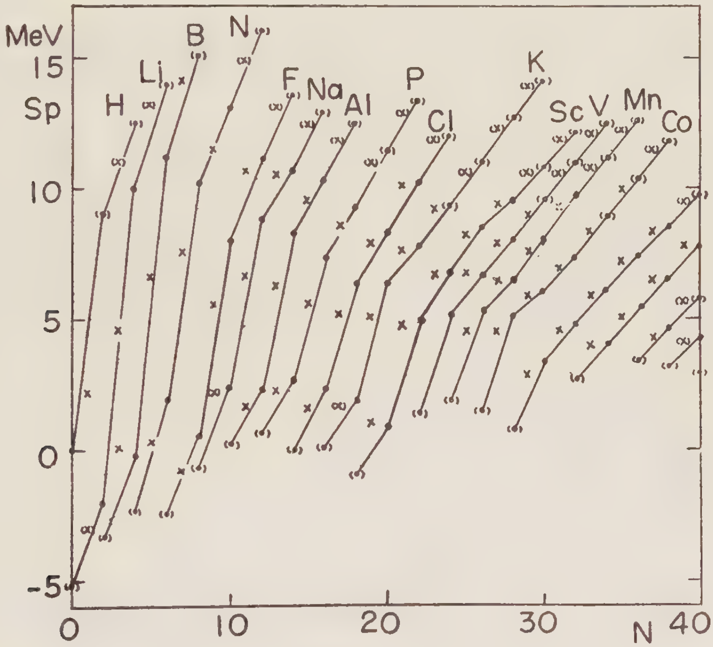

Fig. 2(a).

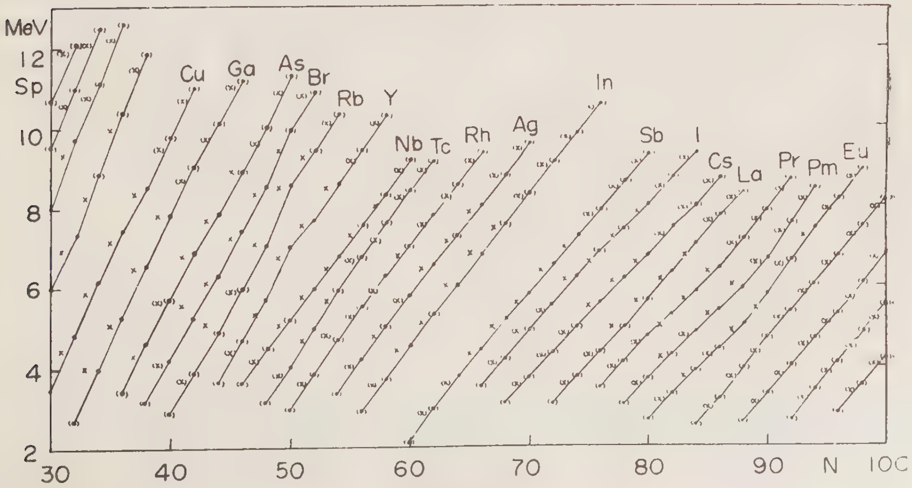

Fig. 2(b).

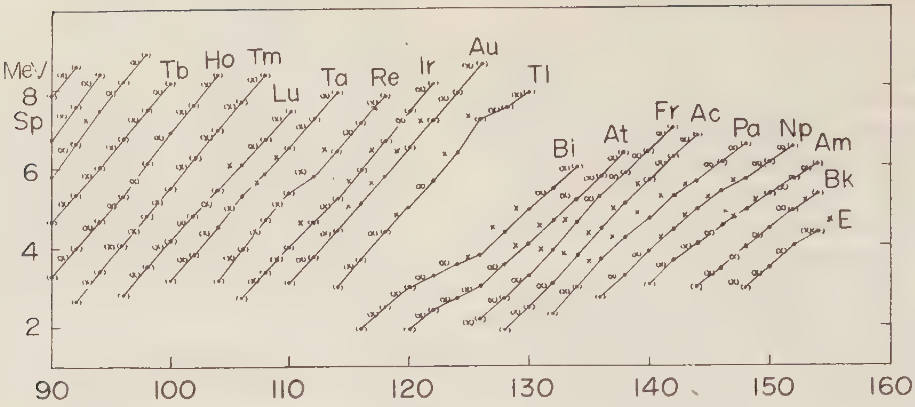

Fig. 2(c).

Fig. 2. The "best" values of S_p(odd-Z, N)'s. The dots are S_p(odd-Z, even-N)'s, and the crosses are S_p(odd-Z, odd-N)'s. The marks with parentheses represent the estimated values, and the marks without parentheses represent the measured (unadjusted or adjusted) or calculated values.

The estimated value is only $\sim 0.5_0$ MeV.

Ge^{66}, Q_ε. Our systematics predicts a considerably smaller value for $Q_\varepsilon(Ge^{66})$ than the β-decay energy systematics[2)]. Ricci et al.[59)] fitted their experimental results to a decay scheme with $Q_\varepsilon = 2.95 \pm 0.15$ MeV in accordance with the β-decay energy systematics. However, it is more likely that the weak 2.0 MeV β^+ does not exist in the decay of Ge^{66} and the strong 1.3 MeV β^+ proceeds to the low-lying states of Ga^{66}. This problem is also related to $Q_\varepsilon(Ge^{68})$. The β-decay energy systematics predicts $\sim 0.7_0$ MeV for $Q_\varepsilon(Ge^{68})$, while our system-

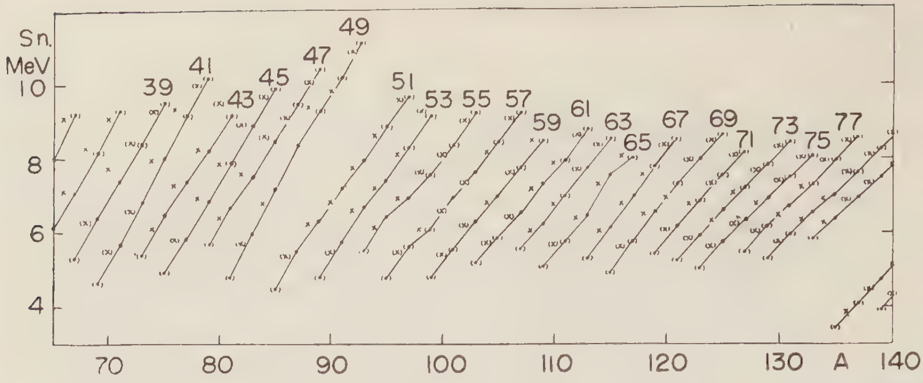

Fig. 4(b).

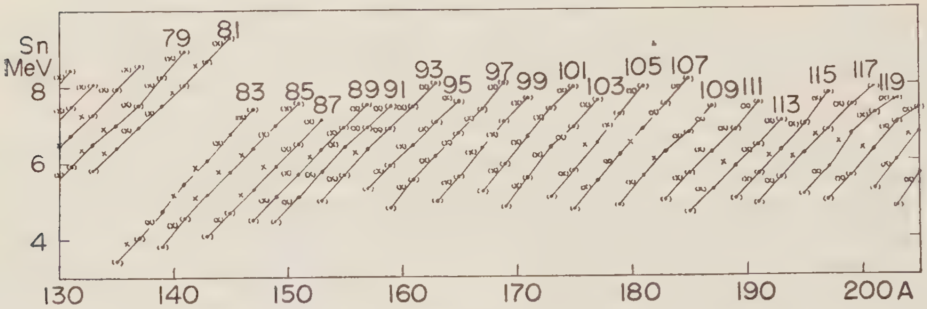

Fig. 4(c).

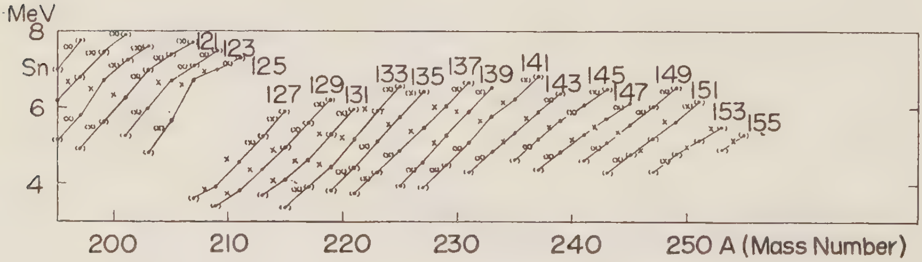

Fig. 4(d).

Fig. 4. The "best" values of $S_n(Z, \text{odd-}N)$'s. The dots are $S_n(\text{even-}Z, \text{odd-}N)$'s, and the crosses are $S_n(\text{odd-}Z, \text{odd-}N)$'s. The numbers attached to the lines are N's. See also the caption of Fig. 2.

atics predicts $\sim 0.2_0$ MeV. The latter value is more plausible since no γ-ray has been observed in the decay of Ge^{68} in spite of the expected lowlying 0^+ state of Ga^{68}.

Br^{79}, S_n. The value obtained from the recent $Br(\gamma, n)$ threshold measurement[60] is too small. This threshold may be due to the excited states of Br^{80}. The mass-spectroscopic data favor this interpretation.

Br^{87}, Q^-. 8.0 MeV obtained by the absorption method[61] is too large for this Q-value. We adopt $\sim 6.6_0$ MeV. It should be noted that this nucleus is a delayed-neutron emitter and its Q^--value cannot be much smaller than 6.5 MeV.

Kr^{74}, Q_ε. The assignment[62] of the 3.1±0.1 MeV β^+ activity to Kr^{74} does not seem to be correct. The estimated value for Q_ε is only ~2.4 MeV. (~1.4 MeV for the maximum β^+ energy).

Rb^{89}, Q^-. The decay scheme is so complicated that a simple measurement of the β-rays with a scintillation spectrometer will not be sufficient. Thus, it will not be unreasonable to amend the original value, 3.92±0.05 MeV[63], to $\sim 4.3_0$ MeV.

Sr^{89}, S_n. The adopted value has been calculated from Q_ε(Y^{88}), S_n(Y^{89}), and Q^-(Sr^{89}). It is appreciably smaller than that obtained from the measurements7) of the Sr(d, p) Q-value. The observed Q-value may, at least partly, be due to the isotopes other than Sr^{88}. The Sr^{88}(d, p) reaction has the smallest Q-value among the Sr(d, p) reactions.

Y^{88}, Q_ε. 3.63±0.01 MeV obtained from the Sr^{88}(p, n) threshold23) is adopted rather than 3.44±0.02 MeV obtained from the β^+ energy7). The former is definitely in better fit to our systematics.

Mo^{98}, S_n. The reported value, 8.29±0.10 MeV, from the Mo^{97}(d, p) reaction64) is too small. The estimated value is ~8.8$_0$ MeV. Therefore, we tentatively assume that the reported value is that for the first excited state of

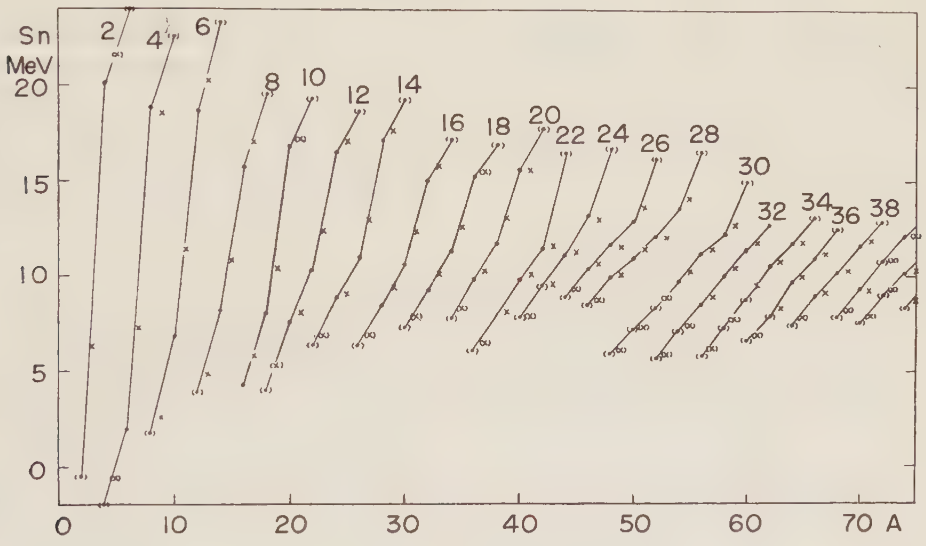

Fig. 5(a).

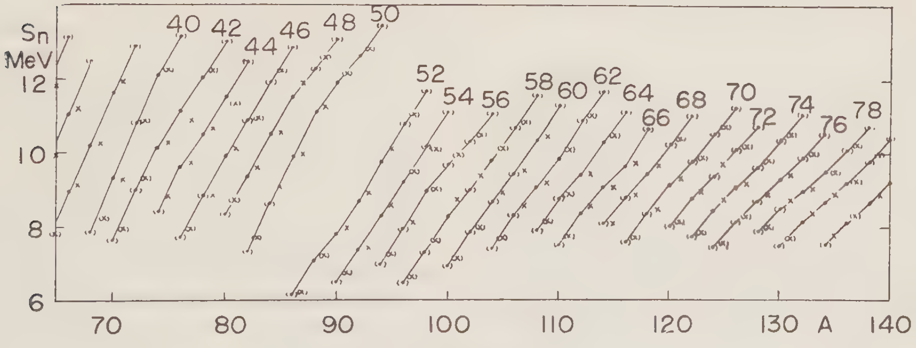

Fig. 5(b).

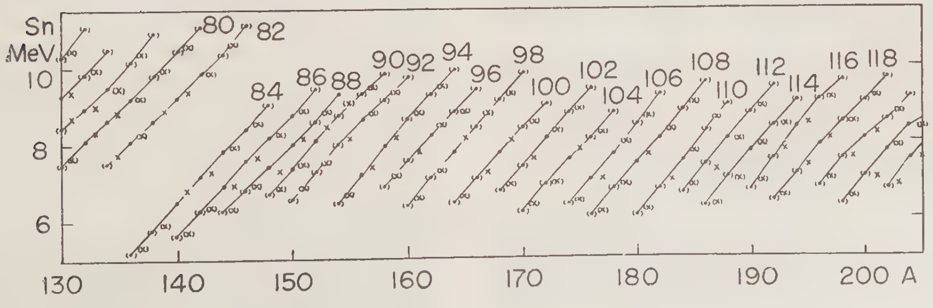

Fig. 5(c).

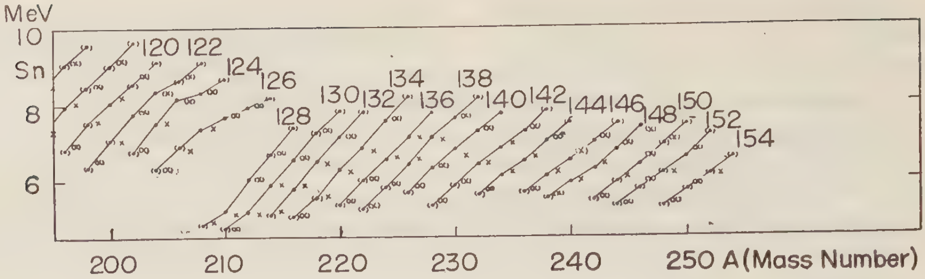

Fig. 5(d).

Fig. 5. The "best" values of $S_n(Z, \text{even-}N)$'s. The dots are $S_n(\text{even-}Z, \text{even-}N)$'s, and the crosses are $S_n(\text{odd-}Z, \text{even-}N)$'s. The numbers attached to the lines are N's. See also the caption of Fig. 2.

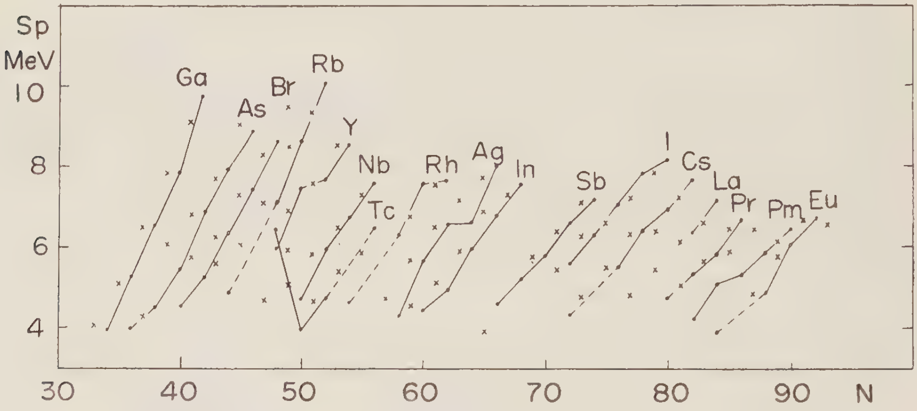

Fig. 6. Unadjusted $S_p(\text{odd-}Z, N)$'s which have been calculated from Reference 1. See also the caption of Fig. 2.

Mo^{98} with the excitation energy of 0.78 MeV, and adopt the smallest value within the error limit. With this value there still remains a fairly large violation of the rules 1 and 2 around Mo^{98}. This violation may be true since the first excited state of Mo^{98} has an anomalously large excitation energy. However, it is also possible that the real value of $S_n(Mo^{98})$ is about 8.8 MeV and the rules 1 and 2 hold better. The increase of $Q^-(Zr^{97})$ and the decrease of $Q^-(Nb^{94})$ would also be helpful to reduce the violation of the rules 1 and 2.

Pd^{99}, Q_ε. Our systematics suggests $Q_\varepsilon \sim 3.2_0$ MeV. Although this value is not very accurate, it is unlikely that the 2.0 MeV β^+ is in coincidence with the 0.67 MeV γ as is stated in Reference 65.

Pd^{101}, Q_ε. A somewhat larger value than the reported value[65], 1.76±0.05 MeV, is preferable. It is likely that a $7/2^+$ level lies slightly above the $9/2^+$ isomer of Rh^{101} and the low-energy γ-ray ($\lesssim 0.05$ MeV) between these states escaped the detection. From the modified rule 2, $5/2^+$ is preferred to $7/2^+$ for the ground state of Pd^{101}.

Pd^{111}, Q^-. The S_n values for the $N=65$ and 66 nuclei do not fit well to the rule 2, either modified or unmodified. Part of this deviation is probably real being due to the large binding energy of the $s_{1/2}$ neutron in the magic nucleus, Sn^{115}. The other part of the deviation may be reduced if $Q^-(Pd^{111})$ is larger than adopted.

Cd^{105}, Q_ε. The value in Nuclear Data Sheets[7] is too large. We tentatively assume that the 1.69 MeV $\beta^{+66)}$ proceeds to the 0.026 MeV level of Ag^{105} instead of the 0.37 MeV level, but the resulting Q_ε still seems to be somewhat too large.

Sn^{113}, Q_ε. There are two contradictory results, 1.3±0.3 MeV obtained from the internal bremsstrahlung[26] and 0.684±0.005 MeV obtained from the $\varepsilon_{LM}/\varepsilon_K$ ratio[67]. Since these experiments are difficult, both data do not seem to be reliable. We adopt ~1.0_0 MeV, but this estimation is not very accurate because of the proton magic number. More experiment is desirable.

$Sn^{120,122,123}$, S_n's. The S_n values of the tin isotopes measured by Cohen and Price[27] seem to be systematically too large. If their S_n values are reduced by 0.1 MeV, they become fit to our " best " values within the errors of ~0.1 MeV.

Te^{118}, $Q_{\varepsilon\varepsilon}$. 4.3 MeV is adopted in Nuclear Data Sheets[7]. However, a somewhat smaller value is preferable. We adopt 4.1 MeV, which is consistent with the new measurements of Q_ε(3.5^m Sb^{118}) as 2.7 MeV by Sorokin et al.[29] and Kocher et al.[30] but not with the old ones[7].

Te^{119}, Q_ε. We adopt the decay scheme of Zaitseva et al.[29] and Nuclear Data Sheets[7]. The decay scheme of Kocher et al.[30] includes several unreasonable points and is in disagreement with our systematics.

I^{128}, S_n. The measured Q-value of the $I^{127}(d, p)$ reaction[64] is too small for the ground-state Q-value. It is probably due to the transition to the excited states of I^{128}.

Cs^{138}, Q^-. It was already pointed out in Nuclear Data Sheets[7] that the reported Q^- is too small. The only way to fit to our systematics is to assume that the 3.40 MeV β^- proceeds to the 1.89 MeV level of Ba^{138} rather than to the 1.43 MeV level.

Ce^{142}, Q_α. There is a report[68] of α-decay with a Q-value of 1.5_4 MeV. The Q-value calculated from the adopted values in Table I is only 1.2_2 MeV. It is unlikely that Ce^{142} decays at an observable rate. Therefore, we neglect the above report. This conclusion is supported by Reference 36.

Nd^{144}, Q_α. The measured value is 1.89 ± 0.02 MeV[36], and we adopt 1.9_1 MeV. This value may be still somewhat too small. The Q_α's of Hf^{174} and Pt^{190} by the same authors[36] also seem to be a little too small. However, the situation is not so clear that we can adjust them beyond the errors.

Pm^{150}, Q^-. We re-interpret the 3.00 MeV β^- as going to the 0.34 MeV level of Sm^{150} rather than to the 0.78 MeV level[7].

Eu^{147}, Q_ε. The reported value[69], 1.29 ± 0.02 MeV, is wrong. We can set a lower bound of this quantity as 1.4 MeV from $Q_\alpha(Eu^{147})$, $Q_\alpha(Sm^{147})$, and the lower bound of $Q_\varepsilon(Pm^{147})$.

Eu^{153}, S_n. The reported (γ, n) threshold value[70] seems to be too large. The excited states of Eu^{150} and Eu^{152} are probably responsible for it. In this deformed-nucleus region several (γ, n) threshold values[70] seem to be somewhat too large. Some of them may be due to the excited-state thresholds.

Gd^{153}, Q_ε. The latest value[38] is in better agreement with our systematics than the older ones[7].

Tb^{154}, Q_ε. $Q_\varepsilon \geq 3.82 \pm 0.05$ MeV[71] of 18^h Tb^{154} is too large for the ground-state Q-value. Therefore, we assume this state to be an excited state. 8^h Tb^{154} may be the ground state.

Dy^{154}, Q_α. The long-lived activity with $Q_\alpha =$ 3.0 MeV[72] is much more likely to be due to the ground state of Dy^{154} than the activity with $Q_\alpha = 3.44 \pm 0.05$ MeV[73]. The pairing energies of the 65-th and 66-th protons in Dy^{150} and Dy^{152} are very large. The assignments of the α-activities of Dy should be checked once more.

Tm^{166}, Q_ε. The highest-energy β^+-decay proceeds to the 0.08 MeV level of Er^{166} rather than to the 0.26 MeV level[74]. The recent measurement[75] of the spin of Tm^{166} as 2 supports this interpretation.

Ta^{182}, Q^-. For the Q-value of $Ta^{181}(\gamma, n)$ 8.1^h Ta^{180} we accept the result of Welsh and Donahue[40] (-7.60 ± 0.08 MeV) rather than that of Geller et al.[70] (-7.852 ± 0.026 MeV), and adopt -7.6_8 MeV. Then, $S_p(W^{182})$ which is calculated from $S_n(Ta^{182})$ and $Q^-(Ta^{182})$[7] seems to be too small. Therefore, we assume that the 0.514 MeV β^- of Ta^{182} proceeds to the 1.290 MeV level of W^{182} instead of the 1.222 MeV level. This interpretation is plausible from a consideration of the β and γ intensities.

Ta^{184}, Q^-. 2.67 ± 0.07 MeV adopted in Nuclear Data Sheets[7] seems to be too small. The experiment is not complete enough to make one stick to this value. We adopt ~3.0_4 MeV.

Ir^{192}, Q_ε. Antonova et al.[76] reported $Q_\varepsilon =$ 1.95 ± 0.01 MeV based on the observation of a low-energy β^+ group ($E_{max} = 0.24 \pm 0.01$ MeV). However, we neglect it because the estimated Q_ε is only 1.1_0 MeV.

Pt^{197}, Q^-. Although we do not change the value of Potnis et al.[77], a smaller value is preferable. It should be checked whether the 0.67 MeV β^- is really in coincidence with the 0.077 MeV γ.

Au^{196}, Q_ε. We adopt 1.5_8 MeV in agreement with the mass-spectroscopic data, while Gupta[78] reported $Q_\varepsilon=0.91\pm0.05$ MeV from the $\varepsilon_L/\varepsilon_K$ ratio. This experiment of $\varepsilon_L/\varepsilon_K$ seems to be too difficult to get a reliable result.

Tl^{202}, Q_ε. 1.11 ± 0.02 MeV obtained from the $\varepsilon_L/\varepsilon_K$ ratio[79] is too small. Our estimated value is 1.4_2 MeV.

Tl^{204}, S_n. 6.54 ± 0.03 MeV obtained from the $Tl(n,\gamma)$ reaction[80] seems to be somewhat too small. The transitions to the excited states of Tl^{204} and Tl^{206} are probably responsible for it.

$Bi^{198,199,201,203}$, Q_α's. The α-activities assigned to these nuclei[8] have too large Q-values. We neglect these data. The assignments should be investigated once more.

Bi^{213}, Q^-. The measured total energy release of the $A=4n+1$ natural decay chain seems to be somewhat too small. The new measurements of the α-energies by Vorob'ev et al.[45] relieved this difficulty a little. We adopt $Q^-(Bi^{213})=1.4_5$ MeV instead of 1.39 ± 0.02 MeV[10,81], and obtain a good fit to our systematics.

Ra^{221}, Q_α. 6.83 ± 0.03 MeV obtained with the ionization chamber[82] seems to be too small. We adopt 7.0_1 MeV. Probably most of the α-decays proceed to the excited states of Rn^{117} as is seen in the α-decays of Ra^{223} and Cf^{249}.

Pa^{234}, Q^-. Although the situation around this nucleus is not very clear, the older value, 2.305 MeV[83], is slightly preferred to the recent value, 2.404 ± 0.003 MeV[84], for $Q^-(1.17^m\, Pa^{234})$. We adopt 2.3_2 MeV for this quantity and 2.3_0 MeV for $Q^-(6.7^h\, Pa^{234})$ as the ground-state Q-value. The latter value is not in good agreement with the reported value, 2.383 ± 0.009 MeV[85]. The complicated decay schemes of $1.17^m\, Pa^{234}$ and $6.7^h\, Pa^{234}$ in References 84 and 85 do not seem to be established well.

Am^{246}, Q^-. The adopted values around this nucleus violate the rule 3 slightly. The easiest way to avoid it is to assume that $25^m\, Am^{246}$ is an excited state, but other ways are possible. Since the situation is not clear, we tentatively assume $25^m\, Am^{246}$ to be the ground state.

$Fm^{251,253}$, Q_α's. The measured α-energies[86] are too small for the ground-state transitions. Probably the main α's proceed to the excited states as is seen in the Cf^{249} decay.

Mass data[7,11,12,54]. Our systematics is not directly related to the mass values themselves but to the mass differences between adjacent nuclei. We can say that the difference between the observed masses of Te^{130} and Xe^{130} is in error. However, it is not easy to decide which mass is in error. We can calculate the masses by adding the adopted S_p's and S_n's. Most of the mass values thus obtained should be assigned enormous errors because many S_p's and S_n's are added. However, it is interesting to see how the "best" mass values fit the measured ones. In the calculation of the "best" masses we have to designate the route of the addition of S_p's and S_n's on the Z-N plane since the rounding-offs in the adopted S_p's and S_n's may cause some differences for different routes. We choose a route near the β-stable line and calculate the masses. The resulting "best" masses may be published elsewhere. The agreement between the "best" masses and the measured values for the nuclei with $A\geq70$ is as follows. (We discuss only the nuclei whose masses were measured in comparison with the nuclei with $A<70$. When more than one experimental mass value are available for a nucleus we use the precisest value.) For 111 nuclei the differences between the "best" masses and the experimental values are less than three times the experimental errors (the errors given in the literatures). The differences are three to five times the experimental errors for 28 nuclei. (Ge^{70}, As^{75}, $Kr^{80,83}$, Rb^{85}, $Pd^{102,104,106}$, Cd^{106}, In^{115}, Te^{120}, Xe^{128}, Cs^{133}, Ba^{134}, Ce^{142}, Nd^{150}, $Gd^{156,160}$, Yb^{170}, Lu^{175}, $Hf^{176,179,180}$, W^{180}, Os^{192}, Pt^{195}, Hg^{200}, U^{235}). The differences are more than five times the experimental errors for 17 nuclei. (Ge^{72}, Nb^{93}, $Pd^{108,110}$, $Te^{126,128,130}$, Xe^{130}, Sm^{147}, Ta^{181}, W^{186}, Re^{187}, $Hg^{196,198,199}$, Pb^{208}, U^{238}). The largest difference is that of Nb^{93}, and is 12 times the experimental error. It is well known that the real errors of the mass-spectroscopic data are three or more times those given in the literatures. Therefore, the above agreements seem to be reasonable.

§ 5. General Discussion

In this paper we have tried to adjust the experimental data so as to fit to our systematics. It remains to be seen whether we have over-adjusted or under-adjusted the data.

As was already mentioned in § 2 the fit of our systematics is not very good in some nuclear regions. We shall get informations on the nuclear structure, especially on the relation between the proton and neutron configurations, by investigating the reason for these anomalies. We do not go deep into this problem in this paper. We also omit the discussion of the pairing energies etc.

As the basic data for estimating unkown separation energies all the experimental data do not have an equal weight. Near the β-stable line on the Z-N plane we have relatively many experimental data, and the weight of each datum is small. In these regions we can detect the wrong data rather easily. On the other hand, the data are few in the regions far from the β-stable line, and the weight of each datum is large. Unfortunately, the detection of the errors in these regions is rather difficult. Therefore, there is a danger that many estimated values in these regions are in error because of a rather small number of wrong experimental data. We hope that the Q-values in these regions will be measured with great care.

The tabulation in this paper is necessarily of tentative nature. We expect that it will be revised in case of necessity.

The authors are greatly indebted to Mr. T. Yamauchi for the preparation and the continual revision of the manuscript of the bulky table.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 16, No. 8, AUGUST, 1961

The $N^{14}(d, \alpha)C^{12}$ Ground-State Reaction in the Energy Range of Deuteron from 1.5 to 3.0 MeV

By Toshiyuki ISHIMATSU
Department of Physics, Kyusyu University, Hukuoka, Japan

(Received March 14, 1961)

The angular distribution for the $N^{14}(d, \alpha)C^{12}$ ground-state reaction was obtained at seven deuteron energies between 1.5 and 3.0 MeV, and the excitation function for this reaction at the laboratory angle of 30° was determined in the same energy range of deuteron. The angular distribution varies remarkably with deuteron energy, suggesting that the reaction proceeds mainly via compound nucleus formation. The energy dependence of the 30°-differential cross section and the total cross section indicate the presence of overlapping resonances at the excitation energy of about 22.6 MeV in the compound nucleus, O^{16}.

§1. Introduction

Many investigations have shown that nuclear reactions induced by particles having energies of 10 to 50 MeV, in which the final nuclei are left in low-lying states, procceed mainly via direct interaction processes. In particular, (d, p) and (d, n) reactions on light nuclei proceed via a stripping process even at deuteron energies below 10 MeV, and in some cases angular distributions for these reactions show patterns characteristic of the stripping process down to deuteron energies of about 1 MeV. So it is interesting to investigate a (d, α) reaction at low deuteron energies and to compare the results, particularly the energy dependence of the total cross section, with those of the (d, p) and (d, n) reactions on the same nuclide in the same energy range of deuteron, in order to understand the reaction mechanisms of these reactions at low energies.

Recently, the $N^{14}(d, p)N^{15}$ and $N^{14}(d, n)O^{15}$ reactions leading to the ground states of the final nuclei have been studied in this laboratory in the energy range of deuteron from 1.5 to 3 MeV[1),2)]. Either of the angular distributions of these proton and neutron groups has a forward peak characteristic of the stripping process in the whole energy range studied, and also has a remarkable backward peak whose intensity relative to the forward peak shows considerable and rather irregular variation with deuteron energy. Moreover, the angular distributions for the two reactions are similar to each other at the same deuteron energy, and the energy dependences of the total cross sections are quite similar to each other, particularly either of them shows a definite peak at the deuteron energy of about 2.75 MeV. In view of these situations, it was attempted to study the $N^{14}(d, \alpha)C^{12}$ ground-state reaction in the energy range of deuteron from 1.5 to 3 MeV. This reaction has such a high Q-value of 13.57 MeV that it is comparatively easy to study it with a conventional scintillation spectrometer even at such low bombarding energies. It seems interesting to see whether the energy dependence of the angular distribution for the $N^{14}(d, \alpha)C^{12}$ ground-state reaction has some correspondence to that for the $N^{14}(d, p)N^{15}$ ground-state or $N^{14}(d, n)O^{15}$ ground-state reaction, and whether the excitation function of the former reaction has a maximum at about 2.75 MeV of deuteron energy where either of the latter two reactions has a definite maximum.

So far, the $N^{14}(d, \alpha)C^{12}$ reactions has been studied by several authors. Booth et al.[3)] measured the differential cross sections for the two most energetic alpha-particle groups at three energies of deuteron below 1 MeV. They carried out an analysis of the angular distributions in terms of Legendre polynomials and found that the terms of higher order polynomials than $P_3(\cos\theta)$ have no appreciable contribution, and inferred that a direct interaction mechanism does not play any important role in the reaction. Gibson and Thomas[4)] measured the angular distribution of the ground-state alpha particles at the deuteron energy of 8 MeV, and found a complex angular distribution. It shows a pattern characterized by strong forward and backward peakings and maxima occurring at approximately symmetrical angular positions about 90°, i.e., at about 40°, 90° and 140°. Hu[5)] studied the angular distributions of the ground- and first-excited state alpha particles at three deuteron energies about 11 MeV, and obtained the results which can be explained fairly well on the basis of a direct interaction mechanism, so called pick-up process. At the deuteron energy of 21 MeV, Fischer and Fischer[6)] studied the same alpha-particle groups as studied by Hu and found the angular distributions not inconsistent with the pick-up process. It is suggested from the above informations that the direct process plays a substantial role in the $N^{14}(d, \alpha)C^{12}$ ground-state reaction at deuteron energies above 11 MeV, and the decrease of deuteron energy from 11 to 8 MeV produces a remarkable change of the angular distribution for this reaction, indicating the decrease of the contribution of the direct process.

§ 2. Experimental Methods

This experiment was carried out with the electrostatic generator at Kyusyu University. The deuteron beam, analyzed with a 45° deflecting magnet, passed through two slits which were 26 cm distant from each other and entered into a scattering chamber, and fell on a nitrogen target mounted at the center of the chamber. The first slit, 80 cm distant from the exsit of the beam-analyzing magnet, consisted of two electrically insulated tantalum plates and served to pick up error signals for the stabilizer of accelerating voltage. Its width could be changed by moving the plates with a screw system drived at the outside of the beam conducting tube, and in this work was set to be 1 mm. The second slit, 30 cm distant from the target, was made of a silver plate pierced with a circular opening of 4 mm in diameter. The scattering chamber of 23 cm in diameter had windows on its side wall at intervals of 15°, starting on one side at 7.5° to the beam direction and at 15° on the other side. Each window consisted of a circular opening of 3 mm in diameter covered with a nickel foil of 0.05 mil in thickness.

The nitrogen target was melamine, $(C_3H_6N_6)$, deposited by vacuum evaporation on a silver foil of 2 mg/cm² in thickness. The thickness of the melamine layer was measured to be 0.39 mg/cm² by weighing the backing foil with a chemical balance before and after the evaporation of melamine onto it. This value of thickness corresponds to an energy loss of about 80 keV for 2.0-MeV deuteron.

Charged particles produced by the deuteron bombardment of the target came out of the scattering chamber through the side windows and entered into a detector mounted close to one of the windows. Two types of detectors were used to detect the alpha particles from the $N^{14}(d, \alpha)C^{12}$ ground-state reaction which we call α_0 hereafter. The first one was a conventional scintillation counter which had been used in this laboratory to study (d, p) reactions on some light nuclei, and consisted of a CsI(Tl) crystal of the dimension of $(1.5\,\text{cm})^2 \times 1$ mm and a DuMont 6291 photomultiplier. When the detector was mounted on the scattering chamber, the distance between the crystal and the nickel foil of the window was about 1 cm. Output pulses from the photomultiplier were amplified and analyzed by a 20-channel pulse-height analyzer. In the pulse-height spectra obtained at angles less than about 105°, the α_0 peak was completely separated from the other peaks of charged particles, as shown in Fig. 3, therefore, the detector of the first type could be used. At backward angles larger than about 120°, the α_0 peak overlapped on the peaks of low energy protons, and the detector of the second type, shown in Fig. 1, had to be used to discriminate alpha particles from protons. This detector was a counter telescope, consisting of a proportional counter that measured specific energy losses of passing particles, and a scintillation counter that determined the energies of incoming particles. The diameter of the cylindrical cathode of the proportional counter was 2.5 cm and the center wire was a steel wire of 0.03 mm in diameter. The particles passed through the proportional counter in parallel with the central wire and entered into a scintillation crystal. The sensitive length of the proportional counter was 2 cm. The entrance for the particles is a circular opening of 6 mm in diameter covered with 0.05-mil nickel foil. The counter was filled with argon mixed with 3 per cent of carbon dioxide at a pressure of 15 cm Hg. The scintillation counter was a CsI(Tl) crystal of 1 mm in thickness mounted on a DuMont 6291 photomultiplier. The sensitive area of the crystal was defined by a circular opening of 10 mm in diameter, 36 mm apart from the entrance. Outputs from the proportional and scintillation counters were fed to a coincidence circuit of resolving time of 1 microsecond after passing severally through an amplifier and a pulse-height discriminator. A 20-channel pulse-height analyzer, gated by the outputs from the coincidence circuit due to the alpha particles, determined the pulse-height spectrum of the alpha particles. Fig. 2 shows a block diagram of the electronic circuits. The bias level of the discriminator following the proportional counter was set as follows. At a forward angle, a pulse-height spectrum was taken in the above mentioned way and was compared to that taken by keeping the gate of the 20-channel analyzer open regardless of the coincidence pulses. Since in the latter spectrum the α_0 peak was separated completely from the other peaks, the areas of the α_0 peaks in the two spectra could be compared with each other after normalized to a fixed number of monitor counts. The bias level was fixed to a value not so high that the area of the α_0 peak in the former spectrum was smaller than that in the latter, and not so low that pulses due to low energy protons remained in the former spectrum. Fig. 3 shows pulse-height spectra taken with the counter telescope at the laboratory angle of 45° and at the deuteron energy of 2.23 MeV, one of which is a coincidence-gated spectrum and the other is a open gate spectrum. A scintillation counter similar to the detector of the first type was mounted on the 22.5° window and was used

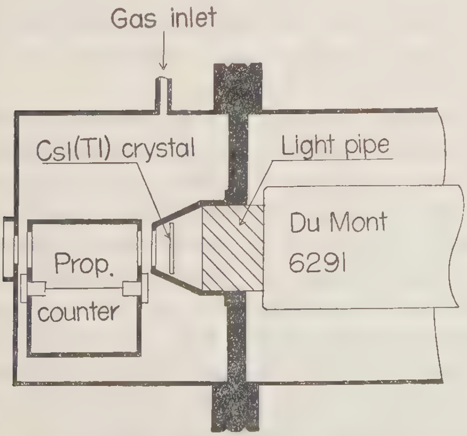

Fig. 1. The schematic diagram of the counter telescope for alpha-particle detection.

as a monitor counter. Of the pulses from the monitor, only the pulses corresponding to the protons from the $N^{14}(d, p)N^{15}$ ground-state reaction were selected by means of a pulse-height discriminator and were registered.

When the counter telescope was used for alpha-particle detection, it was cared that the multiple scattering of alpha particles in the counter gas, the nickel foils on the side window of the scattering chamber and the entrance of the telescope, and the air between these two foils, might cause some losses of alpha particles and distort the alpha-particle angular distributions. So that, the angular distributions of the α_0 group were determined with the counter telescope in the angular range from 15° to 120° at the deuteron energies of 1.94 and 2.47 MeV, and were compared to those obtained with the first type detector at the same deuteron energies. At either energy, the two angular distributions agreed within statistical uncertainties, when they were normalized to each other. It is seen from this fact that, when the counter telescope was used, the multiple scattering would not have any serious effect at least on the shape of the alpha-particle angular distribution, because the sensitive area of the scintillation crystal of the first type detector subtended a sufficiently large solid angle to the side window of the scattering chamber, and therefore, the losses of alpha particles attributed to the multiple scattering may be considered to be negligible when the measurements were done with the first type detector.

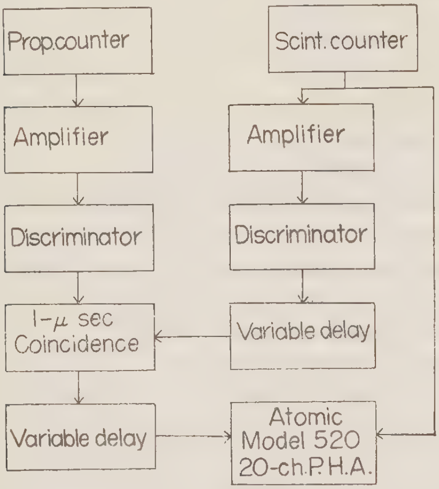

Fig. 2. The block diagram of the electronic circuits for the counter telescope.

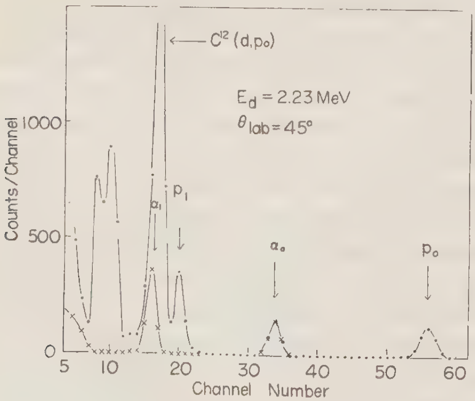

Fig. 3. Pulse-height spectra taken with the counter telescope at the laboratory angle of 45° and at the deuteron energy of 2.23 MeV. The curve connecting crosses is the coincidence-gated spectrum and the curve connecting dots is the open gate spectrum.

The deuteron beam was stopped in a Faraday cup of 3 cm in diameter and 5 cm in depth, and the integrated beam current was determined with a current integrator similar to that designed by Higinbotham and Rankowitz[7]. The secondary electrons emitted from the cup were suppressed by the magnetic field produced by two pieces of Ferite attached to the cup. When the excitation function was measured, the cup was positioned as close to the target as possible in order to avoid the effect of the deuteron scattering in the backing material of the target, since at small angles this effect was expected to be considerable for the deuterons of energies below 3 MeV. The distance between the forward edge of the cup and the center of the target was chosen to be 5 cm, as the excitation function was measured at the laboratory angle of 30°.

The total counts of the α_0 group obtained at different counter angles and a certain deuteron energy were normalized to a fixed number of the monitor counts to get the angular distribution in the laboratory system. The forward angular distribution determined with the first type detector and the backward distribution determined with the second type detector were normalized to each other at two or three angles where the measurements were done with both of the detectors. The excitation function at the laboratory angle of 30° was obtained by normalizing the total counts of the α_0 group obtained at the fixed counter angle of 30° and at different deuteron energies to a certain value of the integrated beam current.

§ 3. Results and Discussions

Figs. 4, 5 and 6 show the angular distributions of the α_0 group at the deuteron energies of 1.48, 1.73, 1.94, 2.23, 2.49, 2.74 and 3.02 MeV. These energy values refer to the mean deuteron energies in the melamine target. Uncertainties of the experimental values shown in these figures are only statistical. Fig. 7 shows the excitation function of the $N^{14}(d, \alpha)C^{12}$ ground-state reaction at the laboratory angle of 30°, and the energy dependence of the total cross section for the same reaction derived from integration of the α_0-group angular distributions shown in Figs. 4, 5 and 6 over the whole solid angle. Each experimental point in the 30°-excitation function given in Fig. 7 represents an average of the values obtained in several runs and the two points at the deuteron energies of 1.94 and 2.49 MeV were both determined as the average of five experimental values, from the distribution of which the standard deviations of the two points are both estimated to be 2%.

The scales on the ordinates of these figures were determined on the basis of the absolute differential cross sections at the laboratory angle of 30°, which were obtained in the 30°-excitation function measurement from the data of the counts of the α_0 group, the target thickness, the integrated beam current and the geometry of the experimental arrangement. The inaccuracy in the scale of the absolute differential cross section is estimated to be ±15%, which is mainly attributed to the uncertainty of the target thickness. Kawai[1)] determined the absolute differential cross section of the $N^{14}(d, p)N^{15}$ reaction in the energy range of deuteron from 1 to 3 MeV, by determining the intensity ratio of the two proton groups, that is, the ground-state proton group from the $N^{14}(d, p)N^{15}$ reaction and the proton group from the $D(d, p)T$ reaction, emitted simultaneously from the deuteron bombardment of a mixture of nitrogen and deuterium gases, and by using the known differential cross section of the $D(d, p)T$ reaction. Accordingly, it was tried to determine the differential cross section of the $N^{14}(d, \alpha)C^{12}$ ground-state reaction, at several deuteron energies, by determining the intensity ratio of the two particle groups, the α_0 group, and the ground-state proton group from the $N^{14}(d, p)N^{15}$ reaction, emitted at the laboratory angle of 30° simultaneously from the deuteron bombardment of the melamine target, and using the differential cross section of the $N^{14}(d, p)N^{15}$ ground-state reaction obtained by Kawai. The values of the 30°-differential cross section obtained by the above mentioned method agree within 5% with those given in Figs. 4 to 7 at every deuteron energies where the measurements where the measurements were done. This excellent agreement is probably fortuitous in view of the experimental accuracies, it is, however,

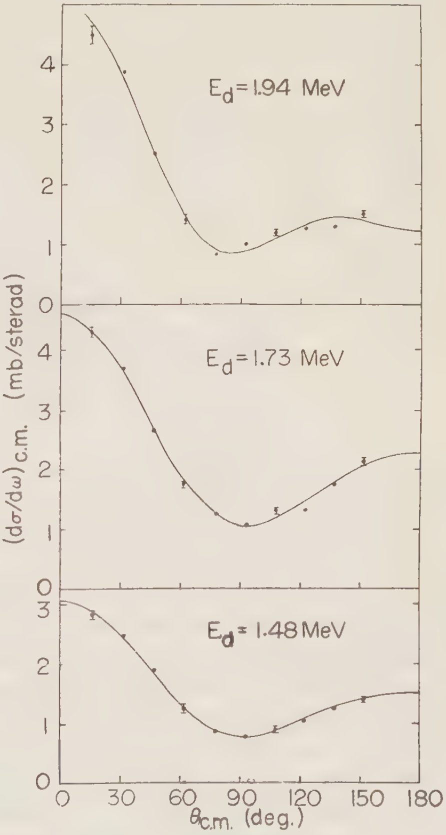

Fig. 4. Angular distributions for the $N^{14}(d, \alpha)C^{12}$ ground-state reaction at the deuteron energies of 1.48, 1.73 and 1.94 MeV. The solid curves represent the series of Legendre polynomials, $\sum_l a_l P_l(\cos\theta)$, where the coefficients a_l were determined by the least square fits of the experimental angular distributions to the series and are given in Table I.

thought to be some evidence of reliability of our methods of target preparation, target-thickness determination and beam-current integration, because, in Kawai's method of cross-section determination, it is unnecessary to know the absolute values of the target thickness and the integrated beam current.

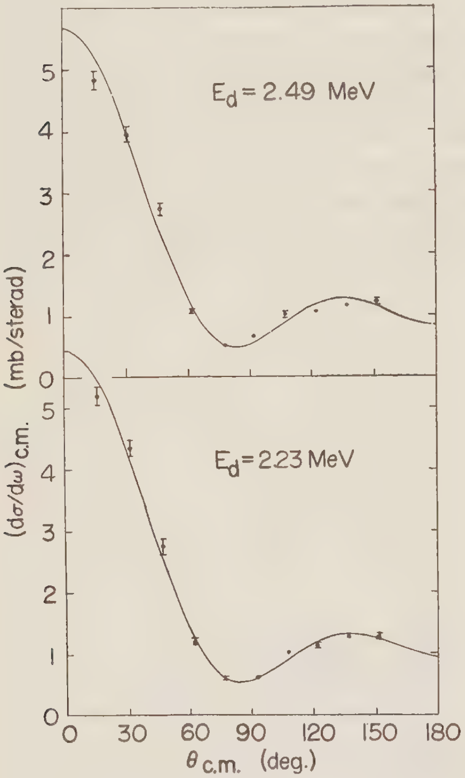

Fig. 5. Angular distributions for the $N^{14}(d, \alpha)C^{12}$ ground-state reaction at the deuteron energies of 2.23 and 2.49 MeV. The solid curves have the same meaning as in Fig. 4.

The angular distribution of the α_0 group changes considerably with deuteron energy and at energies above 2.7 MeV a large second maximum appears at about 120°, and at 3.0 MeV the forward peak, observed at the lower energies, disappears suddenly and an alternative peak appears at about 30°. This behavior of the anfular distribution may be understood qualitatively by assuming that the reaction proceeds mainly via compound nucleus formation and a few excited states in the compound nucleus are involved in the reaction. The asymmetry of the angular distribution about 90° suggests the interference effects between the compound states of opposite parities. The reaction concerned forms the compound nucleus, O^{16}, at an excitation energy as high as 22 to 23 MeV, but there exist some evidences suggesting that O^{16} has a relatively small level density even at such a high excitation energy. For instance, Penfold and Spicer[8] have reported the presence of four levels in O^{16} in the range of excitation energy from 22 to 23 MeV by studying the breaks in the yield curve of the $O^{16}(\gamma, n)O^{15}$ reaction. The present 30°-excitation function for the $N^{14}(d, \alpha_0)C^{12}$ reaction also shows a resonance-like structure which may be indicative of the excited states in O^{16} as discussed later. The energy dependence of the total cross section, obtained by integration of the angular distributions at different energies over the whole solid angle, is similar to that of the 30°-differential cross section, though the similarity is not so definite because of the large intervals between the adjacent experimental points.

Table I. Coefficients, a_l, obtained by the least square fits of the α_0-angular distributions at different deuteron energies to the series of Legendre polynomials, $W(1+a_1P_1+a_2P_2+\cdots)$.

The least square fits of the experimental angular distributions to the series of Legendre polynomials, $\Sigma_l a_l P_l(\cos\theta)$, were carried out. The coefficients a_l obtained in the analysis are given in Table I and the resulting curves are shown by the solid curves in Figs. 4, 5 and 6. The angular distributions at deuteron energies up to 2.47 MeV can be represented approximately in terms of the Legendre polynomials up to $P_3(\cos\theta)$. At 2.74 and 3.02 MeV, large $P_4(\cos\theta)$ terms are required to get the only approximate fits of the experimental results. At 3.02 MeV, the resulting curve has negative values at angles larger than about 160° indicating that the large higher order terms are also required to get the approximate fit of the actual angular distribution over the whole angular range. In general, the fits obtained here are not so good except for the 1.48-MeV angular distribution, but it will be insignificant to obtain further fits with the higher order Legendre polynomials in view of the experimental uncertainties. It is well known that the complexity of the angular distribution in angle of the outgoing particles is not higher than $(\cos\theta)^{2L}$ when a nuclear reaction proceeds via compound nucleus formation and only a restricted range of orbital angular momenta $l \leqq L$ are effective in producing the reaction. But, if the resonance level of the compound nucleus has a total angular momentum J, which is less than the maximum orbital angular momentum L, the complexity is not higher than $(\cos\theta)^{2J}$. In order to get some informations about the angular momenta involved in the reaction concerned, we calculated the relative penetrabilities of the partial waves of incident deuteron into N^{14} nucleus at two deuteron energies of 1.5 and 2.5 MeV, using the data given by Bloch et al.[9] and the value of nuclear radius of 4.8×10^{-13} cm. The results are given in Table II. Energies of the outgoing alpha particles are too high above the potential barrier to impose any restriction to the angular distribution because of the orbital angular momentum. It will be seen that the complexities of the experimental angular distributions at deuteron energies up to about 2.7 MeV are substantially restricted by the maximum effective orbital angular momentum of incident deuteron, L, rather than the maximum of the total angular momenta of the compound states effective in producing the reaction, $J_{\max}$, since these angular distributions are approximately represented in terms of the Legendre polynomials up to $P_4(\cos\theta)$ and L is taken to be equal to 2 at deuteron energies below 2.5 MeV as seen in Table II.

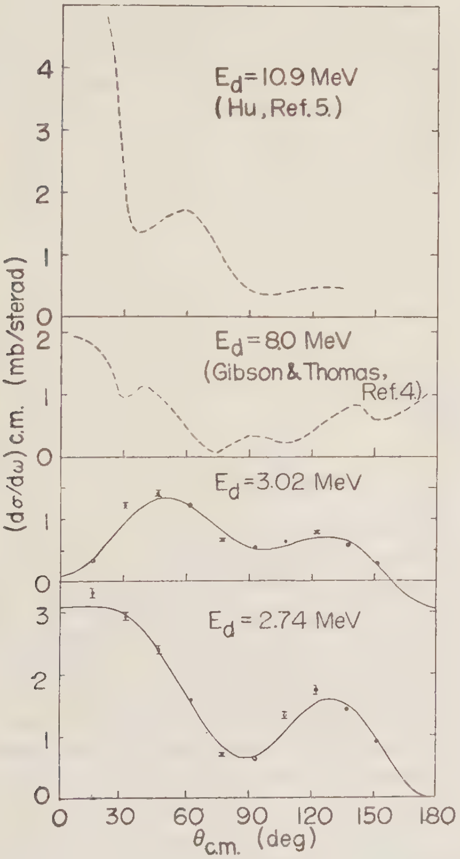

Fig. 6. Angular distributions for the $N^{14}(d, \alpha)C^{12}$ ground-state reaction at the deuteron energies of 2.74 and 3.02 MeV. The solid curves have the same meaning as in Fig. 4. Angular distributions for the same reaction at 8.0 and 10.9 MeV, obtained by Gibson and Thomas[4] and Hu[5] respectively, are also shown for the sake of comparison.

Table II. Calculated relative penetrabilities of the partial waves of deuteron into N^{14} nucleus. The value of nuclear radius of 4.8×10^{-13} cm was used in the calculations.

E_d(MeV)	l			
	0	1	2	3
1.5	1	0.47	0.09	8×10^{-3}
2.5	1	0.64	0.21	0.03

In other words, $2\leqq J_{\max}\leqq 4$ in this energy range of deuteron, because the maximum channel spin of the incident channel is equal to 2. The poorer fit of the angular distribution at 2.74 MeV in terms of $P_l(\cos\theta)$ up to $l=4$ is probably indicative of a small contribution of the incident f wave. The requirement of the terms of higher order Legendre polynomials than $P_4(\cos\theta)$ at 3.02 MeV, however, will not be able to be understood merely by the increased contribution of the f wave or an onset of any reaction mechanism other than the compound nucleus formation. Alternatively, the abrupt change of the angular distribution in the energy range from 2.5 to 3.0 MeV are thought to be due to the level structure of the compound nucleus, O^{16}. In view of the small total cross section at 3.02 MeV, it seems reasonable that at this energy, the contribution of the compound states, which can be excited by the incident wave with orbital angular momentum $l \leq 2$, largely decreases and the contribution of the f wave or some other direct process becomes comparatively important. In that case, the broad peak that is observed in the excitation functions shown in Fig. 7 may be attributed to the overlapping resonances due to the compound states in O^{16}, each of which has a total angular momentum $J \leq 4$. Moreover, parities of these states must be even, if their total angular momenta are even, and must be odd if their total angular momenta are odd, because the total angular momenta and parities of alpha particle and the C^{12} ground state are both zero and even.

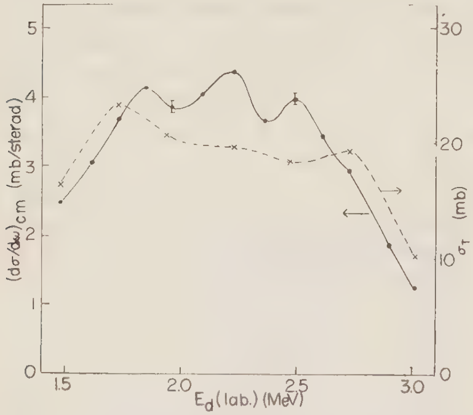

Fig. 7. The excitation function for the $N^{14}(d, \alpha)C^{12}$ ground-state reaction at the laboratory angle of 30° and the energy dependence of the total cross section for the same reaction derived from integration of the angular distributions shown in Figs. 4, 5 and 6. The former is shown by a curve connecting dots, and the latter by a curve connecting crosses.

Some informations about the compound states contributing to the broad peak are obtained, when the 30°-excitation function for the $N^{14}(d, \alpha_0)C^{12}$ reaction obtained in the present experiment is compared with the 0°-excitation function for the $N^{14}(d,n_0)O^{15}$ reaction determined by Weil and Jones[10]. They have determined the absolute cross section for this reaction at 0° to the incident beam in the bombarding energy range from 0.6 to 5.3 MeV. The excitation function shows a strong resonance-like structure, and broad peaks are observed at the deuteron energies of about 1.5, 2.7 and 4.2 MeV. Superposing on the strong gross structure, weaker anomalies are also found at 1.81, 2.18, 2.41 and 2.67 MeV in the energy range of deuteron from 1.7 to 3.0 MeV. On the other hand, in the 30°-excitation function for the $N^{14}(d, \alpha_0)C^{12}$ reaction, peaks are observed at the deuteron energies of about 1.85, 2.2 and 2.5 MeV and perphaps at about 2.7 MeV, in spite of rather poor energy resolution of the measurement. These two excitation functions are shown in Fig. 8. The positions of the anomalies in both excitation functions are coincident very well, suggesting that these anomalies correspond to the excited states in O^{16}. In the excitation function for the $N^{14}(d, n_0)O^{15}$ reaction, anomalies are also present at 1.15, 1.52, 1.62, 2.85 and 3.16 MeV in the energy range of deuteron below 3.5 MeV.

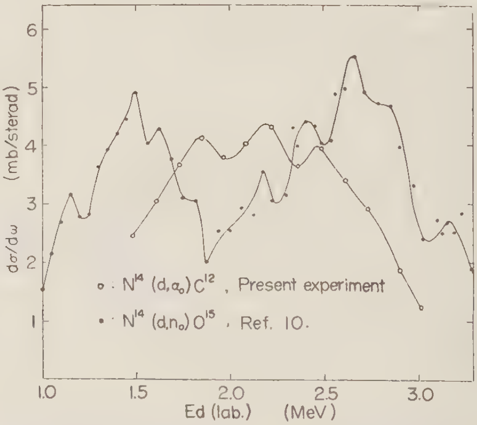

Fig. 8. Excitation functions for the $N^{14}(d, \alpha)C^{12}$ ground-state and $N^{14}(d, n)O^{15}$ ground-state reactions at the laboratory angles of 30° and 0° to the incident beam direction, respectively. The latter is taken from reference 10. The scale of differential cross section refers to c.m. system for the former, and to laboratory system for the latter.

Morita[11] has measured the excitation function for the $N^{14}(d, n_0)O^{15}$ reaction in the energy range of deuteron from 1.0 to 2.2 MeV at the laboratory angles of 0°, 90° and 165° to the beam direction. His result at 0° agrees well with the result obtained by Weil and Jones, showing a broad peak at about 1.5 MeV and weak anomalies at about 1.2, 1.5, 1.6 and

1.8 MeV. The 90°-excitation function is rather flat and shows a similar trend in gross structure to the 0°-excitation function, and a weak anomaly is also seen at about 1.2 MeV. while, the 165°-excitation function shows a prominent broad peak at about 1.9 MeV and a weak anomaly at about 1.8 MeV. It appears that there are some other anomalies in the 90°- and 165°-excitation functions though they are not so definite because of comparatively low energy resolution. Energy level diagrams for O^{16} in the region of excitation from 20 to 24 MeV showing the results of the three experiments are shown in Fig. 9.

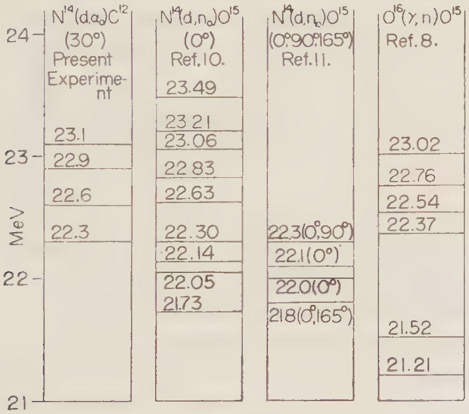

Fig. 9. Energy level diagrams for O^{16} in the range of excitation energy from 20 to 24 MeV showing the results of several experiments.

It is interesting to note that the broad peaks, seen in the excitation function at a certain angle of observation for the $N^{14}(d,n_0)O^{15}$ reaction, do not necessarily correspond to the excited states in O^{16} but to variation of the angular distribution with bombarding energy, and that superposing on them, there are relatively narrow resonances which correspond to the excited states in O^{16}. This resonance-like variation of the angular distribution cannot be explained on the basis of the simple stripping theory, while there exists no positive evidence that the variation is an interference effect due to the level structure of O^{16}. To get further informations about this point, it is desired to study the $N^{14}(d, \alpha)C^{12}$ and $N^{14}(d, p)N^{15}$ reactions at higher energy resolution in the region of bombarding energy concerned.

In Fig. 9, an energy level diagram for O^{16} showing the results obtained by Penfold and Spicer[8] is also shown. It is seen in this figure that the four levels in the range of excitation energy from 22 to 23 MeV observed for the $O^{16}(\gamma, n)O^{15}$ reaction agree in position with those observed for the other two reactions. Penfold and Spicer conclude from an analysis of the widths and integrated cross sections that the four levels observed for the $O^{16}(\gamma, n)O^{15}$ reaction are reached by electric dipole absorption by comparison with Wilkinson's equation[12]. Therefore, these four states should be $T=1$ states, if isotopic spin is a good quantum number. While, isotopic spins of the ground state of N^{14} and deuteron are both equal to zero, so that $N^{14}+d$ can only form $T=0$ states in O^{16}. Accordingly, the agreement in position between the states in O^{16} excited in the three reactions suggests that isotopic spin is not a very good quantum number in this region of excitation as is stated by Wilkinson[13]. The agreement, however, may be accidental in view of the facts that the scale of the excitation energy given in reference 8 can be in error by as much as 300 keV at 23 MeV, and the measurement was not done in the range of excitation energy from 21.5 to 22.1 MeV in reference 8. In any case, it appears that there is no decisive reason that excludes the correlation between the broad resonances in the region of excitation energy from 22 to 23 MeV in O^{16} observed for the $N^{14}(d, \alpha)C^{12}$ ground-state reaction in this work and for the $O^{16}(\gamma,p)$[14,15], $O^{16}(\gamma, n)$[16], $O^{16}(\gamma, 4\alpha)$[17,18] and $N^{15}(p, \gamma)$[19] reactions.

Level Structure of Nd^{144}

By Kazusuke SUGIYAMA, Akira FURUSAWA, Shogo HAYASHIBE
and Motoharu KIMURA

Department of Physics, Faculty of Science, Tohoku University, Sendai

(Received May 1, 1961)

The energies and spins of lower excited levels in Nd^{144} have been established by studies of the beta decay of $Ce^{144}-Pr^{144}$ and the electron capture decay of Pm^{144}. The experiments include the energy and relative intensity measurements, and directional correlation measurements of gamma rays by several NaI (Tl) scintillation counters. The level of Nd^{144} is populated at the 695 keV and 2190 keV from decay of Pr^{144}, and the 695 keV, 1310 keV, and 1780 keV from the decay of Pm^{144}. The levels at the 1220 keV and the 1560 keV which have been found by the neutron capture gamma ray measurements could not be found in both decay in the limit of about one percent.

§ 1. Introduction

The levels of ${}_{60}Nd_{84}{}^{144}$ have been studied by a number of investigators[1] from $Ce^{144}-Pr^{144}-Nd^{144}$ negatron chain decay, and the decay scheme has also been proposed. Moreover, the directional correlation of 1490 keV−695 keV cascade has been measured also by a few investigators[2], and these results were consistent with a 1–2–0 spin sequence though there were some disagreement on the correlation coefficients.

On the other hand S. Ofer[3] has studied an electron capture decay of Pm^{144}, and reported three gamma rays, 695, 610 and 475 keV, and measured directional correlations of these radiations. He proposed 2^+ for 695 keV level, 4^+ for 1310 keV level and 6^+ for 1780 keV level.

Recently, the analyses of gamma rays following neutron capture in Nd^{143} were made by a few investigators[4),5)]. Although many levels in Nd^{144} were reported, there were serious discrepancies against each other. (see Fig. 6).

The purpose of the present work is to clarify the previous results of the level structure of Nd^{144} by means of a coincidence spectrum works and directional correlation measurements of gamma rays not only on the negatron decay of Pr^{144} but also on the electron capture decay of Pm^{144}, and furthermore, to search the 1220 keV 2^+ level[4] and the 1560 keV (2 or 3^+) level[5] found in the de-excitation of neutron capture of Nd^{143}.

§ 2. Experimental procedures

a) Source preparations

Ce^{144} was obtained from the Oak Ridge National Laboratory in the form of $CeCl_3$ in HCl solution. Pm^{144} was produced by the bombardment of Nd_2O_3 with 14 MeV protons in the 160 cm cyclotron of the Institute for Nuclear Study, University of Tokyo. After the bombardment, the activity was separated chemically by an ion-exchange column, and the source was made in the form of the $PmCl_3$ in HCl solution. It was necessary to cool down for a long time since there were severel radioactive isotopes owing to the use of natural Neodymium.

b) Coincidence studies

Gamma-gamma coincidence measurements were examined with a 3 in. dia. × 3 in. long, and a 2 in. dia. × 2 in. long NaI (T1) scintillation counters in combination with a 256 channel pulse height analyser. A diode fast-slow coincidence circuit was used, and it was operated at a resolving time (2τ) of 2×10^{-7} sec.

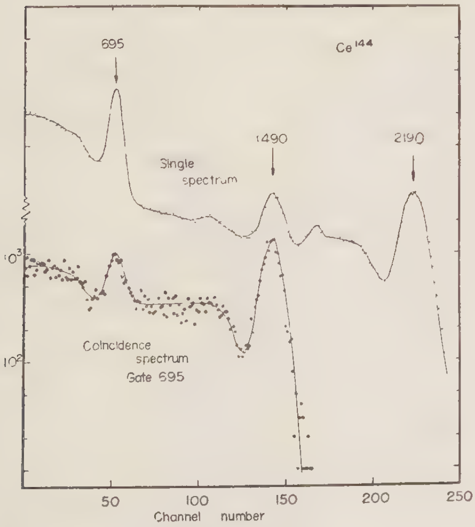

Fig. 1. Scintillation pulse height spectra in Ce^{144} using a 3 in. × 3 in. NaI (T1) with 35 mm dia. 50 mm long lead slit.

——•—— ; single spectrum

In the decay of Pr^{144}, an observed gamma-gamma coincidence spectrum is shown in Fig. 1 with a single gamma ray spectrum.

The coincidence spectra in the decay of Pm^{144} are shown in Fig. 2 also with a single spectrum.

• ; coincidence spectrum with the 615 keV photo-peak

• —— ; coincidence spectrum with the 475 keV photo-peak

c) Directional correlation measurements

The directional correlation measurements were carried out using two 1½ in. long NaI (T1) crystals and RAC 6810A photomultipliers. The potomultipliers were operated at high voltage (1500∼1900 volts) and were fed to the diode fast-slow coincidence circuit which was operated at $2\tau=9\times10^{-9}$ sec. The goniometer is driven automatically, and a camera method to record the data on scalers can be used and in addition a rotating source method was also employed to correct excentricity and inhomogenity in source material. These electronic circuit block diagram and a goniometer are shown in Figs. 3 and 4 respectively.

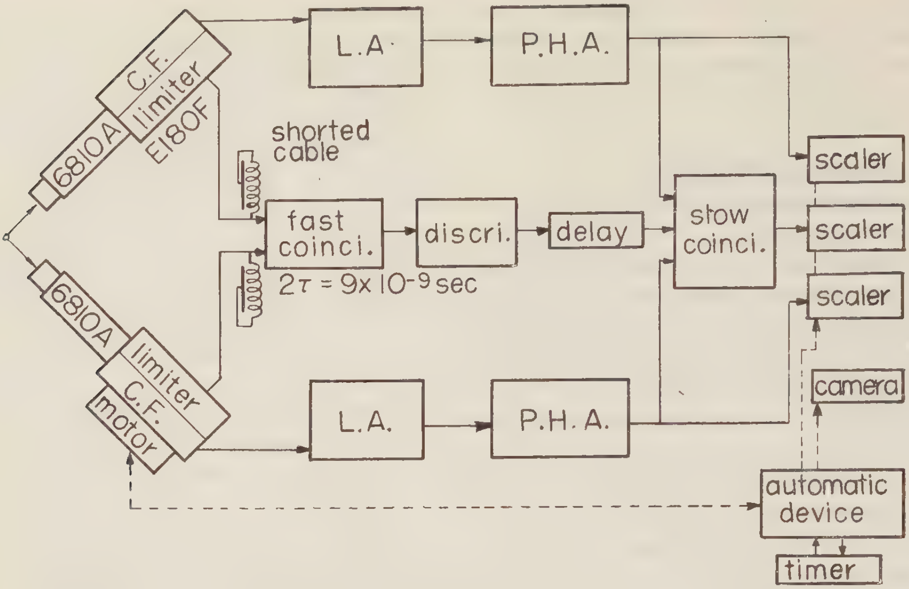

Fig. 3. Block diagram of the gamma-gamma directional correlation arrangement. High voltage power supply for photomultipliers was omitted in this figure.

The measured correlation coefficients were corrected for a finite angle resolution. A method of this correction was employed as follows; finite angle resolutions were measured by using colimated gamma rays through a 3 mm dia. 50 mm long and 10 mm dia. 50 mm long aperture. We used Cs^{137} (661 keV), Co^{60} (1.17 and 1.33 MeV) and annihilation gamma ray from Na^{22} as gamma ray sources. The correction factor $J\nu/J_0$ was calculated using a formula given by Lawson and Frauenfelder[6].

Table I. Energy and relative intensity of gamma radiations in Pr^{144} and Pm^{144}.

	Gamma rays (keV)	Relative intensity
Decay of Pr^{144}	695 1490 2190	100 30 60
Decay of Pm^{144}	695 615 475	100 100 46

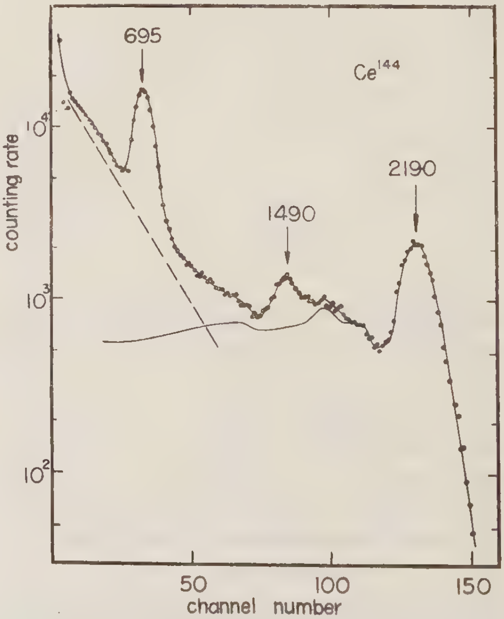

Fig. 5. Scintillation pulse height spectrum in Ce^{144} using a 5 in.×4 in. well type NaI (T1) crystal for summing measurement. The source was contained in a 10 mm dia. plastic cylindrical holder covered by a 0.5 mm thick lead plate.

§ 3. **Results**

a) Gamma rays belonging to Nd^{144} are tabulated in Table I.

These results are not inconsistent with earlier investigations. The 520 keV gamma ray corresponding transition from the 1220 keV 2^+ level to the 695 keV first excited level, and the 970 keV gamma ray corresponding transition from the 2190 keV level to the 1220 keV are not detectable within the limits of one percent. We have tried to find the 1220 keV level reported by Burmistrov et al.[4] using a summing method by a 5 in. dia. and 4 in. long well type NaI (T1) crystal. It was concluded that the 1220 keV level did not exist. It was also concluded by using similar procedures that the 1560 keV did not exist in both decays of Pr^{144} and Pm^{144} in the limit of a few percent.

b) Directional correlation coefficients corrected for the finite angle resolution for each measurement are tabulated in Table II.

Table II. A_2 and A_4 obtained in directional correlation measurements in Pr^{144} and Pm^{144}.

$W(\theta)=1+A_2\cdot P_2(\cos\theta)+A_4\cdot P_4(\cos\theta)$

		A_2	A_4

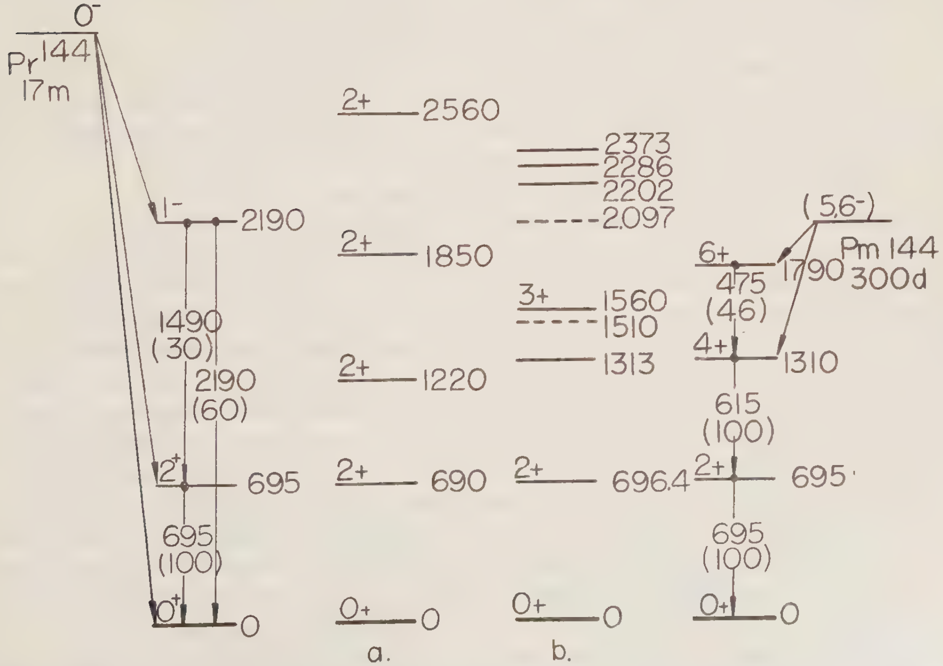

Fig. 6. Energy levels of Nd^{144}. The results of Burmistrov (a) and of Campion et al. (b) obtained by neutron capture gamma ray analysis are also shown.

On the basis of above results, the level scheme of Nd^{144} is given in Fig. 6.

§ 4. Discussion

Many attempts have been made to explain the level structure of even-even nuclei. The Bohr-Mottelson model[7] gives a fairly successful explanation in neutron regions, $90 \leqslant N \leqslant 114$ and $136 \leqslant N$.

However, in the region of so-called intermediate nuclei this model fails to explain many experimental results. Nd^{144} is also this case. $E_4/E_2 = 1.88$ and $E_6/E_2 = 2.56$ for Nd^{144} can not be interpreted even if an interaction of rotation and vibration is taken into account, where E_I is the energy of the first spin I level.

For the even-even nuclei in the region $50 < N < 90$, it has been usual to describe the energy levels as the vibrational excitation. The energy spectrum thus obtained has a uniform spacing

$$\hbar\omega_2 = \hbar\left(\frac{C_2}{B_2}\right)^{1/2}$$

(for quadrupole vibration)

and a level of the energy

$$E^{(n)} = (n + 5/2) \cdot \hbar\omega_2$$

may be characterized as containing n phonons each of which carries a spin 2^+. The first excited level is one phonon excited state, and the two phonon excited states are multiply degenerate, the spin of which are 0^+, 2^+, 4^+, and the three phonon excited states are also multiply degenerate, 0^+, 2^+, 4^+, 6^+. It seems plausible to explain the energy spectrum of Nd^{144} by means of this vibrational model. The 0^+ and the second 2^+ levels are not found in the present experiment, probably because the higher levels have higher spins and will not decay to these levels of low spins, in the decay of Pm^{144}.

If a 0^+ or 2^+ level exists near the 1310 keV 4^+ level, log f_0t to this level in $Pr^{144} \rightarrow Nd^{144}$ beta decay is 4.65 and the beta ray branching ratio is 0.5∼0.1%. Then the 610 keV gamma ray from this level to the first 2^+ level would be observed at 30∼7% of the 695 keV gamma ray. Furthermore the 880 keV gamma ray from the 2190 keV to this level also would be observed at ∼4%. Both gamma rays were not observed. There is no further quantitative prediction from the vibrational model.

From the other point of view, B. J. Raz[8] has proposed a model which took into account an interaction between the nuclear core and two outer particles. He assumed the configuration of two particles was $(7/2)^2$ with $I = 0$, 2, 4 and 6, and the two body interaction which gave a suitable level scheme for Ca^{48} was found to be of reasonable strength.

We apply his method to the present case. According to his theory the two body interaction is given by

$$H_{12} = 3D[3 - \boldsymbol{\sigma} \cdot \boldsymbol{\sigma}_2] \cdot \hbar\omega \cdot \exp(-r^2/r_0^2).$$

This calculation included energy spectra relative to the first 2^+ level changing two parameters D and x which is a nuclear deformation

$$x = k(5/16\pi j \hbar\omega C)^{1/2}$$

If we choose the case of $D = 0.20$ and $x = 0.4$, we find

$$E_4/E_2 = 2.0, \quad E_6/E_2 = 2.5, \quad E'_2/E_2 = 3.3,$$

where E'_2 is the energy of the second 2^+ level. From $E_2 = 695$ keV and above ratios,

$$E_4 = 1390 \text{ keV}, \quad E_6 = 1740 \text{ keV}, \quad E'_2 = 2300 \text{ keV},$$

these values are rather in agreement with the present experimental values, except for the second 2^+ level which is undetectable because of its high energy. A small nuclear deformation $x = 0.4$ is plausible for a near closed shell nucleus ${}_{60}Nd_{84}{}^{144}$.

The levels of odd spin and odd parity are found for many even-even nuclei, and they are interpreted as an octupole vibrational level, and the 2190 keV 1^- level might belong to this kind of level.

Recently A. S. Davydov et al[9]. have developed the axially asymmetric rotor model, in which a nucleus is classified by a parameter γ, which determines the deviation of the shape of the nucleus from axial symmetry through an energy ratio of the second 2^+ level to the first 2^+ level. Many observed energy spectra of even-even neclei, the region of which is much wider than the Bohr-Mottelson model could explain, could be rather satisfactorily explained by assuming various values of γ. Although the values of γ varies between 0 and $\pi/3$, the predicted value of E_4/E_2 is larger than 2.6 over all ranges of γ.

A new development[10] of this model has shown the energy ratio of 1.9 of the first 4^+ level to the first 2^+ level corresponding to

$\gamma=30^\circ$ and $\mu=1.0$, where μ is the non-adiabaticity parameter. Then, the energy ratio of the second 2^+ level to the first 2^+ level is 1.8, and if we take the experimental value of the first 2^+ state of Nd^{144}, the second 2^+ is 1200 keV. Similarly it is concluded that the first 3^+ level is the 1900 keV. This is excluded by the results of Campion et al5). Futhermore, there is a discrepancy on 6^+ level. According to the new Davydov model10), the first 6^+ level of the nucleus having $\gamma=30^\circ$ is 1960 keV, although our experimental result indicates a 6^+ level at 1780 keV.

Acknowledgements

We wish to express our appreciations to Drs. N. Suzuki, S. Oki for the chemical separation of the source material and to Drs. H. Ikegami, E. Takekoshi, K. Nakai, J. Matsumoto for the generous cooperation and the helpful discussions. We are also grateful to the Cyclotron crew and the Beta Group of Institute of Nuclear Study, University of Tokyo, for their help on the Bombardment. This work was supported by the Scientific research grant of the Ministry of Education.

Magnetic Susceptibilities of Cr and Cr-Fe Alloy

By Masao SHIMIZU*

Department of Physics, Faculty of Science,
Tokyo Metropolitan University, Tokyo

and Takeshi TAKAHASHI

Physics Institute, Yamanashi University, Kofu

(Received March 1, 1961)

The magnetic susceptibilities of Cr and Cr-Fe are investigated by the use of the band picture for 3d electrons. The temperature increase of the magnetic susceptibility of Cr is attributed to a minimum of the electron state density. For the shape of the band of Cr two models are adopted, and the calculated susceptibilities are compared with the observed ones. According to this comparison the shape of the band of Cr is discussed, and the result on its shape is compared with that calculated from the specific heat measurement at low temperatures by Cheng et al.

§ 1. Introduction

In the previous paper[1] (we refer this as (I) hereafter) we analyzed the susceptibilities of Cr and Cr-Fe alloy by making use of the band picture and obtained reasonable results. One of the difficulties of our previous calculation is the fact that the calculated susceptibilities at lower temperatures are rather large and are not necessarily in agreement with the observed ones. Since the band shape of our model shown in Fig. 1 of (I) (we refer this as model (1) hereafter) would be rather different from that of the real band in the neighbourhood of the "minimum" of the electron state density, so we could not avoid the disagreement between the calculated values of susceptibilities and their observed values at lower temperatures.

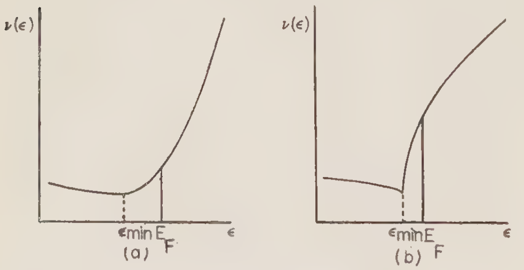

Fig. 1. Electronic state density; (a): model (2), (b): model (3).

Recently, however, McGuire has reported that the susceptibility of Cr increases with decreasing temperature at very low temperatures ($\chi_g=3.9-4.0\times10^{-6}$ e.m.u. g^{-1} at 4.2°K)[2], but details are not reported yet. At any rate, as our model (1) is not so satisfactory, in this paper we attempt to calculate susceptibilities for different models and to find what sort of model for the electron state density of Cr would be the best.

As we described in (I), if the Fermi level at 0°K is near a "real minimum" of the state density the temperature coefficient of the susceptibility is positive at lower temperatures. So we adopt the following band with a real minimum in the state density, $\nu(\mathcal{E})$, (we refer this as model (2)).

$$\nu(\mathcal{E})=\begin{cases} b+a_1(\mathcal{E}_m-\mathcal{E})^2\,, & \text{for } \mathcal{E}<\mathcal{E}_m\,; \\ b+a_2(\mathcal{E}-\mathcal{E}_m)^2\,, & \text{for } \mathcal{E}_m<\mathcal{E}\,, \end{cases} \qquad (1)$$

where $\mathcal{E}_m$ is the energy at which $\nu(\mathcal{E})$ is minimum. This is shown in Fig. 1 (a).

Moreover, calculations are carried out for the model shown in Fig. 1 (b) (we refer this as model (3)). The state density of this model is given by

$$\nu(\mathcal{E})=\begin{cases} b'+a_1'(\mathcal{E}_m-\mathcal{E})^{1/2}\,, & \text{for } \mathcal{E}<\mathcal{E}_m\,; \\ b'+a_2'(\mathcal{E}-\mathcal{E}_m)^{1/2}\,, & \text{for } \mathcal{E}_m<\mathcal{E}\,. \end{cases} \qquad (2)$$

§ 2. Calculations of Paramagnetic Susceptibilities for Models (2) and (3)

From a similar calculation to that in (I), we obtain for model (2)

---

* Now at the Department of Applied Physics, Faculty of Engineering, Nagoya University, Nagoya.

$$\eta+[pF_2(\eta)-F_2(-\eta)]\left(\frac{T}{T^*}\right)^2=\left\{\begin{array}{ll}(1+\frac{1}{3}pr^2)r(T^*/T)\,, & \text{for}\quad r>0\,;\\ (1+\frac{1}{3}r^2)r(T^*/T)\,, & \text{for}\quad r<0\,,\end{array}\right\} \tag{3}$$

and

$$\frac{\chi}{2b\mu_B{}^2}=1+2[pF_1(\eta)+F_1(-\eta)]\left(\frac{T}{T^*}\right)^2. \tag{4}$$

From these equations the Fermi energy, $\mathcal{E}_F$, and the susceptibility, χ, are determined as functions of temperature, respectively. Here, $p=a_2/a_1$, $kT^*=(b/a_1)^{1/2}$, $r=\mathcal{E}_0/kT^*=\mathcal{E}_0(a_1/b)^{1/2}$, $\mathcal{E}_0=(\mathcal{E}_F)_{T=0}$, $\eta=\mathcal{E}_F/kT$, $F_n(\eta)=\int_0^\infty\frac{x^n dx}{e^{x-\eta}+1}$, $n=0, 1, 2$, and μ_B is the Bohr magneton. $\mathcal{E}_F$ is measured from $\mathcal{E}_m$ to the right. Now, let the susceptibilities of a transition metal and its dilute alloy with another metal be χ and $\chi+\Delta\chi$, respectively, we obtain

$$\frac{\mu_B{}^2}{kT^*}\frac{\Delta N}{\Delta\chi}=\frac{\frac{1}{2}+[pF_1(\eta)+F_1(-\eta)](T/T^*)^2}{pF_0(\eta)-F_0(-\eta)}\frac{T^*}{T}\,, \tag{5}$$

where ΔN is the increase of the number of d electrons.

The results of our calculations for the temperature variations of the susceptibility at several values of r when $p=10$ are shown in Fig. 2. We make use of the numerical values of $F_2(\eta)$ and $F_1(\eta)$ which have been given by Rhodes[3]. As we have described in § 1, if $\mathcal{E}_0$ is at the real minimum of the state density χ will increase with temperature monotonously. In fact, as we can see in Fig. 2, for $r\leq 1/\sqrt{p}$ susceptibilities increase with increasing temperature continually. It can also be seen that the increases of the susceptibilities for model (2) at higher temperatures are more rapid than those for model (1). This fact is due to the following reason. As the state density in model (2) is proportional to $\mathcal{E}^2$, the number of electrons which contribute to the susceptibility will increase with increasing temperature rather rapidly. So, as we can see in Eq. (4), susceptibilities for model (2) increase, being proportional to T^2, at higher temperatures. On the other hand susceptibilities for model (1) vary as $T^{1/2}$ at higher temperatures.

For model (3) equations which correspond to Eqs. (3), (4) and (5) for model (2) become

$$\eta+[p'F_{1/2}(\eta)-F_{1/2}(-\eta)]\left(\frac{T}{T'^*}\right)^{1/2}=\left\{\begin{array}{ll}(1+\frac{2}{3}p'r'^{1/2})r'(T'^*/T)\,, & \text{for}\quad r'>0\,:\\ (1+\frac{2}{3}|r'|^{1/2})r'(T'^*/T)\,, & \text{for}\quad r'<0\,,\end{array}\right\} \tag{6}$$

$$\frac{\chi}{2b'\mu_B{}^2}=1+[p'F_{1/2}{}'(\eta)+F_{1/2}{}'(-\eta)]\left(\frac{T}{T'^*}\right)^{1/2}, \tag{7}$$

and

$$\frac{\mu_B{}^2}{kT'^*}\frac{\Delta N}{\Delta\chi}=\frac{1+[p'F_{1/2}{}'(\eta)+F_{1/2}{}'(-\eta)](T/T'^*)^{1/2}}{p'F_{1/2}{}''(\eta)-F_{1/2}{}''(-\eta)}\left(\frac{T}{T'^*}\right)^{1/2}, \tag{8}$$

where $p'=a_2'/a_1'$, $kT'^*=(b'/a_1')^2$, $r'=\mathcal{E}_0/kT'^*=\mathcal{E}_0(a_1'/b')^2$,

$$F_{1/2}(\eta)=\int_0^\infty\frac{x^{1/2}dx}{e^{x-\eta}+1}\,,\qquad F_{1/2}{}'(\eta)=\frac{dF_{1/2}(\eta)}{d\eta}\quad\text{and}\quad F_{1/2}{}''(\eta)=\frac{d^2F_{1/2}(\eta)}{d\eta^2}.$$

The results of the calculations for model (3) are not so different from those for model (1) (Fig. 3(a) in (I)).

Neglecting the difference between densities of pure Cr and dilute alloy of Fe in Cr, and that between the atomic weights of Cr and Fe, we obtain $\Delta N=1.16\times10^{22}qx$ per gram, then

$$\frac{1}{\Delta\chi}=139\frac{T^*}{qx}\frac{\frac{1}{2}+[pF_1(\eta)+F_1(-\eta)](T/T^*)^2}{pF_0(\eta)-F_0(-\eta)}\left(\frac{T}{T^*}\right)^{-1},\qquad\text{for model (2)}\,, \tag{5'}$$

$$\frac{1}{\Delta\chi}=139\frac{T'^*}{qx}\frac{1+[p'F_{1/2}{}'(\eta)+F_{1/2}{}'(-\eta)](T/T'^*)^{1/2}}{p'F_{1/2}{}''(\eta)-F_{1/2}{}''(-\eta)}\left(\frac{T}{T'^*}\right)^{1/2},\qquad\text{for model (3)}\,, \tag{8'}$$

where x is the fraction of Fe atoms and q the increase of d electrons per Fe atom. Both equations give the relation, $1/\Delta\chi \propto T$, at $T \to \infty$.

(b)

Fig. 2. (a) Calculated temperature-variations of susceptibilities in the case of model (2) for $p=10$. (b) Calculated temperature-variations of $\Delta\chi$ in the case of model (2) for $p=10$. $-\cdot-$ is the asymptote for $T\to\infty$.

§ 3. Comparison with Experimental Results and Discussion

In Fig. 3 (a) the observed values of susceptibilities for Cr are compared with the calculated values for model (2) in the case where $p=10$, $r=1/\sqrt{10}$, $T^*=8{,}000$°K and $p=10$, $r=1/2$, $T^*=4{,}000$°K. In Fig. 3 (b) the observed values of $\Delta\chi$ for the alloy of 1.05% Fe in Cr are compared with the calculated values of $\Delta\chi$ for the same parameters with those mentioned above. The values of a, in Fig. 3 (a) are determined so as to get the best agreement between the calculated values and the observed ones for susceptibilities at the highest temperature, and the values of q are determined so as to get the best agreement in the intermediate region of temperature. When r is larger or smaller than the values given above, the agreement between the calculated values of χ and the observed ones becomes unsatisfactory. Anyhow, if the suitable values are taken for parameters the calculated values for model (2) can be fitted with the observed ones for χ. However, by using the same values of parameters with those for χ, satisfactory agreement cannot be obtained between the observed values and the calculated ones of $\Delta\chi$ for model (2). The calculation has been performed for $p=30$, but the result is not so different from that shown in Fig. 3.

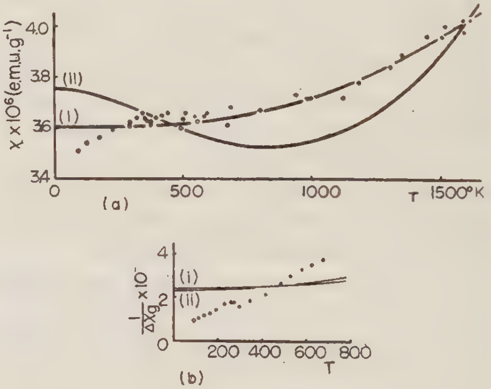

Fig. 3. (a) Comparison between calculated susceptibilities for model (2) and experimental ones for Cr. (b) Comparison between calculated susceptibilities for model (2) and experimental ones for an alloy, 1.05% Fe in Cr. (i) Calculated for $p=10$, $r=1/\sqrt{10}$, $T^*=8{,}000$°K, $a_1k^2=1.64\times10^{26}$ erg^{-1}g^{-1}deg^{-2}, $b=1.050\times10^{34}$ erg^{-1}g^{-1} and $q=14.0$. (ii) Calculated for $p=10$, $r=\frac{1}{2}$, $T^*=4{,}000$°K, $a_1k^2=3.81\times10^{26}$ erg^{-1}g^{-1}deg^{-2}, $b=0.609\times10^{34}$ erg^{-1}g^{-1} and $q=8.0$

• : Experimental results by McGuire and Kriessman[4].

○ : Experimental results by Newmann and Stevens[5].

In Fig. 4 the comparison between the results of the observation and the calculation for model (3) in the cases where $p=10$, $r=1/100$, $T^*=30{,}000$°K and $p=10$, $r=1$, $T^*=350$°K is shown. The results of these cases are similar to those for model (1) (Fig. 6 and 7 in (I)). This resemblance would not be strange because the shapes of the bands that we make use of are similar to each other for both models.

In the first place it has been expected that the calculation would agree with observation when model (2) is adopted, because $\nu(\mathcal{E})$ has a real minimum. Really, at lower temperatures it is possible to obtain a rather good agreement for χ, but for $\Delta\chi$ it is quite impossible. This fact is due to the rapid temperature increase of the calculated values of χ in the higher temperature regions. Namely, we must use the calculated curves of χ in Fig. 2 (a) in the region where T/T^* is rather small in order to get a satisfactory agreement between calculations and observations, but for such small values of T/T^* the calculated curves of $1/\Delta\chi$ in Fig. 2 (b) are not yet straight, and those curves cannot agree with the experimental curve which is proportional to T approximately.

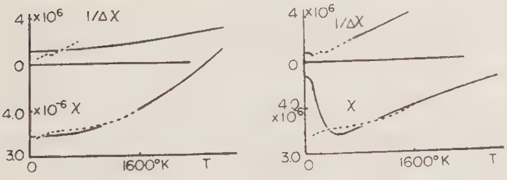
(b) Comparison between calculated susceptibilities for model (3) and experimental ones for an alloy, 1.05% Fe in Cr. (i) Calculated for $p=10$, $r=1/100$, $T^*=30{,}000$°K, $a_1k^{1/2} = 0.0660 \times 10^{34}$ erg^{-1}g^{-1}deg$^{-1/2}$, $b' = 1.14 \times 10^{34}$ erg^{-1}g^{-1} and $q=10.0$. (ii) Calculated for $p=10$, $r=1$, $T^*=350$°K, $a_1k^{1/2} = 0.0151 \times 10^{34}$ erg^{-1}g^{-1} deg$^{-1/2}$, $b'=0.282\times10^{34}$ erg^{-1}g^{-1} and $q=5.2$.
• and ∘ are the same with those in Fig. 3.



(a) (b)

Fig. 5. Schematic representation of comparison between theoretical results and experimental ones, (a) for model (2) and (b) for model (3).

On the other hand for models (1) and (3) the calculated values of χ do not increase so rapid as for model (2). Therefore, we can use the χ *vs.* T/T^* curves in the region where T/T^* is rather large, and then $1/\Delta\chi$ *vs.* T/T^* curves become linear for such values of T/T^*. In Fig. 5 this circumstance is illustrated schematically.

As we have seen, in order to fit the calculated values with the observed ones the temperature dependences of χ at rather high temperature are important, and these dependences are determined by the shapes of the band which we adopt. The highest temperature of the observation is nearly 1,600°K. The calculated values of χ in the neighbourhood of this temperature will be determined by the shape of the band within the region of $\mathcal{E}/k\sim10^3$°K around $\mathcal{E}_0$. From the analyses mentioned above it can be seen that model (3) for the electron state density of Cr is a better approximation than model (2) and that if $\nu(\mathcal{E})$ is more convexed to the axis of energy than that in model (3) it will be more suitable. Moreover, since the real band must be closed it seems to be reasonable to consider that model (3) where the state density is concave downwards is better than model (2) where it is concave upwards.

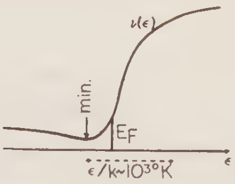


Fig. 6. Schematic representation of the energy band of Cr.

Therefore the conclusion in (I) is supplemented as follows. The state density of the band of Cr is convexed as $\mathcal{E}^{1/2}$ or more within the region of $\mathcal{E}/k\sim10^3$°K around the Fermi level at 0°K in the neighbourhood of a minimum of the state density. Therefore the schematic shape of the band for Cr will be something like the $\nu(\mathcal{E})$ in Fig. 6.

Recently Cheng et al⁽⁶⁾. have calculated the state densities of transition metals and their alloys from the data of the low temperature specific heat. Their results are shown by the curve denoted by C. W. B. in Fig. 7. In the derivation of this curve γ values are not diminished by 1.7×10^{-4} cal mole^{-1} deg^{-2} (the γ value for Cu), for s band would contribute to the susceptibility. Cheng et al. used $\gamma=\frac{1}{3}\pi^2k^2N(E)$ for Cr-Fe, but we calculate $N(E)$ for Cr-Fe so as to fit the saturation values of the magnetic moment with observed ones[7]. So their calculation (Fig. 15 in reference 6) is a little different from ours. In Fig. 7, the state densities calculated for models (2) and (3) by using the values of parameters obtained in Figs. 3 and 4 are shown, too. It will be seen that model (3) is more consistent with the measurements of specific heat than model (2), and that the curve shown in Fig. 6 resembles to the curve obtained by Cheng et al.

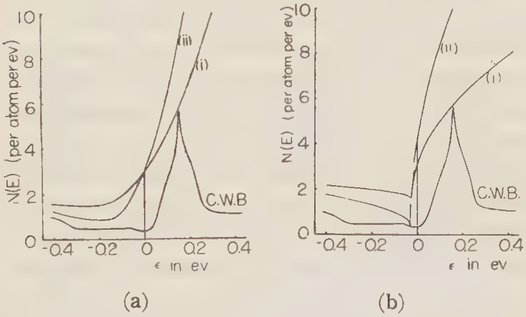

Fig. 7. The numbers of the electronic states per atom per ev: $N(E)$. (a): model (2), (b): model (3), (i) and (ii) are the same with those shown in Figs. 3 and 4. The result by Cheng et al. is shown by the curve denoted by C. W. B. The origin of ε is set at the Fermi energy at 0°K.

Finally, it is pointed out that the fact that the hyperfine effective field of Fe^{57} is not observed from the measurement of the Mössbauer effect of Fe^{57} in Cr-Fe alloy[8] is consistent with the band picture of this alloy, because the definite magnetic moment will not exist on an iron atom in the band picture.

Interaction Effects in Potassium Ferricyanide

By Taiichiro OHTSUKA*

The Research Institute for Iron, Steel and Other Metals. Tohoku University, Sendai.

(Received April 4, 1961)

The character and magnitude of the exchange interaction between the ferric ions in $K_3Fe(CN)_6$ have been investigated by, (1) observation of the paramagnetic resonance spectrum of coupled Fe-Fe pairs in semi-dilute crystals and, (2) adiabatic demagnetization of concentrated crystals. The results show that the exchange between magnetically similar ions contains an appreciable anisotropic part of the order of 0.07 cm^{-1}. No lines corresponding to dissimilar ion pairs were found. From the two types of experiments, it is concluded that the isotropic part of exchange between similar ions, J_s, is about 0.25 cm^{-1} and that the exchange between dissimilar ions is very small.

§1. Introduction

The knowledge of the interaction between magnetic centers is useful in understanding the magnetic properties of the bulk material. Through extensive measurements on $[IrCl_6]$ complexes, it has been shown by the Oxford group that the paramagnetic resonance technique lends a powerful tool in obtaing imformation of this type. The method consists of analysing the features of the resonance lines due to isolated exchange coupled ion pairs existing in crystals diluted by isomorphous non-magnetic ions. In particular, when an anisotropic interaction is present the lines will show a splitting depending on the degree of anisotropy. The anisotropy may be either due to anisotropic exchange[1)] or dipolar interaction[2)].

The possible existence of a relatively large anisotropic exchange in $K_3Fe(CN)_6$ was first noted by Bleaney and Ingram[3)] in their interpretation of the abnormally large line width observed in paramagnetic resonance of concentrated salts. Its existence was confirmed by McKim and Wolf[4)] who observed a large anisotropy of the Weiss constant. They showed, however, that the line width could only be explained when the number of nearest neighbours n is taken to be two whereas the crystal structure suggests $n=6$ of which four are dissimilar and two are similar ions. The Weiss constant, on the other hand, reflects only an average of the existing interactions and it is necessary to discriminate between different species before correlation with some of the bulk properties can be made.

The principal aim of the present work was to investigate the finer details of the interaction by the resonance method.

Adiabatic demagnetization experiments were undertaken in order to obtain knowledge on the possible magnetic transition caused by the interactions. An attempt was then made to correlate the results of the two types of experiments with each other and with the values of the Weiss constant. The analysis has led us to the conclusion that the total exchange interaction between dissimilar ions is very small and that the interaction between similar ion contains a large anisotropic part which amounts to 25% of the isotropic exchange.

§2. Crystal Structure

There has been some controversy as to the structure of the isomorphous series $K_3M^{+3}(CN)_6$ (M=Fe, Co, Mn, Cr) since the first study made by Gottfried and Nagelschmidt[5)]. The foregoing authors reported a monoclinic, pseudo-orthorhombic (C_{2h}^5) structure with $Z=4$ (number of molecules per unit cell) for $K_3Fe(CN)_6$. Barkhatov and Zhdanov[6)] pointed out that the choice of a pseudo-orthorhombic unit cell is incorrect and that the true unit cell is monoclinic with $Z=2$ and $\beta\sim107$. More recent work conducted by Kohn and Townes[7)] has revealed the coexistence of four types of unit cells (polytypism). Of the four, two, namely a monoclinic $1M$ (C_{2h}^5) and orthorhombic $2Or$ (D_{2h}^{14}) cell, were found to predominate.

They found that the orthorhombic cell could be generated by alternate stacking of the monoclinic cell along [100]. No polytypism in $K_3Fe(CN)_6$ has been reported but Kohn et al. note the possibility as an orthorhombic (D_{2h}^{14}) cell has been found by Okaya and Pepinsky[8]. Representative cell dimensions are listed in Table I. We have used the values for the monoclinic cell in calculating the dipolar interaction. The difference between the Co and Fe salts is seen to be small.

The atomic positions for the monoclinic cell is shown in Fig. 1. Each Co (or Fe) ion is surrounded by six CN groups in an approximately octahedral configuration. The axes of the octahedron and the Co-CN, C-N distances have been determined by Barkhatov et al. and more recently by Curry and Runciman[9] who studied $K_3Co(CN)_6$ by neutron diffraction methods. Fig. 2 shows the arrangement of atoms in a projection on a plane normal to the *c*-axis together with the Co-C, C-N distances derived by Curry et al. The arrangement is expected to be similar for the ferric salt.

§ 3. Properties of the Fe^{3+} ion in $K_3Fe(CN)_6$

It is well known that the ground configuration of the Fe^{3+} ion in the $[Fe(CN)_6]^{-3}$ complex is $(d\varepsilon)^5$ with $S=1/2$, in contrast with $(d\varepsilon)^3(d\gamma)^2$, $S=5/2$ observed in ionic salts. This has been attributed to strong covalency and/or to a cubic crystalline field strong enough to destroy the Russel-Saunders coupling. The ground level in a cubic field is thus six-fold degenerate, an orbital triplet with two-fold spin degeneracy. Spin-orbit coupling splits this into a quadruplet and a spin doublet, the doublet lying lowest. Fields of lower symmetry also give similar contributions. In particular they split the excited quadruplet into two doublets. The energy levels have been studied by Howard[10], Kotani[11] and Kamimura[12]. The conclusion relevant to our study is that the ground doublet lies some several hundred cm^{-1} below the excited doublets and hence will be the only level populated at low temperatures. Stevens[13], in his theory of $[XY_6]$ type complexes, gave a general derivation of the energy eigenvalues for octahedral symmetry and, in particular, showed that the ground doublet can be expressed conveniently by a suitable linear combination of d orbitals. This expression has been extended to the case of rhombic symmetry by Bleaney and O'Brien[14].

The expression they give is as follows:

$$\left.\begin{aligned} |+\rangle &= [\sin\gamma|a'\rangle\alpha+\cos\gamma|b_+'\rangle] \\ &\qquad\times\cos\theta+\sin\theta|b_-'\rangle\beta \\ |-\rangle &= -[\sin\gamma|a'\rangle\beta-\cos\gamma|b_-'\rangle\alpha] \\ &\qquad\times\cos\theta+\sin\theta|b_+'\rangle\alpha \end{aligned}\right\} \qquad (1)$$

Here $|a\rangle\sim|xy\rangle$ and $|b_\pm\rangle\sim\mp i/\sqrt{2}\{|xz\rangle\pm i|yz\rangle\}$ where $|xy\rangle$, $|yz\rangle$, $xz\rangle$ denote the angular part of the $d\varepsilon$ wave functions. α and β are the spin wave function. Due to the presence of orbital degeneracy under octahedral symmetry and the action of the spin-orbit interaction, these states contain both orientations of the real spin. The states denoted by $|+\rangle$ and $|-\rangle$ correspond to a doublet which can be expressd by an "effective spin" $s=1/2$. We shall use small and capital letters for the effective and real spins, respectively. Operating with in these states with the magnetic moment operator $(\boldsymbol{L}+2\boldsymbol{S})$ yields the g-factors in terms of the effective spin. The g-factors observed in diluted salts by Baker et al.[15] are: $g_x=2.35$, $g_y=2.10$, $g_z=0.91_5$. Two magnetically similar but differently oriented ions are observed. The symmetry of each ion is orthorhombic. The z-axis coincides with the c-axis for both ions and the x, y axes lie in the ab plane. This implies that the octahedron shown in Fig. 2 is rotated by 45° about the tetragonal axis for the ferric ion. The x-axes for the two ions make angles of ±30°, respectively, with the a-axis. The two ions are thus identical along the a, b and c-axes.

Bleaney et al.[14] found that the observed g-factors could not be fitted by the parameters γ and θ alone and that it was necessary to introduce an additional parameter k and replace $\boldsymbol{L}$ by $k\boldsymbol{L}$. The values for the parameters which give the experimental g-factors are; $\cot\gamma=1.00_6$, $\tan\theta=-0.028$, $k=0.87_5$. The factor k was introduced by Stevens[13] in order to account for the departure of the magnetic electrons from a pure d-state due to charge transfer between the p-electrons of the ligands. The magnitude of k indicates the presence of large covalency between the Fe ion and the CN group. This together with the fact that the CN molecular orbitals of adjacent octahedrons may overlap to a certain degree (Fig. 2) suggests the possibility of superexchange interaction existing between neighbouring Fe^{3+} ions. The relative position of the octahedrons implies that this interaction will be different for similar and dissimilar neighbours. The effect of incomplete quenching of the orbital angular moment on superexchange will be discussed briefly in § 6.

§ 4. Paramagnetic Resonance

1) The Spin Hamiltonian. It has been shown by Baker and Bleaney[16] that the features of the paramagnetic resonance spectrum of two identical ions coupled by anisotropic exchange can be expressed by,

$$\mathscr{H}=g\beta\boldsymbol{H}\cdot(\boldsymbol{s}+\boldsymbol{s}')+\boldsymbol{s}\cdot\boldsymbol{K}\boldsymbol{s} \qquad (2)$$

Here $K_{ij}=J+J_{ij}$ where J and J_{ij} $(i, j=x, y, z)$ denote the isotropic and anisotropic parts of the exchange, respectively. In our case $\boldsymbol{s}$ is the effective spin with $s=1/2$. Eq. (2) can then be written in terms of the total spin $\boldsymbol{T}=\boldsymbol{s}+\boldsymbol{s}'$ as follows,

$$\begin{aligned}\mathscr{H}&=g\beta\boldsymbol{H}\cdot\boldsymbol{T}+\frac{1}{2}J\left[T(T+1)-\frac{3}{2}\right]\\ &\quad+\frac{1}{2}J_{xx}T_x^2+\frac{1}{2}J_{yy}T_y^2+\frac{1}{2}J_{zz}T_z^2\end{aligned} \qquad (3)$$

where $T=0$ or 1. The energy levels for H parallel to z are given by;

$$\left.\begin{aligned} &T=1 \text{ (triplet)}\\ &\left.\begin{matrix}E_2\\E_1\end{matrix}\right\}=\frac{1}{4}J+\frac{1}{4}J_z\\ &\qquad\pm\left[(g_z\beta H)^2+\frac{1}{4}\left\{\frac{1}{2}(J_x-J_y)\right\}^2\right]^{1/2}\\ &E_3=\frac{1}{4}J-\frac{1}{2}J_z\\ &T=0 \text{ (singlet)}\\ &E_4=-\frac{3}{4}J \end{aligned}\right\} \qquad (4)$$

It is seen that the triplet which is seperated from the singlet by J is split by the anisotropic component. The allowed transitions

($T_z=\pm1$) take place between E_1, E_2 ($T_z=\pm1$) and E_3 ($T_z=0$) of the triplet. The use of the isolated ion g-factor for the coupled pair will be discussed in connection with the experimental results.

2) Experimental Procedure. The spin-lattice relaxation time of Fe^{3+} in $K_3Fe(CN)_6$ is very short and resonance can only be observed at low temperatures[3]. Measurements were all made at liquid helium temperatures using a wavelength of 3.2 cm. Description of the apparatus has been given elsewhere[17].

Single crystals of the concentrated salt and salts diluted by $K_3Co(CN)_6$ with various concentrations of Fe^{3+} ranging from about 1% to 10% were grown from a saturated aqueous solution. Crystals which were clear and showed no macroscopic twinning were used. Measurements on concentrated salts gave line widths similar in magnitude ($\sim 0.1\ cm^{-1}$) to those obtained by Bleaney et al.[3] at liquid hydrogen temperatures thus confirming their conclusion that the width is not due to spin-lattice relaxation. A brief description of the results on semi-dilute crystal has already been given[18]. We shall present here the details of the results and the method of analysis.

3) Features of the spectrum. An example of the spectrum along the a and b-axes for a -5% and -10% Fe^{3+} sample is given in Fig. 3. The spectrum for the c-axis is shifted to much higher fields. It is seen that besides the line of strong intensity corresponding to the isolated ion, several satellites appear. The magnitude and the axis of the g-factor for the isolated ion is in good agreement with the results obtained by Baker et al. for more dilute salts. The line width for all the lines is about 40G for the spectrum in the ab-plane and 160G for the c-axis. The large line width for the c-axis has made the resolution and determination of the positions of the lines relatively poor for this direction.

The intensity of the satellite lines was about one tenth of the isolated ion line. This is just about what one would expect from coupled pairs if one assumes that the Fe^{3+} ions are randomly situated. However this does not mean that the satellites are all due to pairs. The problem is thus to pick out those lines due to coupled pairs and then to see which of the two possible types of pairs (similar and dissimilar ion pairs) they arise from. Because of the smallness of the isotropic part, the temperature dependence of the intensity could not be used in the assignment of the lines. This fact also prevented determination of the isotropic part by the resonance method. Actually no change was observed be-

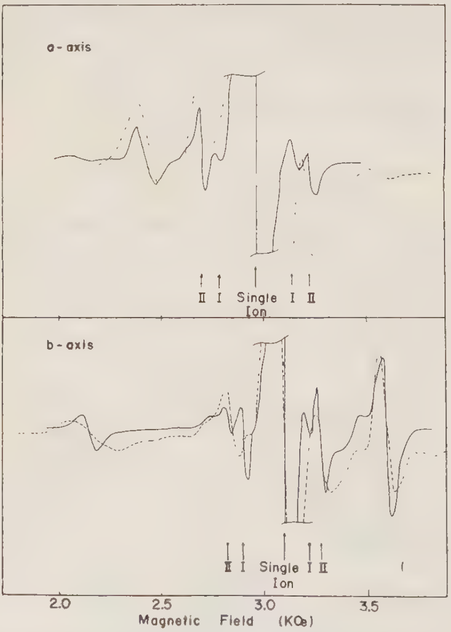

Fig. 3. Spectrum with the magnetic field parallel to the a and b-axes, —— 5% Fe - - - - - 10% Fe The intensities have not been normalized.

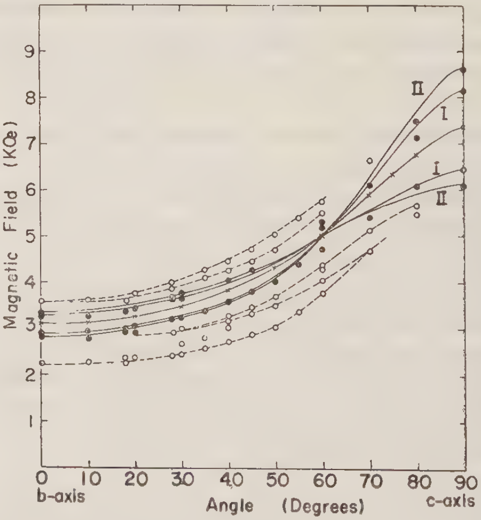

Fig. 4. Angular variation in the bc-plane. Dotted lines have been drawn through experimental points. Solid line for —×— is the single ion line. Solid line for I and II calculated with $|D_I| = 0.041\ cm^{-1}$, $|E_I| = 0.016$; $|D_{II}| = 0.054$, $|E_{II}| = 0.016$.

tween 4.2 and 1.6°K. The criterion we used was to note that the pair lines should be displaced symmetrically about the isolated ion line and that they must have an angular dependence of the dipolar type as can be seen from Eq. 3. It was observed that only the sets of lines marked I and II in Fig. 4 conformed to the properties of a coupled pair. For more concentrated salts I and II could not be distinguished.

The origin of the lines outside of sets I and II is not clear at present. They do not appear to arise from coupled pairs. They also do not seem conform to the anisotropy demanded by Eq. 1. However as they appear reproducibly from salt to salt, we shall briefly summarize their general feature. The lowest field line for the *a*-axis splits into three components when rotated in the *ab*-plane. They merge together again at the *b*-axis at a much lower field with reduced intensity. The anisotropy in the *ab*-plane is just the opposite of that of the isolated ion line except for the for the third component. The intensity of the highest field line is reduced when rotated from the *b*-axis and is barely observable for the *a*-axis. Thus the intensities of the lowest and highest field lines are interchanged in going over from the *a* to the *b*-axis. The weighted mean of all the lines gives $g_a \simeq 2.3$, $g_b \simeq 2.2$. This is in accord with the measurements of the concentrated salt. However Baker et al. have observed that g_b differs appreciably when the direction of the *rf*-field, h_{rf}, is changed from $h_{rf}//c$-axis to $h_{rf} \perp c$. For the former case, $g_b=2.21$ and for the latter, $g_b=2.39$. In connection with this anomalous behaviour, it is interesting to note that the intensity of the lowest field line is observed to be reduced when $h_{rf}//c$ (Fig. 4 shows the spectrum with $h_{rf} \perp c$). No change was observed for the high field line. This would correspond to a shift to low *g*-values in the concentrated salt. The lowest field line may also account for the anomalous behaviour of the susceptibility χ, namely the interchange of the rhombic anisotropy from $\chi_a > \chi_b$ to $\chi_b > \chi_c$ when the sample is cooled below 100°K if it is assumed that the line is associated with a low temperature pase. The occurence of such a phase is inferred from the reported anomaly of χ_a and χ_c[19] and the specific heat[20] at 130°K. The nature and origin of such a phase is, however, difficult to understand. Further studies of the anomalous lines are necessary before definite conclusions can be made.

4) Analysis of sets I and II. From observation of the angular variation of the splittings, the axes for both sets I and II were determined to lie along the crystal *a*, *b* and *c*-axes. The symmetry is rhombic and the principal axis *z* is along the *c*-axis as can be seen from the behavior in the *bc*-plane (Fig. 5). The dipolar type of angular variation is noted. The angular variation in the *ab*-plane is complicated because the two ions in the unit cell are now magnetically different. However the sets I and II can be followed and their variation indicates that both sets arise from a coupled pair of similar ions. From the splitting along the crystal axes, the anisotropic exchange parameters may be deduced using Eq. 4. The values obtained are listed in Table II. The solid line in Fig. 5 was calculated from the formula for the variation of the splitting Δ in a plane which includes the principal axis, namely:

$$\Delta = D(3p^2 \cos^2 \theta - 1) - 3E(q^2 \sin^2 \theta) \qquad (5)$$

Here $|D| = 3/4|J_c'|$, $3|E| = 3/4|J_a' - J_b'|$, $p = g_c/g$, $q = g_b/g$ g is the component of the *g*-tensor in the direction of the field making an angle θ with the *c*-axis. Higherorder terms have

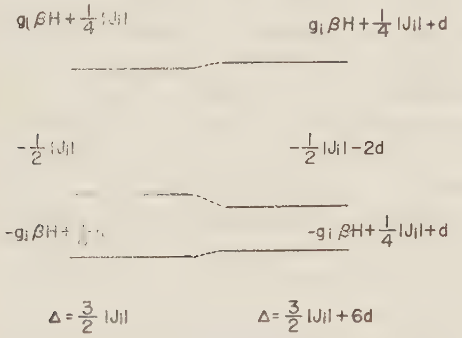
been neglected.

The apparent splitting includes contributions from the dipolar interaction which amounts to about 20% of the observed values and thus cannot be neglected. The contribution depends on the angle between the line connecting the ions and the direction of the applied field and the magnetic moment induced in that direction. The former serves to distinguish between the two possible types of ion pairs and the latter, because of the anisotropic g-factor, to determine the sign of J_c. The interdependence of the sign of J_i and the dipolar interaction is depicted fn Fig. 5.



$g_i\beta H+\frac{1}{4}|J_i|$

Fig. 5. Effect of dipolar interaction. Δ=splitting $d=-\frac{1}{2}g_i^2\beta^2\frac{(1-3\cos^2\theta)}{r^3}$

It is seen that for $J_i>0$ a positive dipolar interaction will increase the splitting due to anisotropic exchange whereas for $J_i<0$, the splitting will be reduced. Because of the difference in the magnetic moment induced for different axes, the condition that the sum of the anisotropic component $J_a+J_b+J_c=0$ will be unbalanced. This is evidenced in the fact that the apparent splittings cannot be made to add to zero. The dipolar interaction was calculated using the observed g-factors, cell dimensions and the atomic positions. The contribution for similar ion pairs are listed in Table II. As the sign of J_i is not determined experimentally, both signs were assumed. It turned out that for $J_{a,b}<0$, $J_a+J_b=J_c$ was fulfilled well after correction (Table 2). For $J_{a,b}>0$ a 10% difference arises between J_a+J_b and J_c. When dissimilar ion pairs are assumed, a 10% difference arises regardless of the sign of $J_{a,b}$. As this is outside the experiment error, it is concluded that I and II are due to similar ion pairs, in accord with the variation in the ab-plane, and that $J_c>0$.

It is not obvious whether one should use the cell dimensions for the ferric or the cobaltic salt in calculating the dipolar interaction. The difference however is small and amounts to only a few percent in the correted values. In this connection, it is noted that lines of I and II are not located exactly symmetrically about the isolated ion line. The asymmetry is small amounting to only about 0.8%. It is, however, systematic in that the asymmetry for the a- and b-axes are opposite. (The c-axis could not be determined with certainty.) As Judd[21] has shown that the difference in the g-factor of a pair and a single ion depends on the non-orthogonality of overlapping orbitals and is negligible, this implies that the rhombic axes for the Fe pairs are rotated by a few degrees in the ab-plane relative to those of the isolated ion. Correction to the absolute value of g is, however, within experimental error and the use of the single ion values is justified.

The existence of two sets of values for similar ion pairs was unexpected. This may be due to the fact that the interaction constants for the two predominant polytypes observed in the cobalt salt is different. Definite evidence of the effect of polytypism on resonance as has been established for the case of Cr^{3+} [7] is, however, lacking for Fe^{3+} * and further studies are necessary to clarify this situation. It is interesting to note that the average of the two sets agrees very well with the values derived from the Weiss constant in both magnitude and sign when the number of nearest neighbours n is taken to be two (Table 2). Although an agreement to this extent may only be accidental because of the possible difference between the interactions existing in concentrated and dilute salts, it gives evidence in favour of the conclusions reached because if one or both of the sets were due to dissimilar ion pairs where $n=4$, the discrepancy would be much too large. The fact that lines attributable to dissimilar ion pairs were not observed may be due to either the smallness of the exchange or the

---

* *Note added in proof.* We have recently made experiments on a sample where resonance which can be associated with ions in a monoclinic cell was clearly observed. The z-axis was found to be inclined 4° from the c-axis.

exchange being isotropic. The results of the magnetic specific heat by McKim et al. infer that the former is most probably the case. The problem of isotropic exchange will be discussed in connection with the results of the adiabatic demagnetization experiments.

§ 5. Adiabatic Demagnetization

The spin Hamiltonian (Eq. 2) yields the following expression for the Weiss constant Θ.

$$-\Theta_i = \frac{s(s+1)}{3k} \sum_i \sum_j n_j K_{ii}^{(j)}\,, \qquad i=x, y, z \qquad (5)$$

Here n_j denotes the number of nearest neighbours of type j. A total of the isotropic exchange may by derived by noting that the anisotropic part must add to zero and that $n=2$ and 4 for similar and dissimilar ion neighbours, respectively. The values observed by McKim et al. yield $2J_d + J_s = 0.28_7\ \text{cm}^{-1}$ where J_d and J_s denote the isotropic exchange constant for dissimilar and similar pairs, respectively. J_d and J_s cannot be distinguished unless an independent relation between the two quantities is obtained. It was with the hope that the possible magnetic transition temperature might provide this relation, although approximate, that demagnetization experiments were undertaken. It turned out, however, that the actual situation is complicated and only a rough estimate could be made. The other purpose was to probe into the nature of the transition created by exchange with a known large anisotropic part.

1) Experimental procedure. Undiluted $K_3Fe(CN)_6$ single crystals of the size necessary for demagnetization experiments (~2 gr) were difficult to grow free of macroscopic twinning. Therefore the samples used were twinned to some degree although clear crystals showing least twinning were chosen. As twinning occurs on the a-plane and the magnetic axes coincide with the crystal axes, no essential change in magnetic properties is expected unless the spin deviates from the crystal axes when ordered. Of the six samples used, one showed a high transition temperature. Outside of this effect no appreciable difference in the properties measured was observed.

Three different types of measurements were carried out; the determination of the 1) entropy-susceptibility, 2) susceptibility-temperature and 3) entropy-temperature relations. The description of the adiabatic cell is given in Fig. 6. For the first type of measurement, a sample (~1.5 gr) ground to an ellipsoidal shape was placed on a pedestal made out of thin walled glass (Fig. 7a). For the second and third measurements, a glass support described in Fig. 7b was used. A flat surface of about 2-3 cm² was ground on the sample with fine emery paper and attached to both sides of a copper plate 0.15 mm thick using

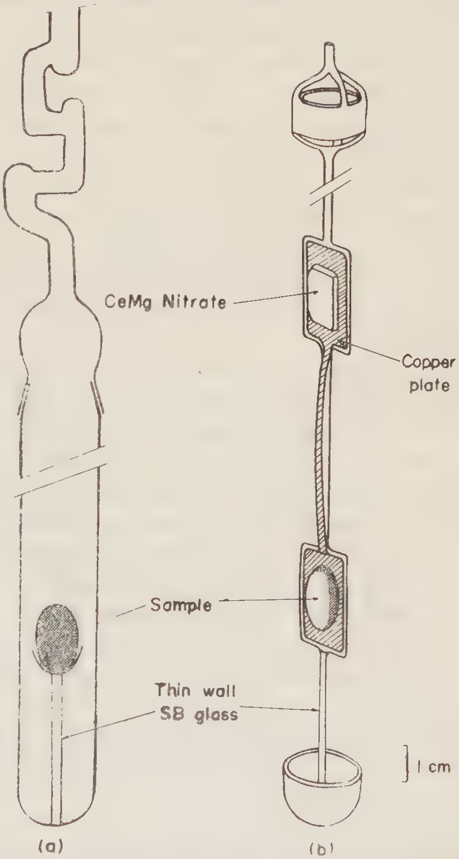

Fig. 6. Adiabatic cell (a) and sample-thermometer support (b).

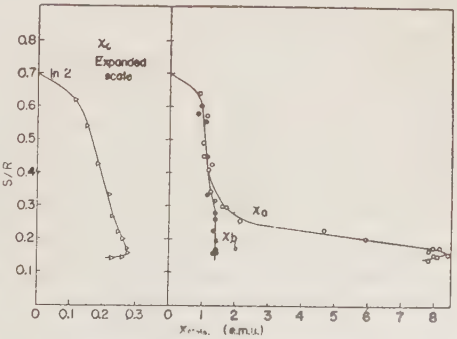

Fig. 7. Entropy versus susceptibility. The scale for χ_c has been expanded.

a n-propyl alcohol-glycerol mixture as a binder. The sample was then bounded tightly by cotton thread. The system was connected to a similar plate 9 cm above via a copper strip. To this a single crystal of cerium magnesium nitrate was bounded by similar means. This was used as the thermometer for temperature determinations. Preliminary measurements using a ferric alum sample proved this type of arrangement to give sufficiently good heat transfer rates at temperatures about ~0.1°K. At the lowest temperature reached in the actual experiment (~0.2°K), the cerium salt and sample came into thermal equilibrium in about one to two minutes. The extraneous heat input into the sample was about 50–80 ergs/min. Separate measurements made with varying vacuum conditions, degree of radiation shielding, types of support and cell indicate that most of this is due to mechanical vibration.

The susceptibility was measured using a mutual inductance Hartsohn bridge circuit. A. C. of 160 cps was used for measurements (1). For (2) and (3), D. C. was used and null detection made by a ballistic galvanometer. Isothermal magnetization was carried out at 1.1°K. A 40 KW electromagnet provided a field of up to 24 KOe in a 63 mm gap. The sample was always magnetized along the a or b-axis. The cerium salt was oriented so that the hexagonal axis, where g is very small, was parallel to the applied field. This was to prevent the possible magnetization of the cerium salt in a fringing field. The dewar and vacuum system is conventional and will not be described.*

The result for the entropy-susceptibility measurement is shown in Fig. 7. The features to be noted are the sharp rise in the susceptibility along the a-axis, χ_a, and the fact that about 85% of the total spin entropy is lost before the susceptibility indicates an anomaly. Thus a peak in the susceptibility was only barely observable after demagnetizing from the highest field. This was unfortunate because it barred detailed measurements to be made below the anomaly. Fig. 8 shows an example of the field dependence of χ_a for two entropy values corresponding, respectively, to a point just below the anomaly and a point at which χ_a starts to rise rapidly. For the higher entropy value the behaviour is paramagnetic whepeas for the lower value, a relatively small field (~10 Oe) produces a sharp decrease down to just about the value one would expect from the Curie-Weiss curve. The inference of the sharp rise and field dependence of χ_a is that a small ferromagnetic component is present along the a-axis.

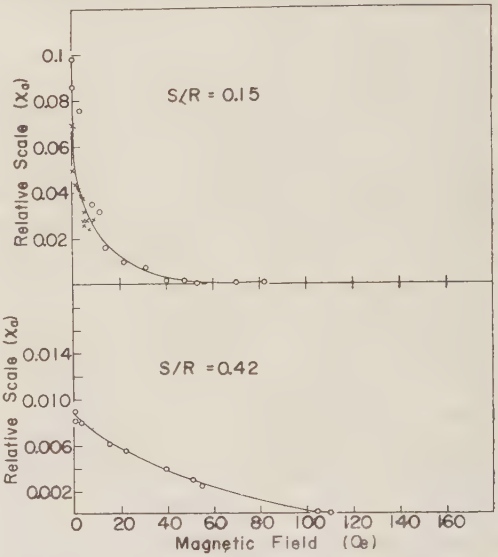

Fig. 8. Field dependence of adiabatic susceptibility along the a-axis.

The susceptibility-temperature relation was determined by alternately measuring the sample and cerium salt susceptibilities during warm up after demagnetizing from various fields. As the heat transfer rate exceeded that of the extraneous heat leak for the lower temperatures, thermal equilibrium was assured. However for temperatures above ~0.5°K, an increased warming up rate caused departures from equilibrium which was reflected in a scatter of the data for the higher temperature region. Reproducibility was good for the lower temperatures. The increased warming up rate is probably due to gaseous conduction of the residual gas as prolonged pumping of the cell reduced the rate appreciably. The high temperature region is, however, not of particular interest because the results around ~0.4°K fall on an extension of the Curie-Weiss curve within experimental error which we estimate to be ~10%. Thus further efforts such as the use of guard salts were not made.

Six different samples were measured. Except for one sample which reproducibly showed deviation towards higher temperatures, the results for different samples agreed with each other within 15%. The results for χ_a near the region of maximum susceptibility showed an appreciable scatter, however, due partly to the fact that the susceptibility changes very rapidly in a narrow temperature range. However the temperature for the anomaly did not not differ. A representative curve is shown in Fig. 9. An annoying fact is that a definite maximum in the susceptibility was not observed in contrast to the entropy-susceptibility measurements. The reason for this is not clear but may be due to the presence of the thermometer salt. The shape of the sample was also not quite spherical. The other features, i. e. the sharp rise in χ_a, a broad flat region for χ_b were, however, common for both types of experiments. It is seen that the anomaly takes place near 0.2°K.

---

* The major portion of the demagnetization apparatus was constructed by Mr. A. Ōtsubo.

The entropy-temperature relation was obtained by measuring the temperature after demagnetizing from different magnetic fields. Measurements were taken for about 3 to 4 minutes after thermal equilibrium had been attained. No change in the susceptibility of the cerium salt was noted during this interval. Due to reasons mentioned previously, the cell was pumped for about 1.5 hrs before demagnetization in determining temperatures above ~0.5°K. The results are shown in Fig. 10.

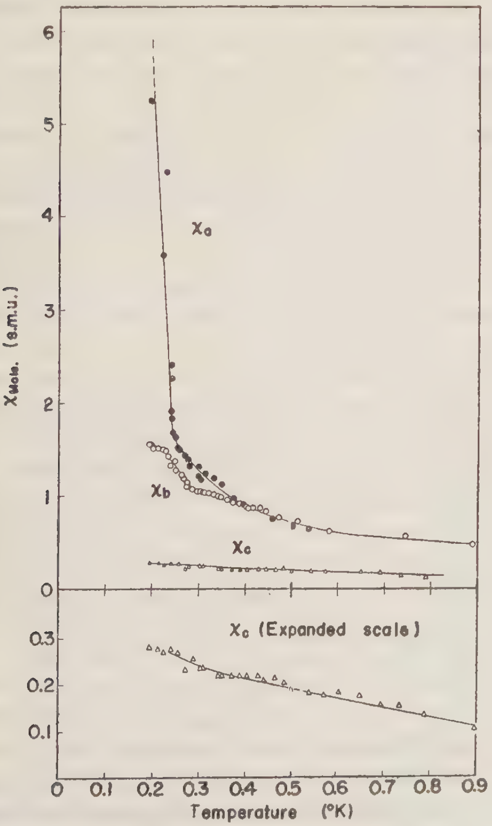

Fig. 9. Susceptibility versus Temperature.

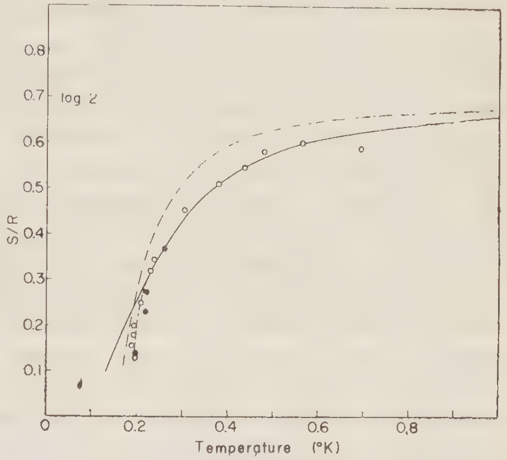

Fig. 10. Entropy versus Temperature. —o— Sampl #4; —•— Sample #6
Solid line: Linear Ising chain with $J_d=0$, $K_c=0.35\ \text{cm}^{-1}$
Broken line: Molecular field approximation with $J_d=0$, $J_s=0.29\ \text{cm}^{-1}$, $J_i=$Table 2.

It is seen that a rapid reduction of entropy takes place at about the same temperature of the magnetic anomaly. This temperature reproduced within 5% for a single sample and showed about a 20% scatter for five different samples. The error in the absolute value of temperature is estimated to be about 20%. Averaging the values obtained for different samples, we locate the "transition" temperature at 0.2±0.04°K. The nature of this "transition" will be discussed below.

2) Discussion of the results. If the interactions J_s and J_d differ from each other, it is expected that initial ordering of the spins will progress through the larger of the two. Now it has been observed by McKim et al.[3] that the magnetic specific heat can only be fitted with the Weiss constant when the number of nearest neighbours is taken to be two. This, together with the fact that resonance attributable to dissimilar ions was unobserved, gives evidence that J_d is small. On the other hand, the magnitude of aniso-

tropic exchange infers that $J_s \gtrsim 0.1\,\mathrm{cm}^{-1}$. Thus it is reasonable to assume that ordering will first take place within mutually independent linear chains of similar ions along the *a*-axis. The fact that the bulk of the total entropy is lost before an anomaly is observed supplies further evidence for this to be the case as it is well known that a linear chain can possess only short range order at finite temperatures. The sign of the Weiss constant and the anisotropic part of the exchange indicate that the spins will be aligned antiparallel to each other along the *c*-axis perpendicular to the chain. A second order transition, if any, will be created by the interchain interaction, namely J_a. Unfortunately there are no reliable theories which express the behaviour near the transition point for such a complicated situation. Onsager[22] has treated a similar case for the two dimensional anisotropic Ising net but extension to three dimensions has not been made. Our assumption demands, however, that the bulk of the entropy curve reflects the properties of a linear chain. Thus we have neglected J_a and have calculated the entropy of an Ising chain in order to see to what extent our assumption holds. The Ising approximation should give a good description as $J_c > J_a$, J_b and $J_s \sim 0.1\,\mathrm{cm}^{-1}$. The entropy is readily derived from the expression of the free energy[23] and is,

$$S = R\{\ln(2\cosh L) - L\tanh L\}$$

where $L = J/kT$. This has been calculated taking $J = J_s + J_c$. The value of $2J_a + J_s$ previously determined gives $J_s = 0.29\,\mathrm{cm}^{-1}$ for $J_a = 0$. For J_c, the average value (Table 2) was used. The results are shown as a solid line in Fig. 10. As the spins are not quite free at the temperature at which the entropy is determined (1.1°K), the experimental points have been corrected neglecting the cross term between the Zeeman and interaction energies. The reduction from the free spin value amounts to 3% at 1.1°K. There is some ambiguity in this correction because different values of J_s and J_a and different approximations lead to different corrections. However as the temperature is high, extreme cases differ by only ~1% and is within experimental error.

It is seen that the Ising chain expresses the observed values well down to $S/R \simeq 0.25$. For comparison, a curve calculated by the molecular field approximation using the same J_s but including J_a and J_b is also shown. The deviation is appreciable at higher entropy values which is expected as the molecular field approximation does not account for short range order. Although it may not be permissible to apply two dimensional calculations to our case, Onsager's rectangular net results indicate a deviation from the linear chain specific heat curve slightly below its maximum for a ratio of intra to interchain exchange as small as 10^{-2}. The specific heat maximum of our Ising chain corresponds to 0.22°K. Thus the deviation of the experimental points from the Ising curve at low entropy values is most probably caused by a small but finite J_a. Its magnitude, together with the location of a possible Néel temperature, however, cannot be estimated with certainty. The presence of a Néel temperature T_N is indicated in the magnetic measurements which also show that T_N cannot be too far below 0.2°K. The best we can say at present is that,

$$J_s \cong 0.25\,\mathrm{cm}^{-1}, \qquad J_a \sim 0.01\,\mathrm{cm}^{-1}$$

The presence of two sets of constants for the anisotropic part may introduce some complication but we believe that this will not alter the estimated value of J_s very much.

As for the susceptibility, the relatively broad region of χ_b may be due to short range order. Not much can be said about χ_c because of the relatively poor accuracy due to its smallness. However it follows the Curie-Weiss curve down to $\sim T_N$. The anomalous behavior of χ_a is possibly connected with the presence of a small ferromagnetic moment along the *a*-axis indicated in the field dependence measurements. The fact that the anomaly is restricted to the *a*-axis can be understood if it is assumed that the ferromagnetic component is due to spins aligned not quite antiparallel to each other in a direction resulting in an incomplete compensation of the magnetic moment along the *a*-axis. Moriya[24] has shown that a sharp increase in the susceptibility near T_N along the direction of the uncompensated moment may be expected. Just how this uncompensation, if any, can occur for our case is not clear. It is noted, however, that polytypism may give rise to this effect if it is assumed that the principal axis of anisotropic exchange deviates from the *c*-axis in the *ac*-plane which can be expected for the monoclinic structure. The resonance results, however, indicate that the deviation must be smaller than the error determined by the residual line width. The spins of dissimilar ions will now align not quite parallel (or antiparallel) to each other in the ordered state due to the strong action of the crystalline field. It can be seen that this spin structure will give rise to an uncompensated moment along the a-axis at the boundaries of the polytypes. A larger moment is expected when the dissimilar spins align (almost) antiparallel because then the boundaries parallel to the a-plane (the twinning plane) contribute. Although the resonance results indicate at least two types of unit cells, further studies are necessary before any conclusions can be made and the discussed model remains only a possibility. The sharp rise, however, would be difficult to understand if the crystal structure is homogeneous.

§ 6. Discussions

Although the isotropic part cannot be determined precisely, it is seen that the exchange interaction between similar ions contains an appreciable anisotropic part. Judd[21] has shown in a general way using group theoretical methods how a wave function of the form Eq. 1 may lead to anisotropic exchange. Some of the consequences of his theory may be seen by observing the form of the product determinantal states for two ions constructed from Eq. 1, namely,

$$\Phi(++) = \frac{1}{\sqrt{2}}\{|+\rangle_1(1)|+\rangle_2(2)-|+\rangle_1(2)|+\rangle_2(1)\} \tag{7}$$

and similar expressions for $\Phi(+-)$, $\Phi(-+)$ and $\Phi(--)$. Here the subscript refers to the ion and the bracketed number, the electron. The explicit expression will not be given but it can readily be seen that various types of exchange integrals corresponding to different combination of orbitals will occur when operated on by an interaction operator. Not all of these integrals participate in the interaction and some physical reasoning is necessary in order to pick out the predominant ones pertaining to the actual arrangement of the ions. Actually the interaction takes place via the CN groups. Thus the orbitals used in the product states should be understood as hybridized orbitals containing $p\pi$ orbitals of the cyanide group with the same symmetry properties as $|a\rangle$ or $|b_{\pm}\rangle$. The arrangement of the orbitals for a similar ion pair is illustrated in Fig. 11. As the magnetic z-axis of the ferric ion coincides with the c-axis, the octahedron observed in the cobatic salt (Fig. 2) has been rotated 45° about the tetragonal axis. The p orbital drawn in Fig. 12 has the same symmetry properties as $|a\rangle$. The relative positions indicate that this orbital will have the largest overlap. Thus the predominant exchange integral will be of the combination,

$$\mathscr{J}=\langle a_1(1)a_2(2)|\mathscr{H}_{\text{exch.}}|a_1(2)a_2(1)\rangle$$

Correspondence with the effective spin exchange constant determined by experiment can be made by operating with the real spin operator $\mathscr{J}\boldsymbol{S}_i\boldsymbol{S}_j$ on the product states (Eq. 7).

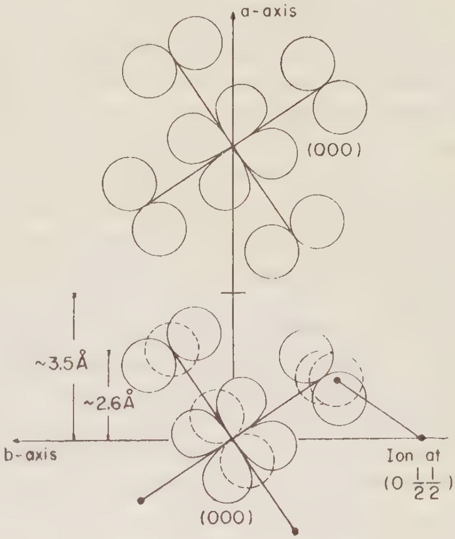

Fig. 11. Arrangement of the orbitals in the ab-plane. The p-orbitals shown have the same symmetry as $|a\rangle$. The octahedron of Fig. 2 has been rotated by 45° about the 4-fold axis. The dashed circle is the p-orbitals which combine with $|\pm b\rangle$.

Neglecting other combinations of orbitals, it can be seen that $1/4\mathscr{J}=J_s$. In other words, the predominant exchange integral pertaining to real spins gives rise to only isotropic exchange in the effective spin formalism. The factor 1/4 arises from the value of the coefficient $\sin^2\gamma=1/2$ as determined by Bleaney and O'Brien. The anisotropic part arises from a combination of the integrals of the from $\langle a_1(1)b_2(2)|\mathscr{H}_{\text{exch.}}|a_1(2)b_2(1)\rangle$ and $\langle a_1(1)b_2(2)|\mathscr{H}_{\text{exch.}}|b_1(2)a_2(1)\rangle$

They cannot be determined uniquely from experiment and the most we can say is that they are of the order of 0.01 cm^{-1}. Integrals involving only $|b_\pm\rangle$ type orbitals are expected to give negligible contribution. The magnitude of the predominant exchange between the p-orbitals of the CN group can also be estimated using the form of hybridized orbital given by Stevens[13)], namely,

$$|a\rangle = N(|a'\rangle + \lambda|a''\rangle)$$

where $|a'\rangle$ refers to the d-orbital and $|a''\rangle$ the p-orbital with the same symmetry. N is the normalizing constant. $N\lambda$ can be determined from the relation $k=1-2\lambda^2N^2$. Inserting the value of k determined by Bleaney et al., we get $N^2\lambda^2=0.0625$. Thus,

$$\langle a_1''(1)a_2''(2)|\mathscr{H}_{\text{exch.}}|a_1''(2)a_2(1)''\rangle \sim 100\ \text{cm}^{-1}.$$

The poor symmetry (Fig. 11) does not allow us to go further and relate this with the properties of the cyanogen molecule as has been done by Griffths et al.[1)] for the chlorine molecule.

As for the dissimilar ion pair, the predominant interaction is expected to take place via $|b_\pm\rangle$ orbitals in contrast to the similar ion case as can be inferred from Figs. 2 and 11. The distance between the CN groups is somewhat (~10%) larger. Although a larger distance suggests a smaller interaction, it cannot be said that this leads, by comparing with the similar ion value, to the order of magnitude estimated from experiment because the arrangement of the orbitals is slightly different for the two cases.

Acknowledgement

I would like to thank Prof. E. Kanda for his encouragement throughout the course of this work. Discussions on some of the technical aspects of the demagnetization experiments with Dr. T. Haseda and Mr. A. Ohtsubo have been invaluable. Mr. T. Sato kindly prepared the single crystals. I also wish to thank Drs. T. Sugano, T. Murao and J. Kanamori for stimulating discussions.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN, Vol. 16, No. 8, AUGUST, 1961

Theory of Seebeck Effect in Plastically Deformed Semiconductors

By Tokio OHTA

Department of Physics, Defense Academy, Yokosuka

(Received April 28, 1961)

The effects of the reduction of free electron density due to the dislocation-acceptors and the scattering due to the space charge around the dislocation on the thermoelectric power of *n*-type materials are theoretically investigated in the temperature covering from impurity- to transition-range and compared with the experimental data for near intrinsic *n*-Ge in only the transition range of temperature. In the intrinsic range of temperature the scattering effect due to the lattice deformation around the dislocation is discussed and compared also with the experimental data.

§ 1. Introduction

Recently many studies[1] have been actively done about the effects of edge dislocation in semiconductors on the electrical conductivity, the Hall effect, and the recombination rate. The experimental data are explained by the assumption[2] that edge dislocations in *n*-type materials act as rows of closely spaced acceptor centers and a dislocation accepts electrons to become a line of negative charge surrounded by the cylindrical layer of positive space charge.

On the other hand it is well known that thermoelectric power informs directly the value of Fermi energy in the crystal and when the crystal is composed of *p*- and *n*-type materials, the contributions to the thermoelectric power from each materials are obtained by rather simple analysis. According to this account the study of thermoelectric power in the deformed semiconductors is believed to be very useful in confirming the dislocation-acceptor model, whether or not the space charge cylinder is of *p*-type, and the scattering mechanism due to the dislocation for both electrons and holes.

Pearson[3] performed preliminary measurements for the effect along the discussion similar to Ohta[4] a few years ago but no conclusive results were obtained. This seems to be attributed to the low resistivity of the used sample. Yamashita and Ohta[5] have measured the effect in near intrinsic *n*-Ge as well as in *p*-Ge in the transition range of temperature. In this paper not only the general theory of the effect in the different temperature ranges is studied but also the foundation of the conversion of near intrinsic *n*-type materials to *p*-type by the cold-worked deformation is discussed comparing with the experimental data.

§ 2. Thermoelectric Power and Fermi Energy

According to the usual method of Boltzmann transport equation, the general expression for thermoelectric power of crystals is written as

$$Q=-(1/(eT))[J_2/J_1-(1/J_1)\times\{B_1(e)/m_e^2\cdot\zeta+B_1(h)m_h^2\cdot(\varDelta+\zeta)\}]\,, \tag{2.1}$$

where $-\zeta$ is the Fermi energy, m_e and m_h are the effective masses of electron and hole respectively, $\varDelta$ is the gap energy between the bottom of *c*-band and the top of *v*-band, e is the magnitude of electron charge, and T is absolute temperature. The notations which denote integrations are

$$\left.\begin{matrix}J_1\\J_2\end{matrix}\right\}=\frac{B_{1,2}(e)}{m_e^2}\pm\frac{B_{1,2}(h)}{m_h^2}\,, \tag{2.2}$$

$$B_j(e)=\int_0^\infty \eta^j l_e(\partial f_e/\partial\eta)\,d\eta\,, \tag{2.3}$$

$$B_j(h)=\int_0^\infty \eta'^j l_h(\partial f_h/\partial\eta')\,d\eta'\,, \tag{2.4}$$

where η and η' $(=\eta+\varDelta)$ are the energies, l_e and l_h are the mean free paths, f_e and f_h are the unperturbed distribution functions of electrons and holes respectively.

Let us give a brief review of the charged dislocation model in order to obtain the Fermi energy in Eq. (2.1). The energy diagram around a charged dislocation is shown in Fig. 1, where δ' and δ_d show the dislocation-acceptor level and chemical donor level respectively.

The positive space charge in the cylindrical volume is $\pi R^2(N_D-N_A)$, where R is the radius of cylinder, N_D and N_A are the chemical donor and acceptor densities. The density of accepted electrons at a dislocation is $f_D(T)/S$, where S is the inter dangling bonds spacing and $f_D(T)$ is a fraction of dislocation-acceptors that are full at T°K, *i.e.*, as many as $N_{\mathrm{disl}}f_D(T)/S$ $(=n_d)$ electrons are accepted at N_{disl} dislocations. As there is no electron in the cylinder the free electron density in the crystal with the dislocation density N_{disl} is reduced to $(1-\mathcal{E})n_e$, where $\mathcal{E}=\pi R^2 N_{\mathrm{disl}}$ and n_e is the value in the absence of dislocations.

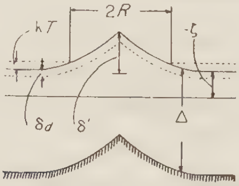

Fig. 1. Space charge potential around a charged dislocation.

The electrical neutrality of the crystal needs

$$(1-\mathcal{E})n_e=n_h+N_b-(n_i+n_d)\ , \tag{2.5}$$

where n_h is the free hole density and is not influenced at low temperature, while it increases by the contribution excited from the dislocation-acceptors in the transition range of temperature, N_b and n_i are the densities of chemical donors which reserve electrons at 0°K and the electrons at impurity levels respectively. Assuming Boltzmann distribution for free carriers and Fermi distribution for the electrons at the impurities[6] and dislocation-acceptors, *i.e.*,

$$f_D(T)=f_D(0)/[1+\exp\{-(\delta'+\zeta)/(kT)\}]\ , \tag{2.6}$$

we obtain the explicit formula for Fermi energy from Eq. (2.5).

In the impurity range of temperature where $\delta'\gg\delta_d>kT$, the Fermi energy is given by

$$\begin{aligned}\zeta=kT\ln\,[&(N_b'-N_D)/(2A_e)\\ &+\{((N_b'-N_D)/(2A_e))^2\\ &+N_D\exp\,(-\delta_d/(kT))/A_e\}^{1/2}]\ ,\end{aligned} \tag{2.7}$$

and in the transition range of temperature where $\Delta>\delta'>kT\gg\delta_d$, it is given by

$$\begin{aligned}\zeta=kT\ln\,[&N_b''/(2A_e)\\ &+\{(N_b''/(2A_e))^2+A_h\exp\,(-\Delta/(kT))/A_e\\ &+N_{\mathrm{disl}}f_D(0)\exp\,(-\delta'/(kT))/(A_eS)\}^{1/2}]\ .\end{aligned} \tag{2.8}$$

In Eqs. (2.7) and (2.8) we put

$$\left.\begin{matrix}A_e\\ A_h\end{matrix}\right\}=\left.\begin{matrix}(1-\mathcal{E})\\ 1\end{matrix}\right\}\cdot\frac{2(2\pi m_{e,h}kT)^{3/2}}{h^3}\ , \tag{2.9}$$

$$\left.\begin{aligned}N_b'\ &=N_b\ -N_{\mathrm{disl}}f_D(0)/S\ ,\\ N_b''&=N_b'-N_{\mathrm{disl}}f_D(0)/S\ .\end{aligned}\right\} \tag{2.10}$$

§ 3. Scattering Effects in Different Temperature Ranges

Assuming the random distribution of the sectional centers of the cylinders of which directions along the length are parallel to each other, we study the scattering effects of the electrons moving on the vertical plane to the dislocation line.

In the impurity range of temperature the electron mean free path due to phonon-scattering is comparable to the cylinder radius, so that the additivity of the reciprocal mean paths is held in so far as inter cylindrical spacing is larger than the mean free path. Then we have

$$l_e^{-1}=l_L^{-1}+l_i^{-1}+l_c^{-1}\ , \tag{3.1}$$

where l_L, l_i, and l_c are the mean free paths due to phonon-, impurity-, and cylinder-scattering respectively. The l_c is given by $l_c=(3/8)/(RN_{\mathrm{disl}})$.

Putting Eq. (3.1) into Eqs. (2.1) and (2.3), we obtain

$$\begin{aligned}Q=(k/e)[&\zeta/(kT)\\ &-\{(2-x^2+x^3\varphi(x))/(1-x^2\psi(x))\}]\end{aligned} \tag{3.2}$$

with

$$\left.\begin{aligned}\varphi(x)&=C_{\mathrm{i}}(x)\sin x-S_{\mathrm{i}}(x)\cos x+\tfrac{1}{2}\pi\cos x\ ,\\ \psi(x)&=-C_{\mathrm{i}}(x)\cos x-S_{\mathrm{i}}(x)\sin x+\tfrac{1}{2}\pi\sin x\ ,\end{aligned}\right\} \tag{3.3}$$

where

$$\begin{aligned}x=[&(1/(2\kappa^2))N_D(1-\mathcal{E})\pi e^4\\ &\times\ln\{1+(3\kappa kT/(e^2(N_D(1-\mathcal{E}))^{3/4}))^2\}]^{1/2}\\ &/\{(kT)(l_L^{-1}+l_c^{-1})\}\ ,\end{aligned} \tag{3.4}$$

κ being the dielectric constant, is the ratio of electron mobility by impurity-scattering to that by both the cylinder- and phonon-scattering, and the expression for l_i given by Conwell and Weisskopf[7] is used. It is noticed that the density of ionized impurity-scatterers is reduced to $N_D(1-\mathcal{E})$. Eq. (2.7) is used in the Fermi term in Eq. (3.2).

As is well known the phonon drag effect is overwhelming in this temperature range and it is necessary to study the interaction effect between the dislocation and the effect.

Phonon drag effect is in general sensitive to the electron density in the valleys, while the lattice deformation around the dislocation would change the density in the different valleys and an anisotropy is expected in the thermoelectric power, but in the impurity range of temperature the cylinder covers almost all of the lattice deformation region so that negligible effects appear. At just below the room temperature there must be an appreciable effect. Drabble[8] has also pointed out the effect. In p-type materials the effect is very complicated and is not studied in this paper.

In the transition range of temperature the effect of charged dislocation on the thermoelectric power is studied on the basis of the following three points of view: (1). The radius of the cylinder decreases but the electron mean free path due to phonon-scattering becomes far less than the radius (a typical ratio is of order 10^{-3}), so that the conducting electron follows curved path that wind around the cylinders. Such distorsion of the electron stream line reduces effectively the apparent mobility μ_e^*, which is related with the free mobility μ_e by $\mu_e^*=g(\mathcal{E})\mu_e$ where $g(\mathcal{E})$ is a factor exhibiting the winding effect[2]. The hole mobility μ_h^* is, however, subject to slight effect and the approximation $\mu_h^*=\mu_h$ is held. (2). There is no electron in the cylinder but intrinsic holes and excited holes from the dislocation-acceptors can exist. Then the cylinder becomes effective p-type materials having no electron even at high temperature. (3). In near intrinsic n-type materials, it is possible that the majority carrier is converted in the presence of high density of the dislocation-acceptors.

The combined thermoelectric power (Q) of the mother material (Q_0) and the cylinder (Q_c) is given by

$$Q=\{(1-\mathcal{E})(1+K)Q_0+\mathcal{E}Q_c\}/\{1+(1-\mathcal{E})K\}\,, \tag{3.5}$$

with

$$Q_0=(k/e)\{-2(K-1)/(K+1)+\zeta/(kT)+\varDelta/(kT(K+1))\}\,, \tag{3.6}$$

$$Q_c=(k/e)\{2+(\varDelta+\zeta)/(kT)\}\,, \tag{3.7}$$

where K is the ratio of electron to hole conductivity and is given by

$$K=(1-\mathcal{E})\,g(\mathcal{E})\mu_e n_e/(\mu_h n_h)\,. \tag{3.8}$$

Eq. (2.8) is used in the Fermi term in Eqs. (3.6) and (3.7).

In the intrinsic range of temperature or in p-type materials the dislocations put off the space charge and the lattice deformation around it scatters carriers. With use of the expression of the mobility given by Dexter and Seitz[9], the effect is adequately taken into account in the expression of the thermoelectric power. It is given by

$$Q=-(k/e)\{(\mu_e/\mu_h-1)/(\mu_e/\mu_h+1)\}[\varDelta/(2kT)+(2-3\sqrt{\pi}\,\alpha/4+\alpha^2-\cdots)/(1-\sqrt{\pi}\,\alpha/2+\alpha^2-\cdots)] \tag{3.9}$$

with

$$\alpha=\frac{3\pi}{32}\cdot\frac{E^2\lambda^2 l_L N_{\text{disl}}}{\hbar(kT)^{3/2}}\cdot\left(\frac{m^*}{2}\right)^{1/2}\cdot\left(\frac{1-2\nu}{1-\nu}\right)^2, \tag{3.10}$$

where the scattering-effect due to the ionized impurity is neglected because the effect is less than that due to the naked dislocation in the intrinsic range of temperature unless the density is very high. Evaluating α for electrons in Ge, so that the coupling constant $E=10$ eV, the magnitude of Burger's vector $\lambda=4$ Å, Poisson ratio $\nu=0.4$, the mean free path due to phonon-scattering $l_L=50$ Å, $m^*=0.6$ m, and $T=400$°K, we find $\alpha=0.1$ for $N_{\text{disl}}=1.6\times10^7\ \text{cm}^{-2}$.

§ 4. Comparison with Experiments and Discussions

Comparing with the experimental data for n-Ge given by Yamashita and Ohta[5], we discuss the present theory. The measured values for n-Ge whose room temperature resistivity is 46 $\Omega\cdot$cm are shown in the transition range of temperature in Fig. 2. The marks ×, ○, and ▲ are referred to the sample as grown, the first sample as bent, and the second sample as bent respectively. The first and the second have the radii of curvature of 1.8 cm and 8.0 cm respectively, the both are annealed after bending in order to remove the annealable point defects which are introduced during the bending. Curve A is plotted with use of Eqs. (3.6) and (2.8) putting $f_D=0$ and the assumed values, $\varDelta=(0.785-4.5\times10^{-4}T)$ eV, $m_e=0.6\,m$, $m_h=0.3\,m$. Curve B is so plotted as it is most fit to the experimental values putting the values $\delta'=0.2$ eV, $S=3.5$ Å, $N_{\text{disl}}=1.6\times10^7\ \text{cm}^{-2}$, $R=10^{-4}$ cm, and $\mathcal{E}=0.5$ into

Eqs. (3.5)~(3.8) and (2.8), then it becomes that $f_D(0)\approx 0.2$, while the value due to Read[2] is about 0.1, and $K\approx 0.2$ at about 300°K. The K-value may be interpreted as follows: The dislocation-acceptor density is 4.7×10^{14} cm^{-3}, while the chemical donor density is 3.6×10^{13} cm^{-3} and hole density increases by the excitation from the acceptors so that the ratio of electron to hole density becomes about 1/2 because the electron density is reduced to below 1×10^{13} cm^{-3} by the trapping at the acceptors. Then the value $g(\mathcal{E})\approx 0.4$ at $\mathcal{E}=0.5$ is obtained by Eq. (3.8). The temperature dependencies of $\mu_{e,h}$ are calculated after Morin and Maita[10].

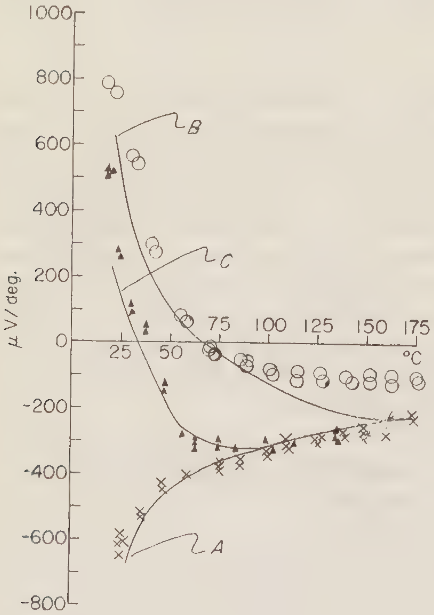

Fig. 2. Experimental data and the theoretical curves for T. E. P. of the deformed 46 Ω·cm n-Ge.

The discrepancy between curve B and the experimental values at above 100°C is attributed to the scattering effect by the naked dislocations. With use of Eq. (3.9) and the proper values of the parameters, the discrepancy will disappear. It is noticed that the effect is appreciable only in the temperature range where thermoelectric power is nearly independent of temperature (the curve is nearly parallel to T-axis) and decreases as temperature exceeds over the range. The effect is also observed in p-Ge[5]. Curve C is plotted in the similar way to curve B assuming $\mathcal{E}=0.1$. In this case both the combination- and the winding-effects are small, while the reduction of electrons and the increase of holes play the essential role. The effect from the naked dislocations is also very small.

The prominent differences of the n-p conversions between by the deformation and by the thermal one are: (1). In the former case the sign of thermoelectric power changes at higher temperature than in the latter case. (2). In the former case the absolute value of thermoelectric power becomes fairly small.

More detailed discussions about the experimental values of various samples will be described in the forthcoming paper[5].

Acknowledgement

The author would like to express his cordial thanks to Prof. Y. Uemura (Tokyo Univ.) for his very useful suggestions and valuable discussions. Thanks are also due to Prof. K. Tomita (Univ. of Kyoto) for his detailed discussions, to Dr. T. Yamashita (Defense Academy) for his valuable discussions about the analysis of the experimental data, and to Dr. J. R. Drabble (Res. Lab. of G.E. Corps.) for his helpful comments about the effect of the strain.

Measurement of Seebeck Effect in Plastically Bent Germanium

By Tadayoshi YAMASHITA and Tokio OHTA

Department of Physics, Defense Academy, Yokosuka

(Received May 4, 1961)

The changes of the thermoelectric powers and the electrical resistivities of several kinds of n-Ge and p-Ge due to plastic bending are measured in the temperature covering the transition- and intrinsic-ranges and analyzed by the theory. The value of the dislocation-acceptor level is estimated to be about 0.2 eV. The n-Ge sample near intrinsic is converted to p-type by the bending, while n-Ge with low resistivity and p-type samples show the slight effect. The difference of n-p conversion due to the deformation from the thermal conversion is discussed.

§ 1. Introduction

The study of thermoelectric power in n-type semiconductors under plastic deformation is very useful to confirm the charged dislocation model[1)]. In the transition range of temperature it provides reliable information of the following three effects: (1). *Scattering-effect.* The carriers are scattered by the space charge cylinder around a dislocation whose radius is far larger than their mean free path, while they are scattered by the lattice deformation when it has no charge. (2). *Combination-effect.* The observable thermoelectric power is the combined one of the n-type mother material with the p-type cylinder. (3) *Conversion-effect of the majority carrier.* In the n-type materials near intrinsic, the type of majority carrier is converted by introducing the high density of the dislocation-acceptors. Ohta[1)] has formulated all these effects and given Eq. (1.1) for the measurable thermoelectric power Q:

$$Q=\{(1-\varepsilon)(1+K)Q_0+\varepsilon Q_c\}/\{1+(1-\varepsilon)K\}\,, \tag{1.1}$$

with

$$Q_0=(k/e)\{-2(K-1)/K+1)$$
$$+\zeta/(kT)+\Delta/(kT(K+1))\}\,, \tag{1.2}$$

$$Q_c=(k/e\{2+(\Delta+\zeta)/(kT)\}\,, \tag{1.3}$$

$$K=(1-\varepsilon)g(\varepsilon)\mu_e n_e/(\mu_h n_h)\,, \tag{1.4}$$

where Q_0 and Q_c are the thermoelectric powers of the mother material and the cylinder respectively, ε is the ratio of the volume of all cylinders to that of the bulk crystal, $-\zeta$ is the Fermi energy, e is the magnitude of electron charge, Δ is the gap energy between c- and v-band, and $g(\varepsilon)$ exhibits the scattering-effect of electron due to the space charge cylinder. The reduction of free electron density and the increase of hole density are expressed in Eq. (1.4), where n_e, μ_e and μ_h are the free electron density, the electron and hole mobilities in the absence of dislocations respectively. n_h is the free hole density in the presence of dislocations.

In the present paper the thermoelectric powers and the resistivities of several kinds of Ge are measured and analyzed from the transition to the intrinsic range of temperature.

The values of the dislocation-acceptor level is estimated by the measured values of the conductivities. The value of K is discussed. The scattering-effects due to the naked dislocation for n-Ge and p-Ge are also studied in the intrinsic range of temperature.

§ 2. Samples and Measurements

Three kinds of antimony-doped (T, E, and O in our sign) and one kind of indium-doped (Y in our sign) germanium-single crystals were cut in wafers of the size of 25×6×3 mm^3. The crystal axes were so chosen that the parallel array of pure edge dislocations are introduced, the inter dangling bonds spacing being about 3.5Å, by bending round the [$\bar{1}\bar{1}$2] -axis as shown in Fig. 1.

On the surface of the wafer two caves with diameter of about 1.5 mm were grounded

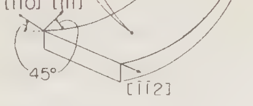

Fig. 1. Bent Ge-wafer and the crystal axes.

whose distance was about 1.0 cm. After polishing with 1200-mesh emery powder the wafers were etched in CP4 soaking in concentrated HNO_3, rinsing in deionized water, soaking in aqueous KCN solution, and again rinsing in deionized water. When the wafer was bent, the edges were put on graphite electrodes and heated to 600~650°C by passing a current through it in the atmosphere of argon gas and bent by pressing it with use of a graphite block having two knife edges. Two thermocouples composed of No. 36 chromel-alumel wires were attached to each cave with use of platinum foil to give good electrical and thermal contact.

The sample was placed inside an apparatus with a graphite contact on one end and another graphite contact with a heater at the other end and inserted holizontally in an electric furnance. The temperature difference between the caves was kept to 1.0°C during the measurement. Both the Seebeck voltages and the resistivities before and after bending were measured at the temperature range between 25°C and 300°C by means of a K-type potentiometer with the attentions pointed out by Middleton and Scanlon[2].

In order to study the effect of annealable point defects introduced during the bending the values as bent and annealed after bending were measured. In the Table I the kinds of samples, the radii of curvature, and the annealing data are listed.

Table I.

Samples	as grown		as bent	annealed

§ 3. Results and Analyses

The values of radius R of the space charge cylinder, the dislocation density N_{disl}, the ratio ε of all the cylinders to mother bulk volume, and the dislocation-acceptor density n_{da} are estimated, assuming that the inter dangling bonds spacing S is 3.5Å and the fraction of dislocation-acceptor density that are full f_D is 4.5×10^{-2} at 300°K, and listed in the Table II.

The resistivity for TNO. 2 at about 300°K increases about ten times as large as the as grown by the deformation, while the change of thermoelectric power is very small.

The measured values of resistivities for E-kind samples are shown in Fig. 2. For ENO. 2 bent heavily the resistivity is reduced appreciably at high temperature and it becomes p-type, while for ENO. 3 bent slightly the resistivity is reduced a little and it also becomes p-type. The n-p conversion corresponds to the effect described in § 1. Curve C in Fig. 2 shows that the annealable point defects introduced during the bending act as effective acceptor-centers because the material shows stronger p-type, the situation is in accordance with the fact hitherto known[3].

The measured values and the analytical curves for E-kind samples are plotted in Fig. 3. The curves are drawn with use of the following semi-empirical method. Estimating n_e, μ_e and μ_h after Morin and Maita[4], the Fermi-term in Eqs. (1.2) and (1.3) are given by

$$(\Delta+\zeta)/(kT)=11.78+\ln(1+K)-\ln\sigma-0.83\ln T\,, \qquad (3.1)^{*}$$

where σ $(\Omega\cdot\mathrm{cm})^{-1}$ is measured conductivity and Δ is assumed to be $\Delta=(0.785-4.5\times10^{-4}\cdot T)$ eV. Curve A in Fig. 3 is plotted after Eqs. (1.2), (3.1) and Fig. 1. Curve B in Fig. 3 is plotted after Eqs. (1.1)~(1.4), into which ε-value shown in the Table II is substituted, and Eq. (3.1). In this case there is no fits unless the value $K\approx0.2$ at about 300°K is given. Using ζ given by Eq. (3.1) with $K=0.2$, we evaluate the carrier density and obtain $n_h/n_e\approx2$. This shows that $g(\varepsilon)\approx0.4$ at $\varepsilon=0.5$.

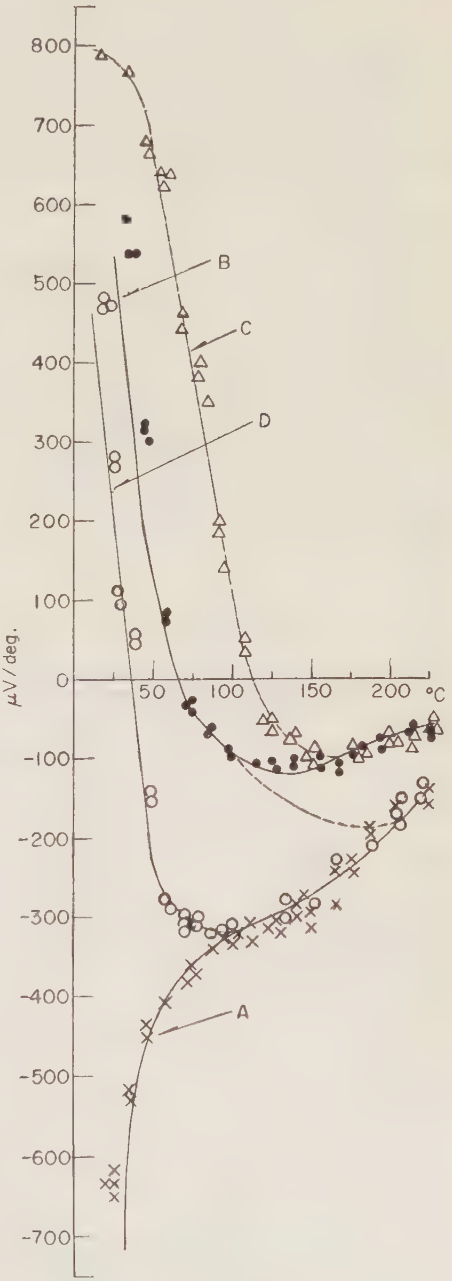

Fig. 3. Thermoelectric powers for E-kind samples. Curve A is referred to the as grown, curve B; to ENO. 2 annealed after bending, curve C; to ENO. 3 as bent, and curve D; to ENO. 3 annealed after bending.

The scattering-effect due to the naked

---

[*] Effective masses $m_e=0.6m$ and $m_h=0.3m$ are assumed.

dislocations is observed at above 100°C and the curve B above 100°C in Fig. 3 is drawn after Eq. (1.2) where the factor 2 is replaced by $(2-\alpha)/(1-\xi)$ with $\xi\approx 0$, $\varepsilon=0$, and $0.5<\alpha<1$, the dotted curve ramified is for the case neglected the effect.

Comparing the experimental value of ζ given by Eq. (3.1) with theoretical equation[1], we obtain the value of about 0.2 eV for the dislocation-acceptor level. Almost the same value is also obtained in the case of ONO. 6.

Curve C in Fig. 3 empirically drawn for ENO. 3 shows that the annealable defects act

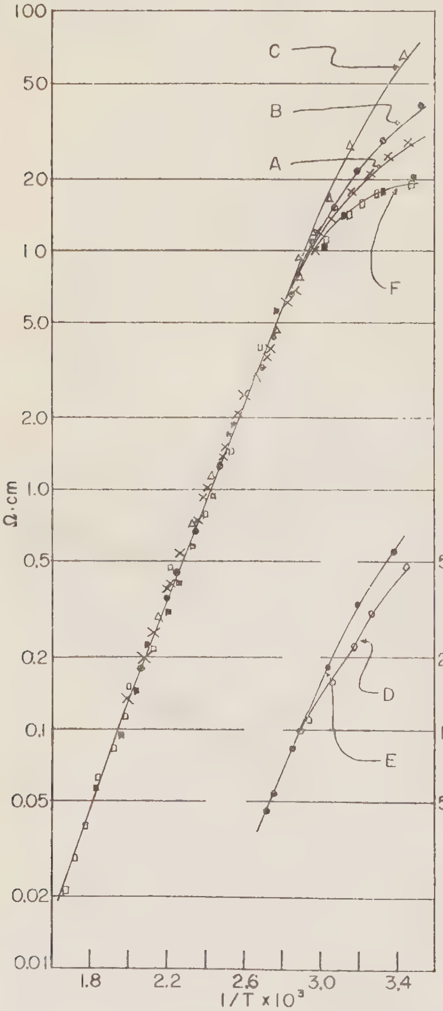

Fig. 4. Temperature dependency of resistivities for O- and Y-kind samples. Curve A is referred to O-kind as grown, curve B; to ONO. 6 as bent, curve C; to ONO. 6 annealed after bending, curve D; to ONO. 7 as bent, curve E; to ONO. 7 annealed after bending, curve F; to Y-kind as grown and as bent.

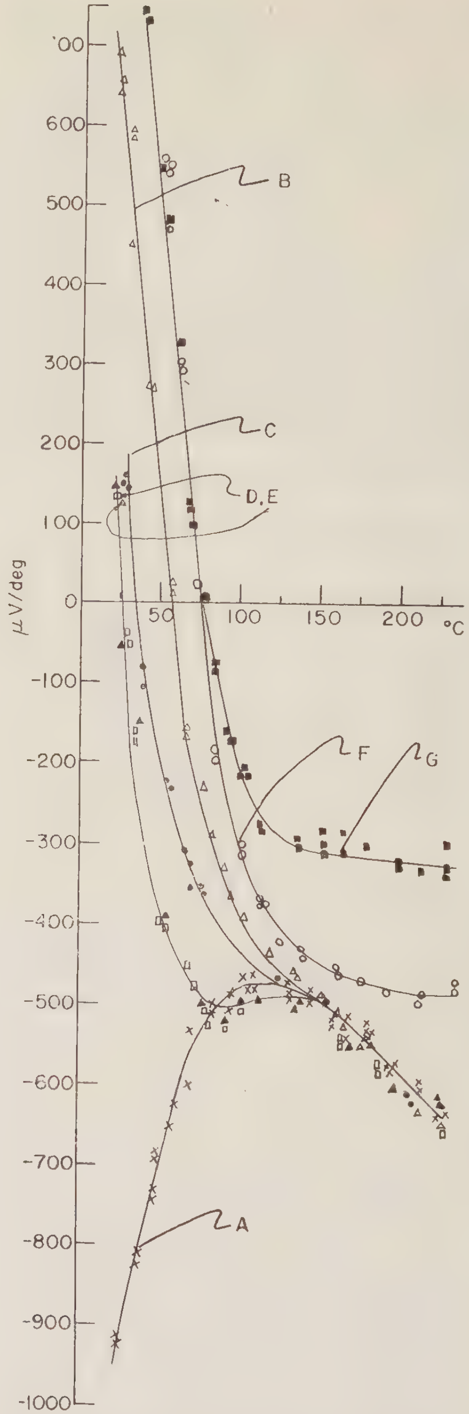

Fig. 5. Thermoelectric powers for O- and Y-kind samples. Curve A is referred to O-kind as grown, curve B; to ONO. 6 as bent, curve C; to ONO. 6 annealed after bending, curve D; to ONO. 7 as bent, curve E; to ONO. 7 annealed after bending, curve F; to Y-kind as grown, and curve G; to Y-kind as bent.

as effective acceptors whose density is so high that an appreciable scattering-effect is observed.

Curve D in Fig. 3 is plotted after the similar manner to that of the curve B in Fig. 3. In this case both the combination- and scattering-effects are small, while the reduction of free electrons and the increase of holes play essential role.

The measured values of resistivities for O- and Y-kind samples are shown in Fig. 4. The effects of charged dislocations are to increase the resistivities in contrast with E-kind case. The change of the values as well as the temperature dependency are explained with use of Read's theory as in the cases hitherto known[5]. Y-kind sample is of *p*-type and the scattering-effect due to the naked dislocations on the resistivity is too small to be observed as is seen from curve F in Fig. 4. The effect on the thermoelectric power is, however, appreciable generally in the temperature range where the thermoelectric power is nearly independent of temperature. The curve G in Fig. 5 is an example case.

All the curves in Fig. 5 are drawn empirically. The explanations for the behaviors of the curves are essentially the same as for E-kind samples. But the following points should be noticed. As shown in curve C in Fig. 5 the charged dislocations reduce the absolute value of thermoelectric power fairly. This informs that the majority carrier in O-kind materials at room temperature is not always converted to hole if we consider the combination-effect with $\varepsilon=0.3$. Such an explanation is supported by curve E in Fig. 5 where the values are shifted more to negative sign side because of the small combination-effect ($\varepsilon=0.1$).

It is, however, incomprehensive that the scattering-effect due to the naked dislocations on the thermoelectric power for ONO. 6 is unexpectedly small in the intrinsic range of temperature although it contains very high density of the dislocations.

Illustrating ENO. 3 as an example case, we show that it is impossible to explain the effect of the deformation on the thermoelectric power by only the effect of the point defects. If the curve C in Fig. 3 is due to the holes ionized from the acceptors whose level depth is $\Delta-(0.1\sim0.05)$ eV[3] the acceptor density must be about $10^{20}\sim10^{18}\,\mathrm{cm}^{-3}$, which is unreasonably high. If the curve D in Fig. 3 is due to the holes ionized from the acceptors surviving the annealing the acceptor density must be about $10^{18}\sim5\times10^{15}\,\mathrm{cm}^{-3}$. The values are enough to cause an appreciable scattering-effect at intrinsic range of temperature, which is not observed in the curve. Therefore we may conclude that the curve is almost perfectly due to charged dislocations.

On the Interference Phenomena of Compton Scattering from Diamond

By Yasuharu Yoneda

Department of Applied Physics Faculty of Engineering
Kyushu University Fukuoka

(Received February 4, 1961)

An explanation is given on the divergent beam pattern due to Compton scattering. The pattern is not caused by a point source of X-rays outside of crystal but by interference of X-rays produced uniformly in a small crystal. It is shown experimentaly that the interference lines can appear even for a pretty small crystal if a micro-beam is used.

§1. Introduction

Grenville Wells[1] obtained divergent-beam patterns from diamond and other crystals with a parallel X-ray beam, and ascribed the origin of such interference patterns to either Compton scattering or scattering due to imperfections, or both. Norman[2] confirmed by using a filter technique that the origin of divergent radiation is due to Compton scattering. He observed: (i) The interference lines appear from imperfect crystals, but not from perfect crystals; (ii) There seems to exist a certain minimum in the size of diamond crystals to give rise to the lines, since the interference lines are observed for a crystal of 2×0.5 mm with the incident X-rays of 1 mm cross-section, but not for a crystal of 0.5×0.5 mm, though both of the crystals are obtained from a same large crystal; (iii) The interference lines have fine structures.

From (i) he concluded it as probable that the Compton interference is caused not only by the primary extinction effect but also by the secondary extinction effect, as Lonsdale[3] suggested for the usual divergent beam patterns obtained with the X-ray point source lying outside the crystal. He considered that crystals must be large enough so that the secondary extinction effect is appreciable to give rise to the interference lines. According to him, the relative position of the light and dark lines in the fine structure are always complementary to that of the Kossel pattern which appears by the dynamical effect in a perfect crystal. This fact supports the explanation of the interference lines by the secondary extinction effect. As to the fine structure of the lines, he compared it with the pair of reflection and deficiency lines in the usual divergent beam pattern given by a X-ray point source outside the crystal, as shown in Fig. 1, and considered that the separation of the two lines become very small if the distance between the source and the crystal and the crystal thickness are reduced.

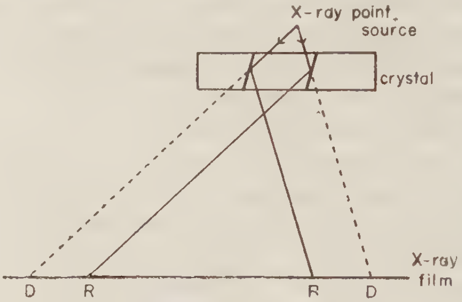

Fig. 1. The explanation of appearance of reflection and deficiency lines by a point X-ray source outside the crystal.

In the present study the interference lines were observed for several specimens of diamond with the parallel beam of X-rays of various sizes, and a conclusion somewhat different from that by Norman[2] was obtained with regard to the condition of the appearance of the interference lines. In order to explain this and the fine structure, we have considered the process of the appearance of the interference lines in more detail, taking into account the fact that the source of the divergent beam due to Compton scattering is not a point source, but distributed over the whole region irradiated with the impinging X-ray beam.

§2. Experiment

The Cu radiation from a rotating anode X-ray source of variable focal-size was used.[4]

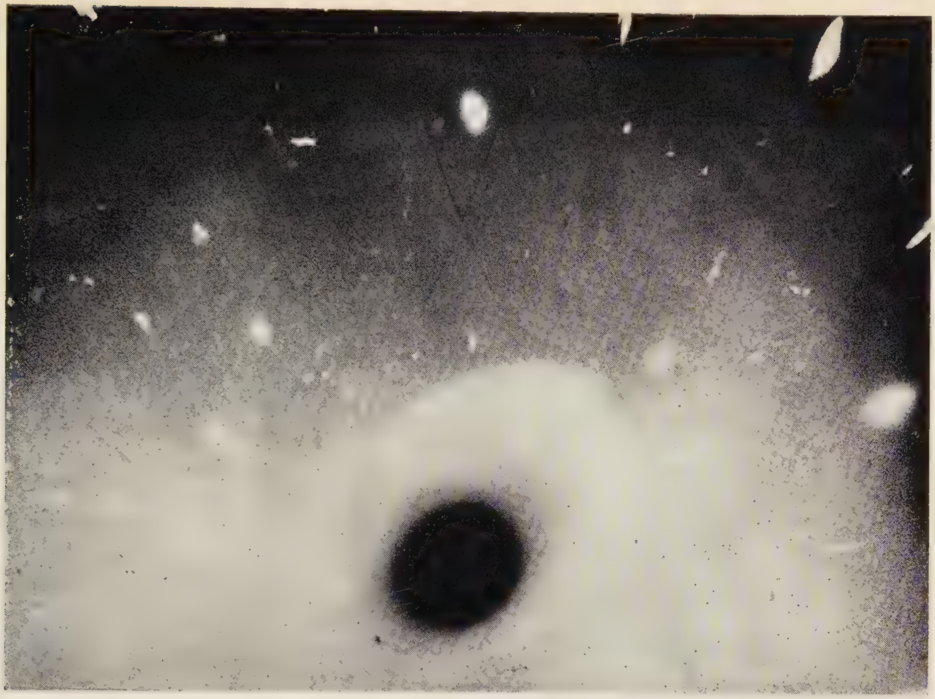

Fig. 2. Divergent beam pattern; Impinging beam in [110] direction, $[1\bar{1}0]$ vertical. No filter Cu radiation 40 KVP, 40 mA, apparent focus 0.2×0.5 mm, exposure time 40 hrs. the diameter of impinging X-ray beam 0.1 mm, distance from specimen to flat film is 30 mm, positive figure. ×2.5.

The source can be operated for a long time without trouble with the focus 0.2×0.5 mm, and with 50 mA at 40 kV.

Several brownish diamond crystals from Borneo, about 3—0.2 mm in size were used. The interference lines with the fine structures were observed as reported by Norman.[2] An example is shown in Fig. 2, where four interference lines corresponding to the reflection {111} with fine structures composed of light and dark lines are observed besides the Laue spots.

This photograph was obtained from a crystal of 0.2×0.4 mm with the impinging X-ray beam of the diameter 0.1 mm. It is to be noted that no interference line was observed from the same specimen with the impinging X-ray beam of the diameter 0.3 mm. The size of the crystal used in the present experiment is smaller than the one used by Norman,[2] which was 0.5×0.5 mm in size. This fact suggests that the minimum size for the appearance of the interference lines, if it exists, seems to be still smaller than he suggested, and that the cross section of the impinging beam is a factor more important than the crystal size for small crystals.

§ 3. Consideration on the appearance of the interference lines

The angular width of Bragg reflection due to the spectral line breadth of X-rays is given by

$$d\theta=\frac{d\lambda}{\lambda}\tan\theta \tag{1}$$

where θ is the Bragg angle of the reflecting planes and λ wave length.

If $\Delta\lambda$ is the line breadth of Compton shift line due to the initial random velocities of electrons bound in atoms, $d\theta$ is given by

$$d\theta=\frac{\Delta\lambda}{\lambda}\tan\theta \tag{2}$$

According to Du Mond and Kirkpatrick[5] and Du Mond,[6] $d\theta$ is estimated to be about 0.51° for the reflection (111) planes with Cu $K\alpha$.

In order to explain the structure of the light and dark lines, it is assumed that the source of the divergent beams are distributed in a small crystal whose absorption is almost negligible, and that the divergent beams are reflected by the lattice planes in the same crystal. Let us first consider the case where the breadth of Compton shift line is neglected, and assume, for simplicity, that the crystal has a rectangular section $\boldsymbol{ABCD}$ in Fig. 3 (a), and AB makes 45° angle with the lattice plane $\boldsymbol{L}(hkl)$, and that the Bragg angle for $\boldsymbol{L}$ is 45°. Incident X-rays $\boldsymbol{i}$ which have been emitted in the crystal, form 90° angle with reflected X-rays $\boldsymbol{r}$. It is not necessary in this case to consider X-rays coming from outside. The reflected X-rays leaving the crystal through the point $\boldsymbol{P}$ should have been reflected at some point on $\boldsymbol{PQ}$, and their incident X-rays should have been emitted at some point within the area $\boldsymbol{ABPQ}$. The variation of intensity of reflected X-rays along $\boldsymbol{AD}$, therefore, is given approximately by the line $\boldsymbol{a}$. The intensification toward the side $\boldsymbol{D}$ may be said as a pile-up effect. On the other hand, a part of X-rays traveling in the direction of $\boldsymbol{r}$ are reflected on the lattice plane $(\bar{h}\bar{k}\bar{l})$. This negative intensity is constant along $\boldsymbol{AD}$ and shown by the line $\boldsymbol{b}$. The line $\boldsymbol{c}$ is the sum of the intensities $\boldsymbol{a}$ and $\boldsymbol{b}$. This explains the appearance of the light and dark line.

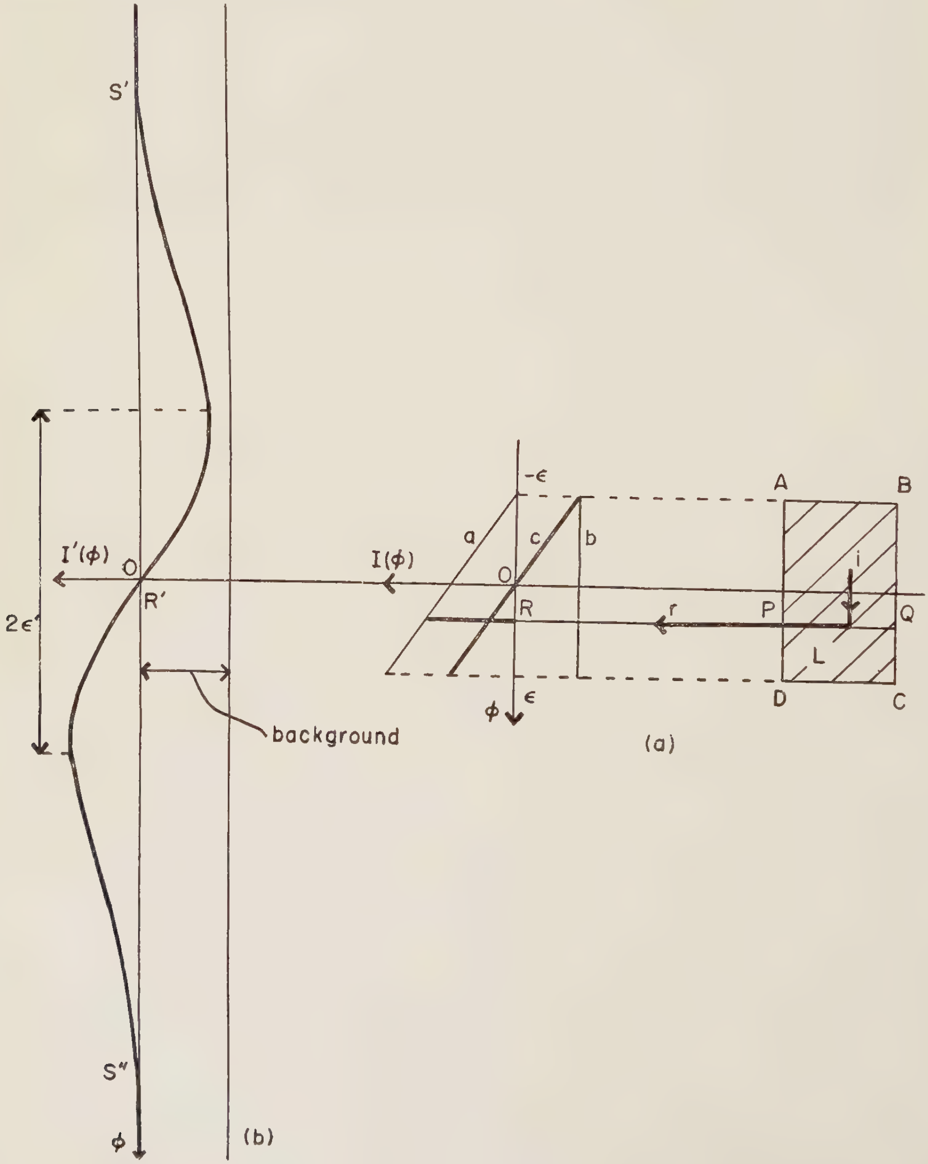

Fig. 3. The interpretation of the fine structure of a interference line due to Compton scattering.

Let us consider next the breadth of Compton shift line. Corresponding to the simple case considered above, the intensity of the light and dark lines is assumed to be as follows:

$$\left.\begin{aligned} I(\phi)&=-m\phi \qquad \text{for} \quad |\phi|\leq\mathcal{E} \\ I(\phi)&=0 \qquad\quad\ \text{for} \quad |\phi|>\mathcal{E} \end{aligned}\right\} \tag{3}$$

where ϕ is the angle measured from the centre of the reflection of X-rays, m a constant and $\pm\mathcal{E}$ the angle of both the ends of the light and dark lines. If the breadth of Compton shift line can be expressed by $1/\sqrt{2\pi}\sigma \exp(-\phi^2/2\sigma^2)$, where the value σ is determined by the wave length and the angle of deviation from the impinging X-ray beam, the intensity of X-rays will be expressed by the convolution of these two functions as follows:

$$I'(\phi)=\int_{\phi-\varepsilon}^{\phi+\varepsilon}\frac{1}{\sqrt{2\pi}\sigma}\exp(-u^2/2\sigma^2)\{-m(\phi-u)\}du$$

$$=-\frac{m\phi}{\sqrt{2\pi}\sigma}\left\{\int_0^{\phi+\varepsilon}\exp(-u^2/2\sigma^2)du\right.$$

$$\left.-\int_0^{\phi-\varepsilon}\exp(-u^2/2\sigma^2)du\right\} \tag{4}$$

$$+\frac{m}{\sqrt{2\pi}\sigma}[\exp\{-(\phi-\mathcal{E})^2/2\sigma^2\}$$

$$-\exp\{-(\phi+\mathcal{E})^2/2\sigma^2\}]\,. \tag{5}$$

The numerical calculations of (5) is shown in Fig. 3 (b), where the half-value width of $1/\sqrt{2\pi}\sigma \exp(-\phi^2/2\sigma^2)$ is taken to be $4\mathcal{E}$. The distance between the minimum and maximum of the intensity is larger than that in Fig. 3 (a), but the centre remains at the same position where the intensity gradient is the largest in both cases. The light and dark lines in Fig. 2 shows slow intensity variation in their both sides. This variation is clearly seen also in the microphotometer traces of Norman,[2)] as is shown in Fig. 4. In the photograph, however, the breadth of the part near R' where the intensity gradient is large, or the maximum and minimum interval ($2\mathcal{E}'$ of Fig. 3 (b)) are apt to be taken for the breadth of the light and dark lines, due to the strong background. For this reason, they sometimes look sharper than the actual width ($S'S''$ of Fig. 3 (b)), as seen in Fig. 2.

The X-rays emitted in ***i*** and ***r*** directions in Fig. 3 (a) have different wave length in accordance with Compton's formula when their angles to the direction of impinging X-rays from outside are different. The lines ***a*** and ***b*** of Fig. 3 (a) should, then, shift slightly corresponding to the difference in the angles of Bragg reflection, but this effect makes no great contribution to the appearance of the light and dark lines. Fig. 2 corresponds to a case with no such difference in wave length.

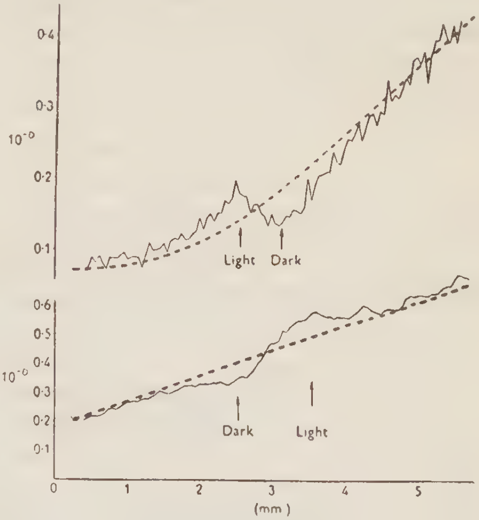

Fig. 4. Microphotometer traces of the interference lines by N. Norman.[2)] Ordinate scale 10^{-D}, where D is film density. Dotted lines are written by the author, as the correspondency to Fig. 3 (b).

The external form of crystal is generally complicated and the relation between incident X-rays and reflected X-rays in a crystal is not so simple as shown in Fig. 2. However an explanation quite similar to the above is possible for a crystal having a cross section of parallelogram formed by the lines paralleled in ***i*** and ***r*** directions. In more general cases, it may be possible to calculate the intensity theoretically by the convolution using more variables. In general, a kind of pile-up effect will always take place, and the breadth of the interference line will be in the order of the linear dimension of the crystal in the direction ***AD*** in Fig. 3 (a). For the crystal used in the observation of Fig. 2, the magnitude of projection corresponding to $2\mathcal{E}$ of Fig. 3 (a) is 0.24 mm, and on the film this corresponds approximately to 0.26°. Since the half width of Compton shift line is about 0.51° as mentioned before, we have $2\mathcal{E}'\approx 0.5°$, and the observed value of $2\mathcal{E}'$ 0.4−1° is in the range of agreement with the calculation.

The author wishes to express his sincere thanks to Prof. T. Futagami for his obtaining necessary diamonds and continued encouragement. The author's thanks are also due to Dr. N. Norman of Central Institute for Industrial Research, Norway for his invaluable comment and advice. Also the author is indebted very much to Prof. K. Kohra of Tokyo University for his kind discussion.

The Crystal Structure of Nickel Chloride Hexahydrate, $NiCl_2 \cdot 6H_2O$*

By Joji MIZUNO

Takarazuka Radiation Laboratory, Division of Sumitomo Atomic Energy Industries, Ltd. Takarazuka Japan

(Received March 30, 1961)

The crystal structure of $NiCl_2 \cdot 6H_2O$ has been determined by the X-ray single crystal method. The unit cell is monoclinic with $a=10.23$ Å, $b=7.05$ Å, $c=6.57$ Å and $\beta=122°10'$. The space group is C_{2h}^3-C2/m and the unit cell contains two formula units. The atomic arrangement is quite the same as that of $CoCl_2 \cdot 6H_2O$ and thus the structure model adopted for this salt has again been confirmed to be correct, as compared with the model proposed by Stroganov *et al.*.

§ 1. Introduction

Previously, the author determined the crystal structure of cobalt chloride hexahydrade, $CoCl_2 \cdot 6H_2O$[1], by the X-ray single crystal method. This crystal structure is as follows: (1) two chlorine atoms and four water molecules are octahedrally coordinated to cobalt atom to form the group $[CoCl_2 \cdot 4H_2O]$, (2) the other two water molecules of the formula unit are located between the groups $[CoCl_2 \cdot 4H_2O]$ arranged in the direction of the b axis and they form the O···H–O type hydrogen bonds with the neighbouring water molecules of the groups $[CoCl_2 \cdot 4H_2O]$, and thus these groups are joined with one another through these hydrogen bonds in parallel with the b axis, and (3) the structure is composed of atomic layers parallel to (001). This structure model was entirely different from that proposed by Stroganov *et al*. and was proved to be reasonable by the following studies on $CoCl_2 \cdot 6H_2O$ at low temperatures: studies on the paramagnetic susceptibilities by Haseda and Kanda[2] and by Haseda[3], on the proton magnetic resonance by Sugawara[4] and on the specific heat by Robinson and Friedberg[5].

Haseda and Date[6] measured the paramagnetic susceptibilities of $NiCl_2 \cdot 6H_2O$ in powdered samples at low temperatures and found the different magnetic behavior from that of powdered samples of $CoCl_2 \cdot 6H_2O$, though the two salts were supposed to be isomorphous. Therefore, it was required to examine whether these two paramagnetic salts were certainly isomorphous or not. The present work was thus undertaken. In the previous paper[1], it was reported that according to the preliminary study, $NiCl_2 \cdot 6H_2O$ seemed to resemble $CoCl_2 \cdot 6H_2O$ in its atomic arrangement. By the present detailed structure analysis, it was proved that the former salt is quite isomorphous with the latter.

---

* This work was done at the Research Institute for Iron, Steel and Other Metals, Tohoku Univ., Sendai, Japan.

From the result of the preliminary study described above, Haseda, Kobayashi and Date[7)] considered that the anomalous magnetic behavior of a powdered sample of $NiCl_2 \cdot 6H_2O$ below about 10°K was also caused by the antiferromagnetic transition, as was the case for $CoCl_2 \cdot 6H_2O$. They measured the paramagnetic susceptibility on a single crystal of $NiCl_2 \cdot 6H_2O$ and confirmed that this salt is antiferromagnetic below about 6°K.

Thus, the structure model concluded for $CoCl_2 \cdot 6H_2O$ was again confirmed to be correct for $NiCl_2 \cdot 6H_2O$ by both the structural and magnetic studies. This increases very much the reliability for the proposed structure model.

§ 2. Crystallographic Data from the Literature on $NiCl_2 \cdot 6H_2O$

In "*Chemische Kristallographie*, I Teil" (Groth, 1906)[8)], the following data are given for monoclinic prismatic $NiCl_2 \cdot 6H_2O$: the axial ratios $a : b : c$ are 1.4678 : 1 : 0.9426, β being 122°30′. The (001)-cleavage is perfect. It is green or grass-green in colour. The density is given as 1.921 gr/cm³.

§ 3. Experimental

The light green single crystals of $NiCl_2 \cdot 6H_2O$ were grown from saturated aqueous solution. They were the same in the habit as described by Groth and accordingly they could be regarded as monoclinic prismatic. The two fragments along the a and the b axes which were about $0.4 \times 0.45 \times 2.5\ \mathrm{mm}^2$ and $0.25 \times 0.3 \times 2.5\ \mathrm{mm}^3$ in dimension, respectively, were cut out of these single crystals, sealed into grass capillary tubes in contact with chronometer oil and used for X-ray study. Under these conditions, they remained stable during the experiment.

Rotation photographs about the a and the b axes and oscillation photographs about the b axis were taken with Ni-filtered Cu$K\alpha$ and Zr-filtered Mo$K\alpha$ radiations. Multiple-film equi-inclination Weissenberg photographs of zero- and the first-layer were taken about the a and the b axes using Zr-filtered Mo$K\alpha$ radiation.

The unit cell parameters measured from these X-ray diffraction photographs are as follows:

$$a = 10.23\ \text{Å},\ b = 7.05\ \text{Å},\ c = 6.57\ \text{Å},\ \beta = 122°10'$$

$$a : b : c = 1.45 : 1 : 0.932$$

From these parameters and the density value, 1.92 gr/cm³, the number of the formula units in the unit cell was calculated to be 1.96, which meant the existence of two formula units per unit cell. From the crystal form and the observed extinctions, (hkl) with $k+k$=odd, $(h0l)$ with h=odd and $(0k0)$ with k=odd, the most probable space group was assumed as $C_{2h}^3 - C2/m$.

The relative intensities of reflections were estimated visually by comparison with the time-exposure calibrated strips. Some intensities, which were very faint and hardly visualized, were estimated as one-third or one-fifth of the lowest intensities of the strips. All of them were corrected for Lorentz and polarization factors in the usual way.

The linear absorption coefficient was calculated to be $30.4\ \mathrm{cm}^{-1}$ for Mo$K\alpha$ radiation. Using this coefficient, the rough absorption correction was made by assuming cylindrical shape of the sample.

§ 4. Determination of the Structure

The unit cell parameters, the values, $\sin\theta/\lambda$, and the relative intensities of reflections on photographs were quite similar to those of $CoCl_2 \cdot 6H_2O$ and thus the same structure model as that of this salt was primarily assumed for the present salt.

At first, based on the assumed model, the atomic parameters could approximately be determined by the trial-and-error method, using the $F(h0l)$'s obtained from oscillation photographs taken about the b axis with Zr-filtered Mo$K\alpha$ radiation. They are listed in Table I. The reliability factor, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, was 0.155. Referring to the data of $CoCl_2 \cdot 6H_2O$, the value of B, the coefficient in the exponent of the isotropic temperature factor $\exp[-B \cdot \sin^2\theta/\lambda^2]$, was assumed to be 1.5 Å² for Ni^{2+} and 3.0 Å² for Cl^- and O^{2-}, respectively.

As the next step, the atomic parameters were refined, using the $F(h0l)$'s and $F(0kl)$'s obtained from Weissenberg photographs. Fourier projections and the difference Fourier projections on (010) and the plane normal to

the *a* axis were synthesized. After these procedures, the atomic parameters were finally determined as shown in the column "Weiss. photo." in Table I. These parameters are almost the same as those of $CoCl_2 \cdot 6H_2O$, except for *z* parameter for Cl^-. The value of *B* for Ni^{2+} was improved to be 2.0 Å^2 for $F(h0l)$'s and 2.4 Å^2 for $F(0kl)$'s, respectively. The reliability factors were 0.133 and 0.088 for all $(h0l)$ and $(0kl)$ structure amplitudes, for which the maximum observed values of $\sin\theta/\lambda$ were 0.8417 and 0.7804, respectively. The numbers of $(h0l)$ and $(0kl)$ reflections were 128 and 45, respectively. A comparison between observed and calculated structure factors is given in Table II. The Fourier projections finally synthesized are shown in Fig. 1 (a) and (b). The calculations of the final Fourier syntheses were carried out with PC–1 Parametron Computer of Tokyo University.

The schematic representation and the arrangement of atoms projected on (010) plane are shown in Fig. 2 and Fig. 3, respectively. As seen from these figures, $NiCl_2 \cdot 6H_2O$ is quite isomorphous with $CoCl_2 \cdot 6H_2O$. That is, two Cl^- ions and four water molecules are octahedrally coordinated to Ni^{2+} ion to form the group $[NiCl_2 \cdot 4H_2O]$ and these groups are joined with one another in parallel with the

b axis by O···H–O type hydrogen bonds between O_I and O_{II}. The structure is also composed of atomic layers parallel to (001). Thus, the perfect cleavage parallel to (001) can reasonably be explained. In Table III, interatomic distances and interbond angles are given and for reference, data of $CoCl_2\cdot 6H_2O$ are added. As shown in Table III, interatomic distances are generally shorter than the corresponding ones of $CoCl_2\cdot 6H_2O$.

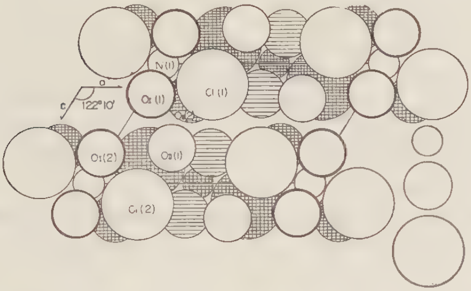

Fig. 3. The arrangement of atoms projected on (010).

§ 5. Discussion

In the structure analysis of $CoCl_2\cdot 6H_2O$, the most probable space group, $C^3_{2h}-C2/m$, was adopted, based on the Laue photograph taken with the radiation perpendicular to (100), the crystal form and the observed extinctions. The structure analysis was carried out and the decidedly reliable structure was found without any inconsistency. Thus, the space group, $C^3_{2h}-C2/m$, was correct for $CoCl_2\cdot 6H_2O$.

In the present study, the structure model was assumed for $NiCl_2\cdot 6H_2O$, based on the assumed space group and referring to the data of $CoCl_2\cdot 6H_2O$ and the analysis was carried out, using (*h*0*l*) and (0*kl*) data alone. Therefore, it must deliberately be examined whether the assumed structure model is correct or not, from the same reason as decribed in the previous paper[1]. Using sixty-one *F*(*h*1*l*)'s obtained from Weissenberg photographs in the present work, observed and calculated structure factors were compared with respect to the four kinds of the atomic arrangement, (I), (II), (III) and (IV) which were discussed on the structure determination on $CoCl_2\cdot 6H_2O$. In the arrangement (I), the reliability factor, *R* was 0.137. In the arrangement (II), *R* was 0.238 and the arrangements (III) and (IV) proved to be out of question. Thus, the structure model (I) and the space group, $C^3_{2h}-C2/m$, adopted for $CoCl_2\cdot 6H_2O$ was confirmed to be correct for $NiCl_2\cdot 6H_2O$, too. This result makes assurance for the present structure model doubly sure. A comparison between $|F_0|$ and F_c for the (*h*1*l*) reflections are given in Table IV.

Table IV. A Comparison between $|F_0|$ and F_c for the (*h*1*l*) reflections.

$$R=\frac{\Sigma|\,|F_0|-|F_c|\,|}{\Sigma|F_0|}=0.137$$

The coefficient of the temperature factor, *B*, for Ni^{2+} ion, was differently assumed for *F*(*h*0*l*)'s and *F*(0*kl*)'s, which gave the highest reliability factor. A more precise experiment must be done, however, to examine whether this result is related or not to the fact that the four water molecules coordinated to Ni^{2+} ion are not strictly arranged in a square, but in a rectangle with two side lengths, 3.00 Å and 2.94 Å.

The interatomic distances are compared between $CoCl_2$, $CoCl_2\cdot 2H_2O$, $CoCl_2\cdot 6H_2O$ and $NiCl_2\cdot 6H_2O$ as follows:

	$CoCl_2$[9]	$CoCl_2 \cdot 2H_2O$[10]	$CoCl_2 \cdot 6H_2O$	$NiCl_2 \cdot 6H_2O$
Co(or Ni)–Cl	2.51	2.53, 2.54	2.43	2.38
Co(or Ni)–O		1.93	2.12	2.10
Cl–O		3.18, 3.19	3.22	3.17

The author wishes to express his sincere thanks to Professor S. Ogawa of the Research Institute for Iron, Steel and Other Metals, Tohoku Univ. for his continued encouragement throughout the present work. His hearty thanks are also due to Professor T. Sugawara of the Institute for Solid State Physics, Tokyo Univ. and Dr. T. Haseda, Mr. T. Ukei and Mr. T. Sato of the Research Institute for Iron, Steel and Other Metals, Tohoku Univ. for their valuable discussions and the preparation of the good single crystals. He is also indebted to Dr. Y. Takeuchi and the members of Professor R. Sadanaga's Laboratory, Tokyo Univ. for their aids in calculations using PC-1 Parametron Computer.

The Dynamic Bulk and Shear Viscosity of High Polymers, 1.

By Ryusuke KONO

Department of Applied Physics, Defence Academy,

(Received March 6, 1961)

The result of the transverse and longitudinal wave measurement on two groups of high polymers were presented as a function of temperature at frequency of 2.5 Mc. One group contains those polymers with no or slight steric hindrances, i. e. polyvinylchloride, vulcanized rubber and polytrifluoromonochloroethylene. The other includes the materials with strong steric hindrances i. e. polyethyl methacrylate, poly-n-butyl methacrylate and poly-i-butyl methacrylate.

The relaxation of shear deformation can be explained by the widely distributed relaxation times irrespective of the coupling between the molecules and the steric hindrance of side chain groups on the main chain. On the other hand, the relaxation of volume deformation depends on the intermolecular force and the steric hindrance. In poly-i-butyl methacrylate, the relaxation associated with volume deformation may be explained by the single relaxation theory.

§ 1. Introduction

In recent years an energy-dissipating process associated with volume deformation for high polymers has been studied by several workers. The information on this subject is rather contradictory for the primary dispersion region of high polymers. Marvin et al[1]. have found that the imaginary part of bulk modulus is of comparable order of magnitude with that of shear modulus, whereas Nolle and Sieck[2], Cunningham and Ivey[3] have claimed that the imaginary part of bulk modulus is much smaller than that of shear modulus. Recently Wada et al[4]. have arrived at a reliable conclusion that the imaginary part of bulk modulus in styrene-butadiene rabber was of the same order of magnitude as that of shear modulus, so that the prediction by Cunningham and Ivey might not be true in GR-S which is a sort of styrene-butadiene rubber.

The activation energies associated with volume and shear deformation have been found to be almost the same in polyisobutyrene. The curve of the imaginary part of bulk modulus against frequency or temperature is sharper than that of shear modulus in polyisobutyrene and butyl rubber. This means that distribution of the relaxation time associated with volume deformation is narrower than that with shear deformation. In case of polystyrene, on the other hand, it was reported in the previous paper[5] that the activation energy associated with volume deformation was somewhat larger than that associated with shear deformation, so that the molecular mechanism involved in the two types of deformation may be different. In polyisobutyrene there is, from stereochemical reasons, little steric hindrance of side chain groups on the main chain, while in polystyrene and polymethyl methacrylate there should be some steric hindrance of side chain groups. One might then expect some effect of the side chain on the volume and the shear deformation mechanisms.

It is the purpose of this work to present the results of the transverse and longitudinal wave measurements on high polymers as functions of temperature.

As usual, the propagation of longitudinal and transverse waves in a viscoelastic medium is described, if steady-state sinusoidal time dependence of stress and strain is achieved, by emloying the complex bulk modulus $K^* = K_1 + iK_2 = K_1 + i\omega\zeta$ and the complex shear modulus $G^* = G_1 + iG_2 = G_1 + i\omega\eta$, where ζ is the dynamic bulk viscosity, η the dynamic shear viscosity and ω the radian frequency. If the longitudinal-wave modulus is written as $M^* = M_1 + iM_2 = K^* + 4G^*/3$, the relations among the velocity, the attenuation and the modulus at a given radian frequency ω can be described as follows.

$$G_1 = \frac{\rho v_t^2 (1 - (\alpha_t^2 v_t^2/\omega^2))}{(1 + (\alpha_t^2 v_t^2/\omega^2))^2} \qquad (1)$$

$$G_2 = \frac{\rho v_t^2 (2\alpha_t v_t/\omega)}{(1 + (\alpha_t^2 v_t^2/\omega^2))^2} \qquad (2)$$

$$M_1 = K_1 + 4G_1/3 = \frac{\rho v_l^2 (1 - (\alpha_l^2 v_l^2/\omega^2))}{(1 + (\alpha_l^2 v_l^2/\omega^2))^2} \qquad (3)$$

$$M_2 = K_2 + 4G_2/3 = \frac{\rho v_l^2 (2\alpha_l v_l/\omega)}{(1 + (\alpha_l^2 v_l^2/\omega^2))^2} \qquad (4)$$

where v_l represents the velocity of longitudinal waves, v_t the velocity of transverse, α_l the attenuation of longitudinal waves, α_t the attenuation of transverses waves, and ρ the density. The values of G_1, G_2, K_1 and K_2 are calculable using the measurable values of ρ, v_l, v_t, α_l and α_t.

There is, however, a basic experimental difficulty in obtaining the data of K_2. The value of K_2 is derived from a comparison of the velocity and attenuation of shear waves and longitudinal waves. Since the attenuation of shear waves in polymers is generally very large, the observed values of velocity and attenuation are likely to include appreciable errors. When the value of G_2 is of the comparable size with M_2, probable error in the calculated values of K_2 for vulcanized rubber presented in this work amounts to 40 percent, K_2 being obtained as a combined result of shear and longitudinal wave measurements. When the values of G_2 is much smaller than M_2, as in the case of polystyrene and polymethyl methacrylate, probable error in K_2 is less than 10 percent. In this case the accuracy in K_2 and G_2 is sufficient to permit a more detailed evaluation as to the relations between the shear and volume deformation mechanisms.

The experimental apparatus here employed for the longitudinal and transverse wave measurement is the same as that reported in the previous paper[5]. Silicone oil and ethyl alcohol were used as transmission medium above and below the room temperature, respectively. The rate of heating was kept at about 15 deg/hr.

§ 2. Samples

Experiments were made on vulcanized rubber with 5 percent sulphur, polyvinylchloride (PVC), polytrifluoromonochloroethylene (Kel-F), polyethyl methacrylate (PEMA), poly-n-butyl methacrylate (PnBMA), poly-i-butyl methacrylate (PiBMA). The sample thickness of vulcanized rubber ranged from 0.03 to 0.5 cm. The composition of vulcanized rubber was 100 gr. Hevea smoked sheet and 5 gr. sulphur. The samples were cured for 120 minutes at 150°C±1°C. PEMA, PnBMA and PiBMA were prepared by block polymerization from carefully purified monomers. Original stocks were plates of 0.5 cm in thickness. The PVC and the Kel-F were supplied by Nagahama Plastic Company and Du Pond Chemical Company, respectively. Original stocks of each samples except vulcanized rubbers were annealed at 100°C for one hour and cut out from a common plate in order to reduce variation between samples. These samples were 0.05 to 0.5 cm in thickness.

§ 3. Results

In Figs. 1～6, K_1, K_2, G_1, and G_2 are plotted against temperature for vulcanized rubber, Kel-F, PVC, PEMA, PnBMA and PiBMA, respectively, calculated from the smoothed experimental results according to the relations (1), (2), (3) and (4). It was impossible to make any measurements for the shear wave in the region shown by the dotted line because of the high attenuation. The direct determination of the values of K_1 and K_2 in dotted line was impossible, but they can be determined since the longitudinal waves were measured throughout the temperature range covered, and since the values of G_1 and G_2 were very small in comparison with that of M_1 and M_2. In these figures it is obviously seen from the experimental results that an energy-dissipating process associated with volume deformation is found in all these polymers. The curves of K_2 and G_2 versus temperature all exhibit peaks in the temperature region studied. For vulcanized rubber, PVC and Kel-F the temperature at the peak of K_2 is almost the same as that of G_2, while for

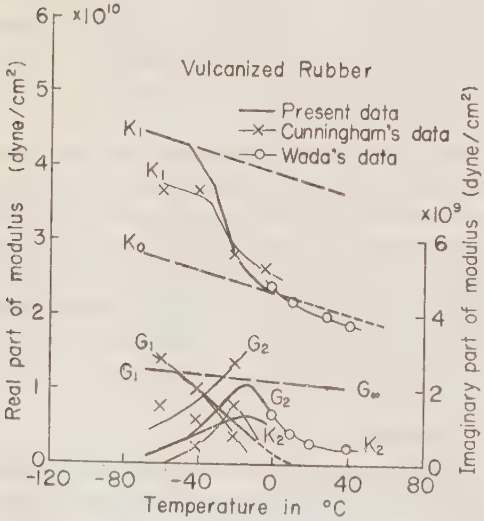

Fig. 1. Real and imaginary part of the shear and bulk modulus versus temperature for vulcanized rubber.

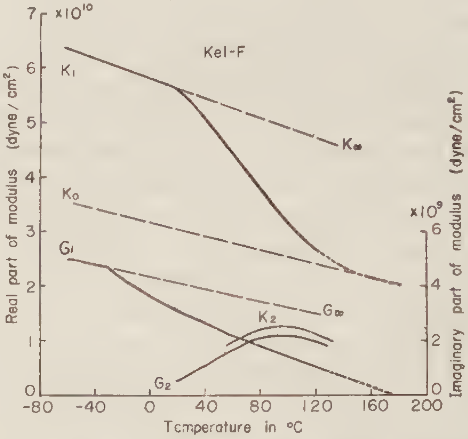

Fig. 2. Real and imaginary part of the shear and bulk modulus versus temperature for polytrifluoromonochloroethylene.

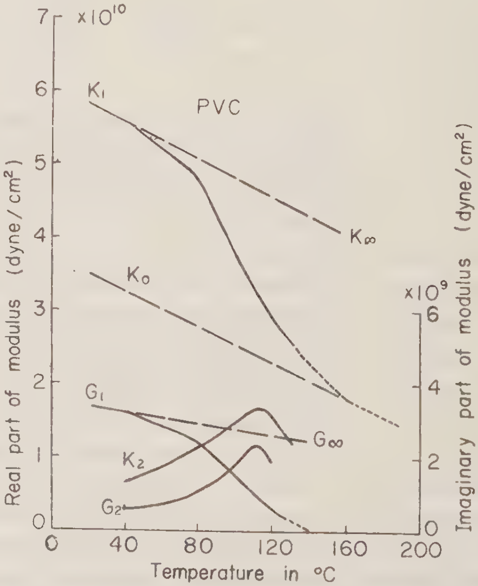

Fig. 3. Real and imaginary part of the shear and bulk modulus versus temperature for polyvinylchloride.

PEMA, PnBMA and PiBMA, the former is somewhat higher than the latter as shown in Fig. 4, 5 and 6.

The results of vulcanized rubber are shown in Fig. 1 together with Cunningham's[3] and Wada's[4] data. Above 0°C, the values of K_1 in the present work and Wada's work are in statisfactory agreement, with each other, whereas our K_2 is somewhat smaller than Wada's value. The values of G_2 of the present work is smaller than Cunningham's data and is rather comparable with their K_2. It may be safely said that the prediction of $K_2 \ll G_2$ might not be the cese, as already mentioned by Wada for GR-S.

It is obviously found from these experimental results that the temperature dependence of the molecular mechanism associated with volume deformation in vulcanized rubbers, PVC and Kel-F is very similar to that with the shear deformation, as is the case with styrene-butadiene rubber,[4] butyl rubber[3] and polyisobutyrene.[1]

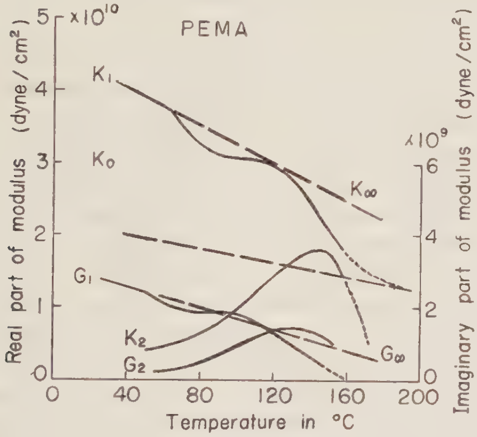

Fig. 4. Real and imaginary part of the shear and bulk modulus versus temperature for polyethyl methacrylate.

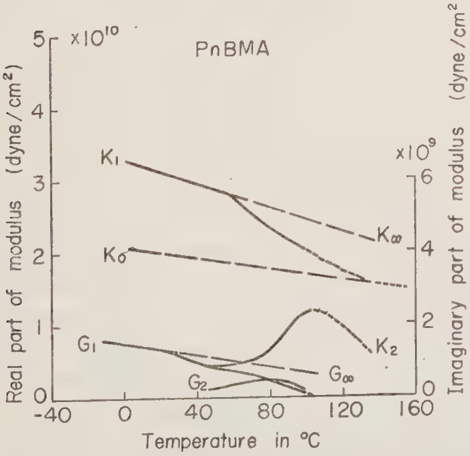

Fig. 5. Real and imaginary part of the shear and bulk moduls versus temperature for poly-n-butyl methacrylate.

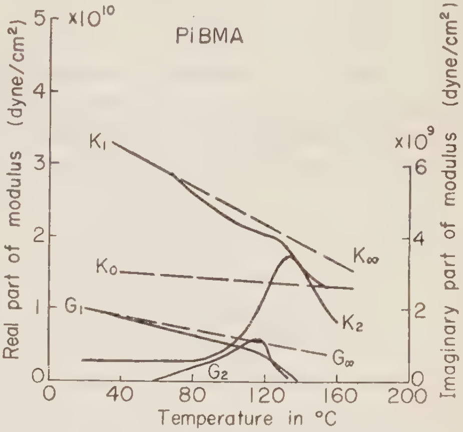

Fig. 6. Real and imaginary part of the shear and bulk modulus versus temperature for poly-i butyl methacrylate.

From the viewpoint of the chemical structure of these polymers, a coupling between the dipoles, crystallization or vulcanization contributes significantly to the cohesion, for substances where no or slight steric hindrance exists. As reported in the previous paper for polystyrene, the temperature at the maximum value of K_2 is higher than that of G_2 and the activation energy associated with volume deformation is larger than that of shear deformation. The molecular mechanisms involved in the two types of deformation are different. In these polymers they are subjected to steric hindrance by side chain groups on the main chain. It is expected that the difference between the volume and the shear deformation mechainisms might be related to steric hindrance, and so the methacrylate series were investigated.

Density, $T(K_{2m})$ and $T(G_{2m})$ versus numbers of side chain C-atoms in methacrylate series are shown in Fig. 7, where $T(K_{2m})$ and $T(G_{2m})$ represent the temperatures at the maximum value of K_2 and G_2, respectively. The dashed portions of the curves indicate the data for the case of isobutyl group. Density decreases with increasing number of side chain C-atoms. The values of K_1 and G_1, $T(K_{2m})$ and $T(G_{2m})$ decrease with increasing length of side chain except PiBMA. One get $T(K_{2m}) \fallingdotseq T(G_{2m})$ in Fig. 7, extraporating to zero side chain C-atom, where no or slight steric hindrance exists. $T(K_{2m})$ is less dependent on length of side chain than $T(G_{2m})$. The difference between $T(K_{2m})$ and $T(G_{2m})$ increases with increasing length of the side chain. Thus it is expected that the intramolecular degrees of freedom associated with volume deformation are more decreased by length of the side chain than those associated with shear deformation.

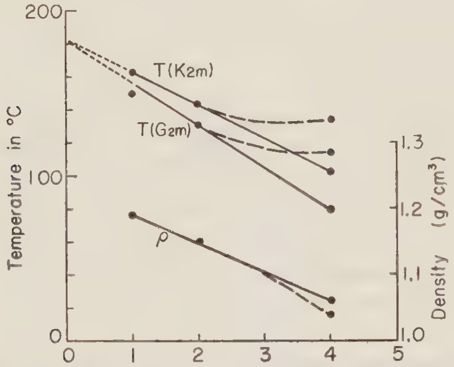

Fig. 7. Density, $T(K_{2m})$ and $T(G_{2m})$ versus numbers of side chain C- atoms for methacrylate series.

§ 4. Discussion

Eyring[6] has proposed a hole theory of liquids which has been very successful in explaining experimental data and has had great influence on theoretical considerations of the viscosity. The problem of shear viscosity is fundamentally the same for long-chain polymers as for simple liquids unless the cooperative movements between the molecules exist. Long chain molecules are flexible and can take up many different shapes and each segments in the long chain molecules have individual relaxation times, so that relaxation times for shear viscosity should be widely distributed. When a shearing stress is put on such a molecule, segments of the molecule connected by chemical-bonds are forced to move cooperatively. Thus they are transformed from one configuration to another configuration. A model in such a case is schematically shown in Fig. 8a, where ● represents a segment and ○ a hole. Through a number of successive segmental jumps the resultant movement of the molecule as a whole is accomplished. These segmental jumps caused by the application of a shearing stress produce a shear deformation. On the other hand when an external pressure is applied to these molecules as shown in Fig. 8b, only several segments of the molecule arround the hole will be locally displaced due to rearrangement of the segments. Hence, in the case of bulk viscosity, the difference between long chain polymers and simple liquids is expected to be much less than in the case of shear viscosity, as pointed out by Hirai and Eyring.[7] Therefore in the case of bulk viscosity, K_2 in dependence on frequency or temperature is expected to be explained by a single relaxation theory.

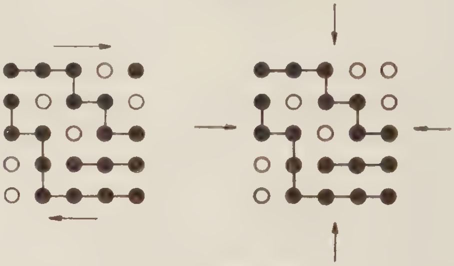

Fig. 8. A model for shear deformation (a) and volume deformation (b) in long-chain polymer.

When a distribution of relaxation times exists for the shear and bulk relaxation processes, the expressions for G_1, G_2, K_1 and K_2 are given as follows (cf. Litovitz[8]):

$$\frac{G_1}{G_\infty}=\int_0^\infty \frac{\omega^2\tau_s^2 g(\tau_s)d\tau_s}{1+\omega^2\tau_s^2}\equiv I(G_1) \qquad (5)$$

$$\frac{G_2}{G_\infty}=\int_0^\infty \frac{\omega\tau_s g(\tau_s)d\tau_s}{1+\omega^2\tau_s^2}\equiv I(G_2) \qquad (6)$$

$$\frac{K_1-K_0}{K_\infty-K_0}=\int_0^\infty \frac{\omega^2\tau_v^2 k(\tau_v)d\tau_v}{1+\omega^2\tau_v^2}\equiv I(K_1) \qquad (7)$$

$$\frac{K_2}{K_\infty-K_0}=\int_0^\infty \frac{\omega\tau_v k(\tau_v)d\tau_v}{1+\omega^2\tau_v^2}\equiv I(K_2) \qquad (8)$$

Here G_∞ is the shear modulus in the high frequency or in the glassy state, $G_\infty g(\tau_s)d\tau_s$ the contribution to the shear modulus by those molecules which have relaxation times in a range $d\tau_s$ near τ_s, K_∞ the bulk modulus in the high frequency or in the glassy state, K_0 static bulk modulus or bulk modulus in flow state, $(K_\infty-K_0)k(\tau_v)d\tau_v$ the contribution to the high frequency bulk modulus of those molecules having individual relaxation time in a range $d\tau_v$ near τ_v. $g(\tau_s)$ and $k(\tau_v)$ are the distribution functions of shear and volume deformation, respectively.

If one assumes a Gaussian distribution, one can show that for $\omega\tau'_s=\omega\tau'_v=1$,[9] i. e., at the maximum value of G_2 and K_2

$$I(G_1)=I(K_1)=\frac{1}{2} \qquad (9)$$

$$I(G_2)<\frac{1}{2},\ I(K_2)<\frac{1}{2} \qquad (10)$$

where τ_s' and τ_v' determine the position of the maximum of the distribution and represent the most probable relaxation times. The narrower the distribution of relaxation times, the larger becomes the maximum value of $I(G_2)$ and $I(K_2)$, approaching to the maximum value 1/2 of the single relaxation process.

The values of $I(G_1)$, $I(G_2)$, $I(K_1)$ and $I(K_2)$ in PVC, vulcanized rubber and Kel-F are plotted against temperatures in Fig. 9. In these polymers, it is to be seen that $T(K_{2m})\doteqdot T(G_{2m})$ and the maximum value of $I(K_2)$ and $I(G_2)$ are 0.15. The value of $I(K_1)$ and $I(G_1)$, $I(K_2)$ and $I(G_2)$ are almost the same throughout the temperature region studied. Thus it can be expected in the case of PVC that volume deformation mechanism becomes closely related to shear deformation mechanism. These circumstances may be explained as follows. When external pressure is applied as shown in Fig. 8b, the process of the rearrangement of molecules consists of combined elemental processes, each elementary process being very similar to that in shear viscosity. The combined process consists of movements of several segments arround a hole. The displacement of one segment to the hole has a great influence upon the motion of the neighbouring segments and the cooperative movement may take place due to a strong coupling of the molecules in PVC.

As shown in Fig. 9, the value of $T(K_{2m})$ is almost the same as that of $T(G_{2m})$ in Kel-F and vulcanized rubber. The relation (9) nearly holds true at the temperature of $T(K_{2m})$. This suggests that the activation energy in shear deformation is almost the same as that in volume deformation and $g(\tau_s)$ and $k(\tau_v)$ might be Gaussian distribution functions. On the other hand, temperature dependence of $I(K_2)$ is different from that of $I(G_2)$. The former is dependent more strongly on temperature than the latter. So relaxation times associated with volume deformotion may probably be distributed over narrower region than that

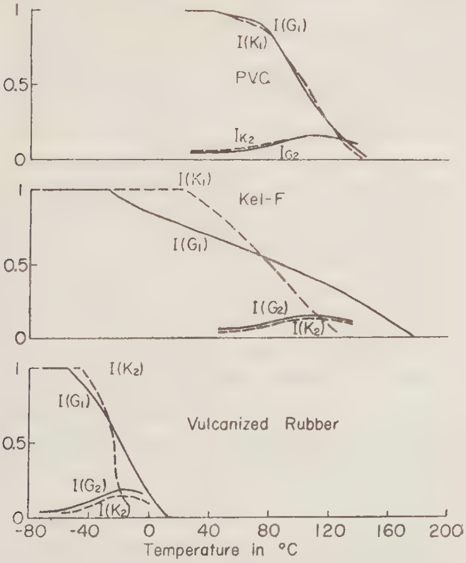

Fig. 9. The relaxational part of the bulk and the shear modulus versus temperature for polyvinylchloride, polytrifluoromonochloroethylene and vulcanized rubber

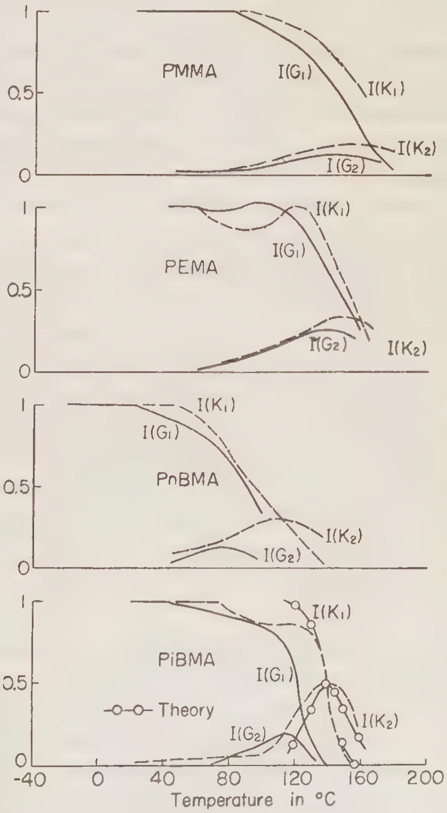

Fig. 10. The relaxational part of the bulk and the shear modulus versus temperature for methacrylate series

with shear deformation. Moreover the lower values of $T(K_{2m})$ and $T(G_{2m})$ in Kel-F and vulcanized rubber than in PVC, may be ascribed to the weaker coupling of the molecules in vulcanized rubber and Kel-F than in PVC. The weaker the coupling of the molecules, the more the volume deformation mechanism may be different from the shear deformation mechanism. This situation is much remarkable in the cases of polystyrene and methacrylate series where strong steric hindrances exist.

The value of $I(G_1)$, $I(G_2)$, $I(K_1)$ and $I(K_2)$ in methacrylate series are plotted against temperatures in Fig. 10. Although the maximum values of $I(G_2)$ in methacrylate series are almost the same, the maximum values of $I(K_2)$ increase towards the maximum value of 1/2 with increasing number of side chain C-atoms. The curve of $I(K_2)$ versus temperature in PiBMA approaches to the shape predicted by the single relaxation theory using the experimental value of activation energy 30 Kcal/mol.[10] This result probably means that no or slightly cooperative motion between the segments takes place in the case of volume deformation. Thus only several segments of the molecule arround a hole are displaced when external pressure is applied to those molecules of PiBMA as shown in Fig. 8b.

In these polymers studied, the relaxation of shear deformation is explained by the widely distributed relaxation times irrespective of the coupling of the molecules and the steric hindrance of side chain groups. On the other hand relaxation of volume deformation depends on the intermolecular force and the steric hindrance of side chain groups. The volume deformation becomes more different from the shear deformation with increasing length of side chain groups in methacrylate series.

§ 5. Conclusion

From the foregoing consideration, it seems reasonable to conclude as follows

1) The value of K_2 is of comparable size with G_2 and an energy dissipating process associated with volume deformation is found in all the polymers studied. It may be safely side that the prediction of $K_2 \ll G_2$ by Cunningham is not valid for vulcanized rubber.

2) The difference between $T(K_{2m})$ and $T(G_{2m})$ increases with increasing length of the side chain methacrylate series. Thus it is expected that intramolecular freedom associated with volume deformation is more restricted by the existence of the side chain than that associated with shear deformation.

3) The volume deformation mechanism is different from the shear deformation mechanism. The difference between the two types of deformation may be explained by the hole theory. In the case of shear deformation, the resultant movement of a molecule due to a large number of successive segmental jums to a hole is important. On the other hand, in the case of volume deformation, several segments of the molecules arround a hole are displaced, so that the hole plays an important role. In PiBMA the curve of relaxational part of bulk modulus versus temperature approaches to the shape predicted by the single relaxation theory.

Acknowledgements

I wish to express my sincere gratitude to Dr. N. Hirai of Okayama University, not only for the discussion of the problem, but also for his criticism and encouragement. Thanks are also due to Professor K. Shimo and Professor A. Soeya of Defence Academy for some valuable suggestions. The aid of Mr. I. Aoe at the Institute of Dainihon Gum in obtaining the sample of vulcanized rubber is gratefully acknowledged. Mr. Y. Yatabe at Nihon Kogaku Plastic Co. furnished the sample of methacrylate series, for which I thank him.

Ionization Efficiency Curves for A^+, Kr^+, N_2^+, and CO^+ by Electron Impact

By Yozaburo Kaneko

Department of Physics, Faculty of Science, Tokyo Metropolitan University,
Setagaya, Tokyo

(Received April 10, 1961)

The shape of ionization efficiency curves (I. E. curves) obtained by essentially monoenergetic electron is studied by means of the threshold law. In the I. E. curves for N_2^+ and CO^+, some humps which are attributed to autoionization processes are found. These processes occur at 16.2 ± 0.1 eV for N_2^+ and at 15.6 ± 0.1 eV and 18.4 ± 0.1 eV for CO^+. Though the shape of I. E. curve for Kr^+ obtained in this work is similar to that of Fox et al and Frost et al, it is difficult to interpret this shape by autoionization process only. The I. E. curve for A^+ shows large tailing of 0.50 ± 0.05 eV which can not be explained by doublet of ground state of A^+. The ionization potentials determined for rare gases and some diatomic molecules agree well with spectroscopic values and the previous electron impact data.

§1. Introduction

In ionization process by electron impact, the curve representing the variation of ion current as function of energy of ionizing electron is called "Ionization Efficiency curve (I. E. curve)"[1]. A number of studies on the shape of the I. E. curve near threshold have been made recently. Theoretical investigations of the threshold law of I. E. curve were made by Wigner[2], Wannier[3], Geltman[4], and Morrison[5].

In an experimental investigation of the I. E. curve, it is very powerful to use monoenergetic electron beam. Fox, Hickam, Kjeldass, and Grove[6,7] developed an experimental technique, so-called R. P. D. method, in which ionization is made by essentially monoenergetic electron. From the experiments on I. E. curves of rare gases, Fox deduced the following rules; the probability of single ionization near the threshold is proportional to the excess electron energy, and the probabilities for various ionization processes can be superposed independently. The R. P. D. method has been used by several investigators and brought many successful results in the study of fine structure of I. E. curves.

On the other hand, Morrison[8] proposed a method to measure the first differential of I. E. curve directly. It is thought that the method has an advantage to separate different processes superposed, because a differentiation makes a break in I. E. curve prominent. By use of this method, autoionization process in the ionization of N_2 was detected by Dorman, Morrison and Nicholson[9]. This process was not observed by Fox et al[10], and Frost and McDowell[11] by the use of R. P. D. method. In fact, as most I. E. curves consist of more than two processes, they must be analyzed carefully.

In this report, the I. E. curves for A^+, Kr^+, N_2^+ and CO^+ obtained by R. P. D. method are analyzed by means of threshold law, and the results obtained are compared with that of the other workers.

§2. R. P. D. Method

The principle of R. P. D. method which was developed by Fox et al is described briefly in this section. By using R. P. D. method though a monoenergetic electron beam is not produced actually, substantially the same effect is obtained in ionization as by a monoenergetic electron beam.

There is an electrode in the path of electron beam. By applying a retarding potential to this electrode, a part of electrons which has smaller kinetic energy than this potential is prevented from passing through the electrode. Ionization is made by the other part of electrons which has passed through the electrode, being accelerated by the potential Va between tihs electrode and the ionization chamber.

Now, by varying the retarding potential by a small amount of ΔV_R, "difference ion current ΔI" is obtained in correspondence to this ΔV_R. The difference ion current ΔI should be essentially the same to the ion current which would be obtained by the electron beam having an energy of Va and an energy width of ΔV_R. Thus, the method is called "Retarding Potential Difference Method (R. P. D. method)".

Strictly speaking, Fox's method is a combination of R. P. D. method and the pulsing method which will be described in section 3. However, the term "R. P. D. method" is often used in the same meaning as Fox's method.

§ 3. Apparatus and Experimental Procedure

The mass spectrometer used in this experiment is of a 90° sector type, and the ion orbit radius is 11.5 cm. R. P. D. method is used for ion source of this mass spectrometer, so that ionization may essentially be effected by monoenergetic electron. Electrodes of the ion source, however, are somewhat different from Fox's ion source. Details of this apparatus were described elsewhere[12].

A schematic diagram of the ion source and the control circuit is shown in Fig. 1. There are three electrodes between filament and the ionization chamber. The slits in electrodes 1, 2 and 3 are 1 mm wide and 3 mm long, and the entrance slit of the ionization chamber 4 is 0.5 mm wide, 3 mm long, and 1 mm deep. In order to avoid immersion field, all of the slits are covered with tungsten nets which are 140 mesh/inch (56 mesh/cm). The electrodes are gold plated to prevent the contact potential. Retarding potential is applied to the electrode 3, and electron accelerating voltage is applied between this electrode and the ionization chamber. The value of ΔV_R, namely, energy width of ionizing electron, can be selected as any value, and is usually decided as 0.1 eV.

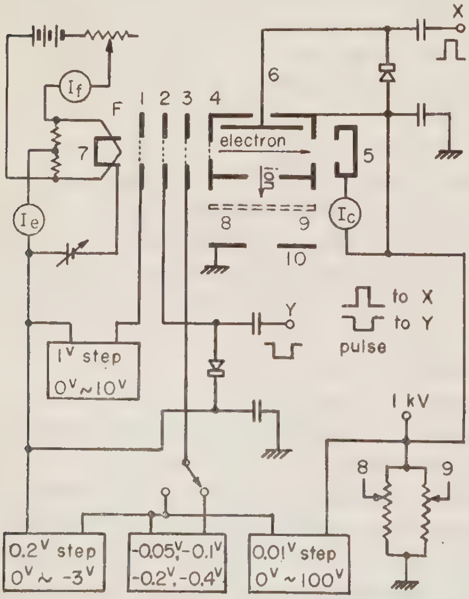

Fig. 1. A schematic diagram of the ion source and the control circuit.

In the previous study[12], characteristics of this ion surce were studied and an adequate operating condition was found. For example, when potentials of the electrodes 1, 2 and 3 measured from the filament are 2 V, 0 V and -0.8 V respectively, and ΔV_R is selected as 0.1 eV, difference ion current becomes 15% of total ion current. This efficiency is three times as good as that of the other workers[7], and increases signal to noise ratio relatively. There is an ion repeller electrode 6 in the ionization chamber. Generally, ion repelling voltage disturbs the energy distribution of electrons greatly. Two synchronized square wave pulses as shown in Fig. 1 are applied to the electrode 2 and the ion repeller electrode in order to make ionization in field free space. To determine the ionization potential, energy scale must be corrected, but the correction in this experiment is always less than 0.2 eV for fresh electrodes.

The combination of secondary electron multiplier and Barth's circuit electrometer with UX-54, or sometimes the electrometer solely, is used for ion current detector. The multiplier is an Inghram type and consists of fifteen dinodes of Ag-Mg (Mg 1.7%). The total gain is 5×10^5 for total voltage of 4.5 KV applied, and the noise level at no-signal is found to be 2×10^{-17} A. The galvanometer connected to the output of the electrometer has a zero point compensation circuit, so that difference ion current may be measured in full scale.

It is important to keep the "effective" number of ionizing electron constant when electron accelerating voltage is varied. As ions detected at the collector of mass spectrometer seems to be made at a very small part in the ionization chamber, electrons only which pass through this part could be "effective". It is very difficult to examine experimentally that the "effective" number of electron is kept constant. For example, to keep electron collector current constant not always means to keep "effective" number of electron constant. However, in the previous study, it was found that the "effective" number of electron seems to be almost constant in the energy range of 10 V between the accelerating voltage of 10 V and 100 V, though it is not accurate in larger range. For more precise study, it is necessary to measure simultaneously the I. E. curves of the sample gas and referring gas of which I. E. curve lies in the same energy range. In this experiment, the measurements were made for A and N_2, CO and Kr simultaneously. Pressure of the gases was controled as to obtain almost the same slope for each I. E. curve. All of the curves were measured more than ten runs. Though the ion source was dismantled to refresh the electrodes several times through the experiment, the typical shapes of I. E. curves which are described in section 4 did not change. The sample gases used in this experiment are purest in commercial grade, and are not refined specially.

§ 4. Experimental Results and Discussion

A^+

As the difference of ionization potential between A and N_2 is only about 0.2 eV, the shapes of I. E. curves particular to these two gases can be obtained without instrumental effects, by introducing the two gases into the mass spectrometer simultaneously. The curve is shown in Fig. 2.

Fox, Hickam, Kjeldaas and Grove⁶⁾ applied for the first time the R. P. D. method to A^+ and found that it is linear in the range of about 1.5 eV above threshould. Cloutier and Schiff¹³⁾, measuring I. E. curve for A^+ by means of the modified R. P. D. method, reported that it is quite linear in the range of about 2.5 eV above threshold and that the effect of doublet of the ground state of A^+ on the I. E. curve is too small to be detected. In this experiment, however, the I. E. curve for A^+ shows a large tailing below 17.2 eV though it is linear at higher energy. This is quite different from the results of Fox et al and Cloutier et al. In this experiment, the difference between initial onset of the curve and the crossing point of energy axis and extension of linear part is measured to be 0.50±0.05 eV*, and the difference between the initial onset and the position where the curve deviates from linear part is 1.6±0.1 eV*.

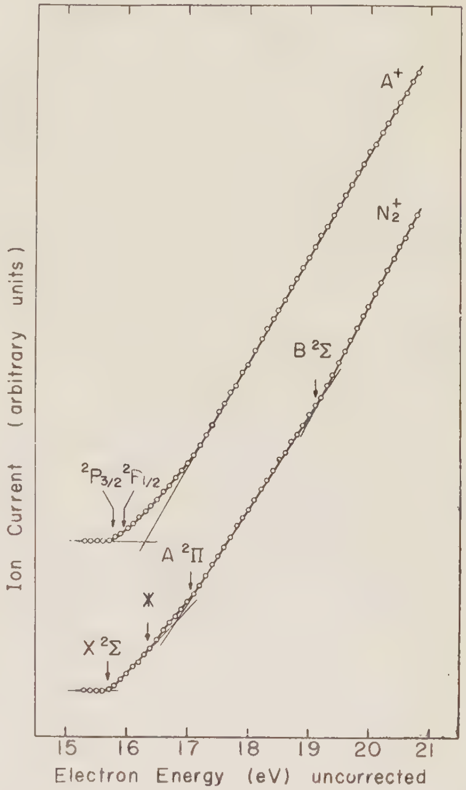

Fig. 2. I. E. curves for A^+ and N_2^+. Arrows indicate the positions where successive ionization processes occur.

The possible causes of this tailing of I. E. curve for A^+ could be instrumental and/or essential. There could be the following three factors in the instrumental effect on the I. E. curve:

1. thermal energy distribution of electron emitted from hot filament,
2. immersion field of ion accelerating voltage penetrating into ionization chamber, and
3. variation in number of effective ionizing electron.

The first factor of thermal energy distribution would not be larger than 0.05 eV, provided that the experiment is made by means of the R. P. D. method using $\Delta V_R=0.1$ eV. There is little possibility that the second factor, though emphasized by Cloutier[13], has an effect on this curve, because in addition to that the pulsing method is used in ion repeller voltage to make ionization in field free space, the ion focusing half plates 8 and 9 in Fig. 1 are at the same potential as the ionization chamber at the expense of focusing efficiency. Furthermore, both the facts that initial onset of the curve almost constantly appears at 15.7 eV nearly similar to the ionization potential for A^+ without correction of energy scale, and that a distinctly fine structure is found at N_2^+ curve, show electron energy spread is negligibly small. There is no way to examine the third factor experimentally. The N_2^+ curve measured simultaneously, however, does not show a tail as seen in the A^+ curve, and resembles those obtained by the other workers[10]. Granting that this I. E. curve for A^+ is caused by some experimental factor, if the curve was tried to be corrected linear by using a suitable normalizing function, the N_2^+ curve then would be a quite strange one. From these considerations, the shape of I. E. curve for A^+ seems not to be instrumental but substantial.

---

* These values are corrected by effect of 0.1 eV of electron energy spread.

Though ground state of A^+ is doublet of $^2P_{3/2}$ and $^2P_{1/2}$, this cannot be a cause of the tailing, because separation of this doublet is only 0.18 eV. Any excited state is not known for more than 13 V above the ground state. No conclusion, therefore, can be deduced on the tailing of I. E. curve for A^+. It should be remarked, however, that Stevenson and Hipple[14] found that A^+ has a longer tail by 0.3 eV than Ne^+ in their measurement using electron of wide energy spread, and that Mariner and Bleakney[15] pointed out that this difference cannot be explained by doublet of ground state of A^+.

N_2^+

Three distinct breaks are observed in the N_2^+ curve, and the curve between these breaks is nearly linear. These breaks are considered to correspond to ionization to $X\,^2\Sigma$, $A\,^2\Pi$ and $B\,^2\Sigma$ state of N_2^+, and their ionization potentials, as shown in Table I, agree well with the spectroscopic values and the electron impact values obtained by Frost and McDowell[11]. Though Frost reported a large break corresponding to $C\,^2\Sigma$ at 23.53 eV, the I. E. curve for N_2^+ increases almost linearly up to 25 eV as well as A^+ and does not show such a large break in this experiment. Relative ionization probabilities to each state calculated from gradient of each linear part differ remarkably from the value of Frost and McDowell, as shown in Table II.

$I(C\,^2\Sigma)/I(X\,^2\Sigma)$	—	—	~36

a: calculated by the author from Fig. 3. of reference (11).

The points measured deviate above from the linear curve at about 16.5 eV. This part is demonstrated with expanded scale in Fig. 3**b**. The length of vertical lines indicates the amount of mean deviation of the points measured. The hump of the curve is thought to correspond to the autoionization process pointed out by Dorman et al[9]. Autoionization is the ionization caused by radiationless transition to an ionic state from an excited state of molecule which lies above ionic state, for example:

$$N_2+e \longrightarrow N_2^*+e, \quad N_2^* \longrightarrow N_2^+ +e\ .$$

Morrison[5,9] suggested that the threshold law for excitation process should be a step function or proportional to square root of excess energy. Provided that probability of single ionization is linear to excess electron energy, and each process is superposed independently, the I. E. curve theoretically predicted should be as shown in Fig. 3**a**. The first ionization begins at the point O, the autoionization begins at P, and the second ionization begins at R in the theoretical curve. The solid line iodicates a step function law and the dotted line, a square root law. The curve **a** and **b** in Fig. 3 are in a very good correspondence. The results of the experiment fit the square root law better than the step function law, but a positive conclusion cannot be drawn from this owing to scattering of measured points. Fig. 3**c** is I. E. curve for N_2^+ obtained by Clarke[16] using a mass spectrometer which has an electron energy selector in the ion source. Fig, 3**d** is integration by the author of Dorman's first differential I. E. curve for N_2^+[9]. They resemble much in shape. It is no wonder that Dorman's curve has a large tailing, in proportion to a large energy spread of electron. What should be surprising is that a fine structure can be detected by the method of Dorman et al. even using electron of so large energy spread. A structure corresponding to this process is not found in the I. E. curves by Fox et al.[10], Frost et al.[11] and Cloutier et al[14].

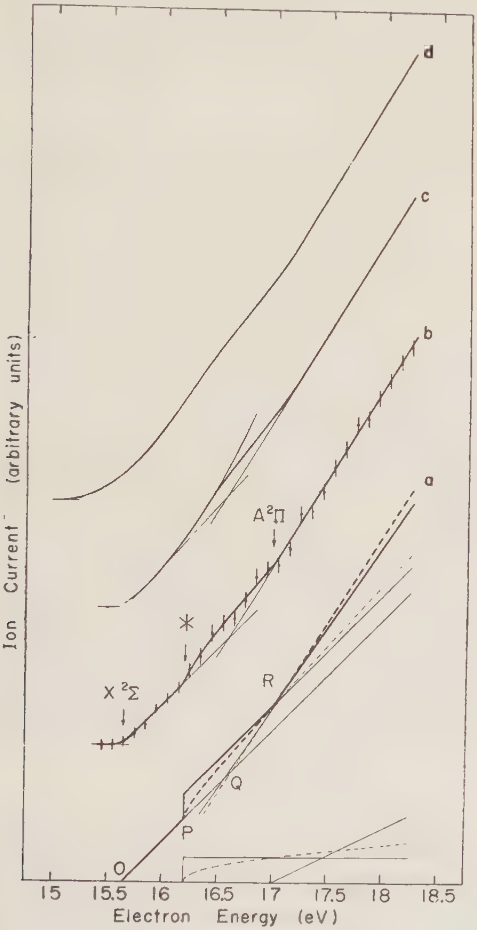

Fig. 3. Comparison between the theoritical and experimental I. E. curves for autoionization process in N_2^+. Curve **a** is theoretically predicted I. E. curve, the solid line indicates a step function law and the dotted line, a square root law. Curve **b** is experimental I. E. curve in the present work, and length of vertical lines indicate the amount of mean deviation of measured points. Curve **c** is experimental I. E. curve obtained by Clarke. Curve **d** is I. E. curve calculated from Dorman's first differential I. E. curve by integration.

As deduced from the above considerations, the second ionization potential should not be a crossing point, Q, of extensions of two linear parts but R in Fig. 3**a**. Each threshold value determined by referring to Fig. 3**a** is shown in Table 2. This seems to be more reasonable than Clarke's explanation that the shape of N_2^+ curve is due to excitation to vibrational states of N_2^+, and the second ionization potential is defined as a crossing point of the extensions of linear parts.

CO^+

CO^+ is similar to N_2^+ in electron configura-

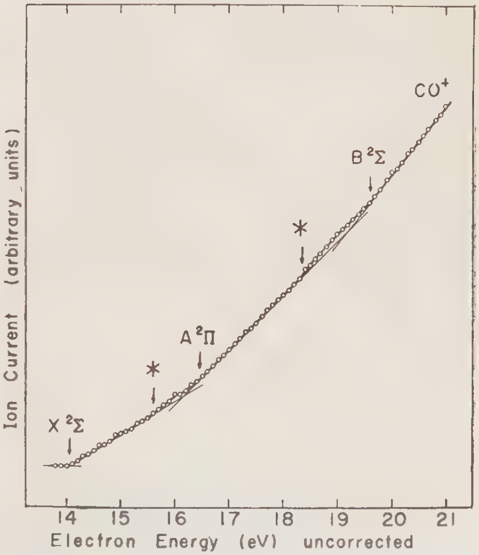

Fig. 4. I. E. curve for CO^+. Arrows indicate the positions where successive ionization processes occur.

tion. Fox, Hickam and Kjeldass[10] reported an autoionization process of CO at about 19 eV. The I. E. curve obtained is shown in Fig. 4. The I. E. curve for CO^+ may be divided into three linear parts as N_2^+. Deviation of the measured points from the linear curve can be observed also at about 16 eV in addition to about 19 eV. From the same analysis as used for N_2^+, it proved that autoionization processes occur at 15.5±0.1 eV and 18.5±0.1 eV. Each of the threshold values shown in Table III, agree satisfactorily with the spectroscopic value and Weissler's[18] value by photoionization.

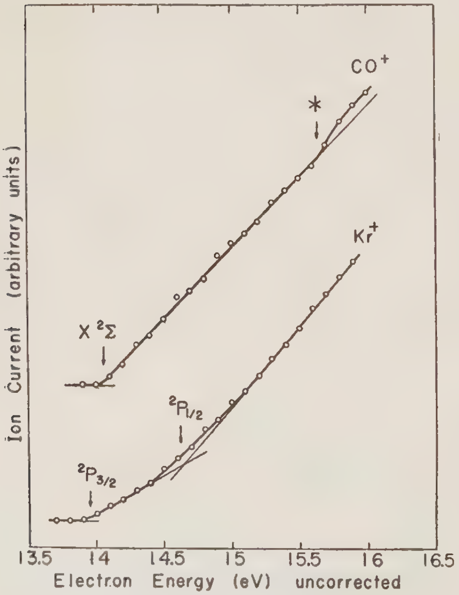

Fig. 5. I. E. curve for Kr^+. The curve for CO^+ is superposed for reference. Arrows indicate the positions where successive ionization processes occur.

Kr^+

The I. E. curve for Kr^+ is shown in Fig. 5, and the curve for CO^+ is superposed for reference. The ground state of Kr^+ is doublet of $^2P_{3/2}$ and $^2P_{1/2}$,and $^2P_{1/2}$ state lies 0.67 eV above $^2P_{3/2}$ state. The extensions of lower and upper linear part of Kr^+ curve cross at about 0.7 eV above the initial onset, so this crossing point seems to correspond to ionization to $^2P_{1/2}$ state. However, the I. E. curve for Kr^+ does not break but bends at about this crossing point. This shape of Kr^+ curve is the same as that of Fox et al[19]. and Frost et al[11].

Fox attributed this bending to autoionization. From the previous considerations, however, autoionization should produce such an I. E. curve as shown in Fig. 3**a**, and the second ionization potential most not be at Q but at R in Fig. 3**a**. Nevertheless, in this experiment the difference between the crossing point of extensions of two linear parts and the initial onset of the curve appears to be 0.7 eV, which almost corresponds to the enegy separation of doublet. So were the results of measurements by Fox et al. and Frost et al. The bending of I. E. curve for Kr^+, therefore, cannot be explained by autoionization process, unless it is assumed that excitation probability abruptly decreases with increase of electron energy. Though the autoionization process may be one of the possible causes, yet a consideration should be given on any other causes, such as the one that produced a bending in the I. E. curve for A^+.

§ 5. Conclusion

The R. P. D. method is powerful. In case of autoionization, however, deviation of the measured points from linear curve is certainly very small, so that I. E. curve should be analyzed carefully. It is not unreasonable that Dorman et al. remarked on a doubt on validity of the R. P. D. method. However, as proved by present experiment on N_2^+ and CO^+, it is not very difficult to detect autoionization process by a careful study of the I. E. curves obtained. In addition, because of a small electron energy spread in R. P. D. method, the critical energy values obtained have a high accuracy and are fully comparable with the spectroscopic value or data of photo ionization.

To explain the experiment on Kr^+, more knowledge on probability of the excitation process is required. The reason of the bending in I. E. curve for A^+ can not be explained. A^+ has been used frequently as a calibration ion of energy scale in the appearance potential study. However, it is proved by this experiment that initial onset method must be adopted when A^+ is used as calibration ion of energy scale and that a true value of appearance potential is obtained* in this way. Ionization potentials of rare gases and some diatomic molecules obtained in this experiment by means of R. P. D. method and the initial onset method using A^+ as calibration ion are shown in Table IV. These agree well with the spectroscopic values and the previous electron impact data.

Table IV. Ionization potentials of rare gases and diatomic molecules (eV).

Three-Level Maser Action in Gas
I. Theory of Multiple Quantum Transition and Doppler Effect in Three-Level Gas Maser

By Tatsuo YAJIMA

Department of Physics, Faculty of Science, University of Tokyo, Tokyo

(Received March 4, 1961)

The multiple quantum process in the off-resonant condition of the three-level gas maser is discussed. The intensity of the emission produced by this process is calculated by a perturbation theory and also by a more general treatment which is the application of Javan's theory to the off-resonant case. Some graphical representations of the signal line under off-resonant pumping are given for the purpose of comparison with experiment.

The Doppler effect in three-level maser action is analyzed from both semiclassical and quantum mechanical points of view under the presence of collision relaxation. It was shown that in a saturation process between two levels, Doppler effect behaves as to contribute to both line-width and relaxation time for the transition, and that under strong pumping, Doppler effect in pumping transition has a marked influence on both intensity and shape of the signal line through the effect of multiple quantum transition.

§ 1. Introduction

The three-level masers have been extensively studied on paramagnetic solid state materials. It is to be noted, however, that any other system can possibly be used as a three-level maser if there are three energy levels between which two appropriate transitions are allowed. The possibility and usefulness of the three-level gas maser as a spectrometer as well as an amplifier has already been discussed[1)-6)], and its applications to radio-frequency and microwave spectroscopy have been demonstrated experimentally in certain molecules[3),5)]. The three-level maser action in gas system involves various effects which cannot be treated by a simple theory, and the full accounts of these are of importance for further development of gas maser.

The first of these is the quantum mechanical behavior of the three-level maser. It brings out various interesting phenomena which cannot be predicted from the semi-classical theory dealing with only the population change as has been developed by Bloembergen[7)]. It provides a new type of maser action which produces net induced emission without the requirement of " negative temperature " of the system. The quantum mechanical theories of the three-level maser have been worked out by several authors[2),8)-12)] using a density matrix or its equivalent representation. However, very few experiments concerned with these effects have been carried out probably because of the experimental difficulties.

The three-level gas maser is quite favorable for the study of the quantum mechanical effect, because this effect can be realized more easily in the gas maser than in the solid state maser for the following reason. The quantum mechanical effect in the three-level maser arises from the phase coherent interaction between molecules and radiation fields which produces such phenomena as resonant modulation effect in the emission line and multiple quantum transition* like Raman process. All such effects increase with increasing pumping power. The general condition for the marked appearance of the quantum mechanical effect can then be stated as that the pumping transition must occur appreciably within a time of phase coherence or transverse relaxation of the system. This is expressed in the form as

---

* The word of double or multiple quantum transition is used sometimes for particular cases where two or more photons of the *same* frequencies are simultaneously absorbed or emitted. Here, the word is used for more general cases where frequencies of photons are *not equal*.

$$\frac{\mu\mathcal{E}}{\hbar} \gtrsim \frac{1}{T_2} \sim \Delta\nu \tag{1}$$

where $\mathcal{E}$ is the electric or magnetic field strength of the pumping radiation, μ the electric or magnetic dipole matrix element involved in the transition, T_2 the transverse relaxation time, and $\Delta\nu$ the line-width. In the gas system for which $T_1 \approx T_2$, where T_1 is the longitudinal relaxation time, Eq. (1) is nearly equivalent to the condition for saturation of pumping transition, and the quantum mechanical effect appears with the saturation. On the other hand, in the paramagnetic materials met in most solid state masers for which $T_1 \gg T_2$, the effect appears at the pumping power level of far beyond the value necessary for saturation. The interaction energy between the radiation field and the dipole moment, $\mu\mathcal{E}$, is much higher in the gas maser than in the solid state maser, because the former involves electric dipole transitions, while the latter involves magnetic dipole transitions. In the same radiation field, the interaction energy for 1 Debye, the order of molecular electric dipole moment, is larger by about 100 times than that for 1 Bohr magneton, the order of electron spin magnetic moment. The line-width of gas molecules can be reduced to 100 kc or below by lowering the gas pressure, while minimum attainable line-width of electron spin resonance is of the order of 1 Mc. These facts mean that in the gas maser the condition (1) can be attained using the pumping power of about 10^{-6} times as large as the power required in the solid state maser, if the circuit conditions are the same for both cases.

The resonant modulation effect in a three-level maser is important when the radiation is nearly resonant. This has been discussed by various authours.[2),9),10),12)] The multiple quantum transition involved in the three-level maser action[2),11)] appears in a clear form when the three-level maser is operated in the off-resonant conditions. The off-resonant behavior has been treated by Yatsiv[11)] for particular condition of frequencies and general relaxation processes which can conveniently be applied to the case of magnetic resonance.

It this paper we shall discuss the theory of the off-resonant three-level gas maser in the form which is convenient for comparison with the experiment to be described in II. Also the influence of Doppler effect on the behavior of the three-level maser will be discussed because of its basic importance and the close relation with the off-resonant behavior mentioned above.

§ 2. Perturbation Treatment of Double Quantum Transition

Consider a three-level system of a gas molecule as shown in Fig. 1. The two transitions (1↔3) and (2↔3) are assumed to be allowed and their frequencies are designated as ν_{p0} and ν_{s0}, respectively. If the ratio ν_{p0}/ν_{s0} has an appropriate value and a large radiation power at the frequency ν_{p0} is applied to saturate the transition (1↔3), then the net induced emission at the frequency ν_{s0} will occur as a result of population inversion between the levels 2 and 3. This is the usual three-level maser action in a semiclassical explanation.

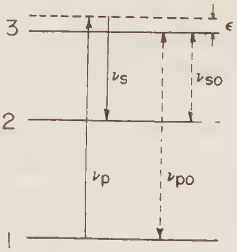

Fig. 1. Double quantum transition in a three-level system.

Quantum theory predicts, however, that even when the frequencies of the fields, ν_p and ν_s, are off-resonant beyond the line-width, the molecular transition can also occur accompanied by simultaneous absorption and emission of radiations, if the frequency condition

$$\nu_p - \nu_{p0} = \nu_s - \nu_{s0} = \mathcal{E} \tag{2}$$

is satisfied. This is the pure double quantum transition associated with the three-level maser. In this transition process, the molecule initially in the state 1 makes a transition to the state 2 with the simultaneous absorption of one photon of $h\nu_p$ and emission of one photon of $h\nu_s$, and the molecule initially

Table I.

State of total system	State of molecule	Number of photons, $h\nu_p$	Number of photons, $h\nu_s$	Total energy
Initial (I)	1	n_p	n_s	$W_I = W_0$
Intermediate (M)	3	n_p-1	n_s	$W_M = W_0 - h\varepsilon$
Final (F)	2	n_p-1	n_s+1	$W_F = W_0$

in the state 2 makes a transition to the state 1 by the reverse process. Then, net induced emission occurs at the frequency ν_s when the population of lower state 1 exceeds that of 2.

Let us calculate the intensity of this emission by a second order time-dependent perturbation theory using quantized field[13]. Although the same result can be derived from a more general equation given later, the perturbation treatment may be helpful in understanding the essential feature of the process. Similar kind of calculation will also be useful for the consideration of a more complicated case such as triple quantum transition.

consider a quantum mechanical system consisting of one molecule and two radiation fields of frequencies, ν_p and ν_s, which are assumed to satisfy Eq. (2). Two radiations are here called the pumping and the signal, respectively. Suppose the three states of the total system as described in Table I.

The perturbation Hamiltonian for electric dipole transition is written as

$$\begin{aligned} \mathscr{H} &= -\boldsymbol{\mu}\cdot(\boldsymbol{E}_s+\boldsymbol{E}_p)\,, \\ \boldsymbol{E}_s &= (q_s+q_s^*)\boldsymbol{u}_s\,, \\ \boldsymbol{E}_p &= (q_p+q_p^*)\boldsymbol{u}_p\,, \end{aligned} \tag{3}$$

where $\boldsymbol{E}_s$ and $\boldsymbol{E}_p$ are the electric fields, and $\boldsymbol{\mu}$ is the molecular electric dipole moment. The subscripts s and p indicate signal and pumping, respectively. Here q_s, q_s^*, q_p, q_p^* are the operators representing the amplitudes of the fields, whose non-zero matrix elements are $q_{n,n+1}=q^*_{n+1,n}=\sqrt{\hbar(n+1)/4\pi\nu}$. The vectors $\boldsymbol{u}_s$ and $\boldsymbol{u}_p$ represent space distribution of the fields. For simplicity of treatment they are assumed hereafter to be uniform and mutually parallel.

The probability that the system which exists in the state I at the time t_0 makes transition to the state F through the state M during a time $t-t_0$ is given by

$$p(t-t_0)=\left|\frac{(F|\mathscr{H}|M)(M|\mathscr{H}|I)}{W_M-W_0}\right|^2\frac{(t-t_0)^2}{\hbar^2}\,. \tag{4}$$

There are also other transition paths via other intermediate states, but these may be neglected because of their small transition probabilities relative to the one given above, when the frequency deviation ε is much smaller than transition frequencies of the molecule.

Using the relation $\langle \boldsymbol{E}^2\rangle = E^2/2 = \langle 2qq^*\rangle \boldsymbol{u}^2$, and considering the situation n_s, $n_p \gg 1$, Eq. (4) becomes

$$p(t-t_0)=\left(\frac{|\bar{\mu}_{31}|E_p}{2\hbar}\right)^2\left(\frac{|\bar{\mu}_{23}|E_s}{2\hbar}\right)^2\frac{(t-t_0)^2}{4\pi^2\varepsilon^2}\,, \tag{5}$$

where E_p and E_s are the peak electric fields, $\bar{\mu}_{23}$ and $\bar{\mu}_{31}$ the dipole matrix elements along the direction of fields for the transition $(2\leftrightarrow 3)$ and $(3\leftrightarrow 1)$, respectively. The reverse process where initial and final states are interchanged occurs with the same probability as far as the spontaneous emission can be neglected.

When the random collisions of molecules with the mean free time τ is assumed, the rate of net population change between states 1 and 2, whose equilibrium populations are n_1 and n_2, is given by

$$(n_2-n_1)\int_{-\infty}^{t}\frac{p(t-t_0)}{\tau^2}e^{-(t-t_0)/\tau}dt_0\,. \tag{6}$$

Then, the net absorption coefficient at the frequency ν_s becomes

$$\begin{aligned} \alpha_s &= \frac{2(n_2-n_1)h\nu_s w_s w_p}{P_s\tau\varphi^2}\,, \\ w_s &\equiv \left(\frac{|\bar{\mu}_{23}|E_s}{2h\Delta\nu}\right)^2, \quad w_p \equiv \left(\frac{|\bar{\mu}_{13}|E_p}{2h\Delta\nu}\right)^2 \\ \varphi &\equiv \frac{\varepsilon}{\Delta\nu}\,, \end{aligned} \tag{7}$$

where $\Delta\nu = 1/(2\pi\tau)$ is the half line-width and P_s is the incident radiation power at the frequency ν_s, and w_p is called a "pumping parameter" hereafter.

On the one hand, the absorption coefficient at the center of the transition (2↔3) without saturation and pumping radiation is given by

$$\alpha_{s0}=\frac{2(n_2-n_3)w_s h\nu_{s0}}{P_s\tau}\,. \qquad (8)$$

Taking the ratio of Eq. (7) and Eq. (8), one obtains

$$\frac{\alpha_s}{\alpha_{s0}}=-\left(\frac{n_1-n_2}{n_2-n_3}\right)\frac{w_p}{\varphi^2}\,\frac{\nu_s}{\nu_{s0}}\,. \qquad (9)$$

Considering the situation where $h\nu_s$, $h\nu_p \ll kT$ and $\nu_s \sim \nu_{s0}$, it becomes

$$\frac{\alpha_s}{\alpha_{s0}}=-\left(\frac{\nu_{p0}}{\nu_{s0}}-1\right)\frac{w_p}{\varphi^2}\,. \qquad (10)$$

Eq. (10) shows that α_s is always negative (representing the presence of emission) as long as $\nu_{p0}>\nu_{s0}$, and that $|\alpha_s|$ increases proportionally with the pumping power and rapidly decreases with the deviation of frequency from resonance.

The intensity of the emission, α_s, in an actual gas can be estimated easily from Eq. (10), since α_{s0} and $|\bar{\mu}_{13}|^2$ can be calculated at once by the usual method of microwave spectroscopy[14].

When w_p/φ^2 increases to a value of the order of 1, the saturation of double quantum transition occurs, and the approximation used here breaks.

§ 3. General Off-Resonant Behavior

In order to obtain the results for arbitrary strength and frequency of two radiation fields, the time-dependent schrödinger equation must be solved directly without using the perturbation theory. A general solution of this problem has been obtained by Javan[2)] for the gas system under strong collisions, and the resonant behavior was discussed. The off-resonant behavior of the three-level gas maser, which has not fully been discussed, is considered here together with the examination of the validity of perturbation treatment given in § 2.

Consider the three-level system as in Fig. 1, but the applied frequencies, ν_p and ν_s, are now assumed to be arbitrary. Then, the absorption coefficient α_s at the frequency ν_s for small signal power under the pumping radiation of the frequency ν_p and of arbitrary power level is given by the following formula according to the method of Javan,

$$\begin{aligned}\frac{\alpha_s}{\alpha_{s0}}=&\left\{(1+a)^2-(R-1)\frac{w_p}{\beta^2}\right\}\frac{1}{4\{1+(\beta-\delta)^2\}}+\left\{(1-a)^2-(R-1)\frac{w_p}{\beta^2}\right\}\frac{1}{4\{1+(\beta+\delta)^2\}}\\&-\left\{(1-a^2)+(R-1)\frac{w_p}{\beta^2}\right\}\frac{(\beta^2-\delta^2)(1+2\beta^2)-1}{(1+4\beta^2)\{1+(\beta-\delta)^2\}\{1+(\beta+\delta)^2\}}\\&\equiv f(\varphi_s,\varphi_p,w_p,R)\,, \qquad (11)\end{aligned}$$

where

$$\beta\equiv\left(\frac{1}{4}\varphi_p{}^2+w_p\right)^{1/2},\qquad \delta\equiv\frac{1}{2}\varphi_p-\varphi_s\,,\qquad a\equiv\frac{\varphi_p}{2\beta}\,,$$

$$w_p\equiv\left(\frac{|\bar{\mu}_{13}|E_p}{2h\Delta\nu}\right)^2=\frac{2\pi|\mu_{13}|^2P_0}{3ch^2(\Delta\nu)^2S}\,,\qquad |\bar{\mu}_{13}|^2=\frac{1}{3}|\mu_{13}|^2\,,$$

$$R\equiv\nu_{p0}/\nu_{s0}\,,$$

$$\varphi_s\equiv(\nu_s-\nu_{s0})/(\Delta\nu)\,,$$

$$\varphi_p\equiv(\nu_p-\nu_{p0})/(\Delta\nu)\,,\qquad \Delta\nu=1/(2\pi\tau)\,,$$

Here α_{s0} is the absorption coefficient at $\nu_s=\nu_{s0}$ without pumping, P_0 the pumping power for plane polarized wave, S the cross-sectional area of the power flow.

Eq. (11) is equivalent to Eq. (16) plus Eq. (19) in Ref. (2), but here the expression has been slightly modified for the convenience of studying off-resonant behavior and of numerical representations of the results. In Eq. (11), the approximations $\nu_s/\nu_{s0}\approx 1$ and $h\nu/kT\ll 1$ are also used as before.

When we have $\nu_p-\nu_s=\nu_{p0}-\nu_{s0}$ or $\varphi_p=\varphi_s\equiv\varphi$, Eq. (11) reduces to a relatively simple form as

$$\frac{\alpha_s}{\alpha_{s0}}=\frac{(1+w_p)(1+4w_p+\varphi^2)-Rw_p\{3(1+w_p)+\varphi^2\}}{(1+4w_p+\varphi^2)\{(1+w_p)^2+\varphi^2\}}\,. \qquad (12)$$

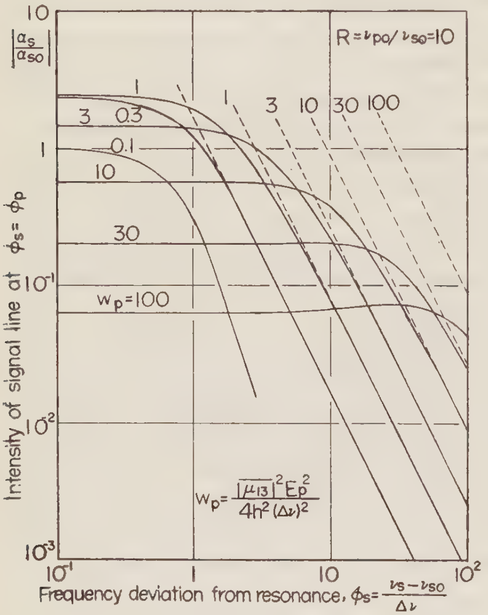
For $\varphi=0$, it reduces to

$$\frac{\alpha_s}{\alpha_{s0}}=\frac{1+w_p(4-3R)}{(1+4w_p)(1+w_p)}\ . \tag{13}$$

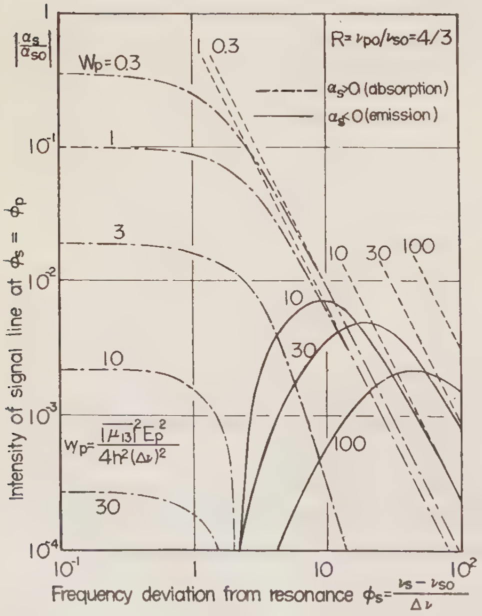
This is a relation for the resonant three-level gas maser. For $\varphi^2\gg1$, Eq. (12) approaches to the asymptotic formula

$$\frac{\alpha_s}{\alpha_{s0}}=\frac{1}{\varphi^2}-\frac{(R-1)w_p}{\varphi^2}\ . \tag{14}$$

The first term represent the tail of original absorption line arising from the first order or the single quantum transition between levels 2 and 3. The second term represents the emission due to the pure double quantum transition which is in full rgreement with the result of perturbation theory given by Eq. (10). Note that, when $w_p>1/(R-1)$, the double quantum transition dominates over the single quantum transition and the emission can be obtained.



(a)



(b)

Fig. 2. Signal intensity in a double quantum transition, when $\nu_p-\nu_{p0}=\nu_s-\nu_{s0}$.
(a) $\nu_{p0}/\nu_{s0}=10$. (b) $\nu_{p0}/\nu_{s0}=4/3$.

Eq. (12) is plotted as a function of normalized frequency deviation, φ, in Fig. 2 (a), (b) in order to show a saturation behavior of the double quantum transition. The dotted lines represent the result of Eq. (14). It can be seen from Fig. 2 that the perturbation treatment is approximately valid in the region where $\varphi\gtrsim w_p$. Also, as shown in Fig. 2 (b), appreciable emission can occur at a sufficiently off-resonant region even in the case of $R\leq4/3$, where the emission does not occur for $\varphi=0$ at any pumping power level.

In addition to the saturation of intensity, the frequency shift of the double quantum transition from the relation $\varphi_s=\varphi_p$ occurs when w_p/φ^2 becomes fairly large. Therefore, in the region where saturation effect cannot be neglected, the peak intensity of emission is somewhat higher than that indicated in Fig. 2. It can be seen from Eq. (11) that in general two peaks of emission or absorption in a single line occurs approximately at

$$\varphi_s=\frac{1}{2}\varphi_p\pm\left(\frac{1}{4}\varphi_p^2+w_p\right)^{1/2}. \tag{15}$$

When the pumping frequency is far off-resonant ($\varphi_p^2\gg1$), one of the peaks approaches to the center of the original line, and the other peak goes to the emission line corresponding to $\varphi_p=\varphi_s$. For $w_p/\varphi_p^2\ll1$, Eq. (15) can be expanded in powers of w_p/φ_p^2, and the latter peak occurs at

$$\varphi_s=\varphi_p\left(1+\frac{w_p}{\varphi_p^2}+\cdots\right). \tag{16}$$

This represents the frequency shift of the double quantum transition in the first order approximation. It is noted that in this approximation the fractional frequency shift of the double quantum transition is proportional to its intensity. This can be explained in the following way. For appreciable occurrence of the higher order transition such as double quantum transition, considerable mixing of the two states by a strong pumping field is necessary. This causes a frequency modulation of wave functions which depends on the field intensity, and then results in the shift of transition frequency from that of the pure double quantum transition. Thus the intensity and the frequency shift of double quantum transition are unseparably related. Further, because the frequency shift of the double quantum transition at off-resonance can be considered to arise from the same origin as that of the resonant modulation effect which splits the emission line at resonance, the multiple quantum effect and the resonant modulation effect in the three-level masers are also closely related. That is, when one of the effects is large, the other effect is also large.

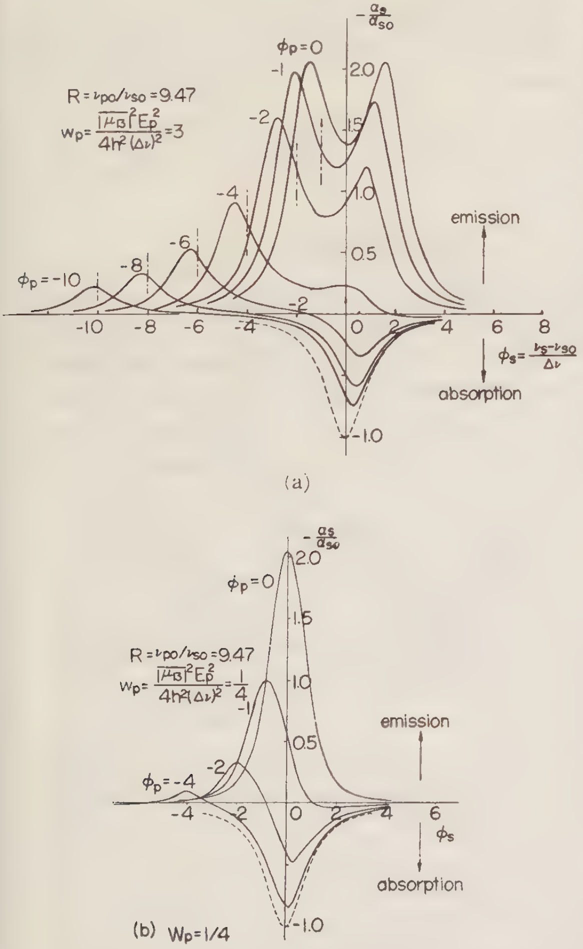


Fig. 3. Shape of signal line under off-resonant pumping. The dotted curve shows absorption line without pumping, and the vertical lines indicate the position of $\varphi_s=\varphi_p$.
(a) $w_p=3$. (b) $w_p=1/4$.

The whole behavior of the three-level gas maser from resonance to far off-resonance is clearly represented by plotting the shape of signal lines according to Eq. (11). This is shown in Fig. 3 (a), (b). For relatively strong pumping, the effects of resonant modulation, frequency shift of double quantum transition, and the double quantum emission line at far off-resonance are illustrated notably in Fig. 3 (a). On the other hand, for a weaker pumping, all the above effects scarcely appear as shown in Fig. 3 (b). The value of *R* in Fig. 3 is that of the three-level system used in the experiment to be described in II, and then these curves can be directly compared with experiment.

In actual molecules, each spectral line of the three-level system consists of several Stark or Zeeman components which coincide in frequency without external static field. Therefore, the above treatment is not exact but only describes an average characteristics, because individual components have different dipole matrix elements and hence show different behavior in a pumping process. Correct account of this effect will result in some deviations from the results given above. However, we shall not deal with the effect here since it complicates the problem very much.

§ 4. Doppler Effect

In general, the effective operation of a three-level gas maser is achieved at a low pressure, where Doppler broadening may no longer be neglected against pressure broadening. In this section we discuss the Doppler effect in a three-level gas maser where arbiary ratio of pressure broadening and Doppler broadening of a spectral line occurs. Before proceeding the calculation, we make following assumptions to simplify the problem.

(a) The molecular collision is hard, i.e., the radiation process is perfectly interrupted upon each collision, and immediately after collision the molecules redistribute their velocity as well as their internal energy according to the Boltzmann law.

(b) The presence of radiation fields does not affect the above distribution immediately after collision.

These assumptions may be a good approximation in treating the electric dipole transition of gas molecules at microwave frequencies. Under these assumptions, each radiation process between two successive collisions can be considered as an elementary process which is statistically independent. Then, Doppler effect in any radiation process can be calculated simply by averaging the process over the Maxwell-Boltzmann velocity distribution of molecules.

Consequently, when the Doppler effect is taken into account, a physical quantity, $nF(\nu)$, should be replaced by the form

$$n\int_{-\infty}^{\infty} F(\nu+\nu_d)\frac{q}{\sqrt{\pi}}\exp(-q^2\nu_d^2)d\nu_d\ , \tag{17}$$

where

$$q=\frac{c}{\nu}\left(\frac{m}{2kT}\right)^{1/2}=\frac{1}{(\Delta\nu)_d}\ .$$

Here n is the equiliblium population of a level, ν the applied frequency, and $(\Delta\nu)_d$ the Doppler width*.

(i) *Semiclassical Aspect*

Semiclassical approximation of the three-level maser action requires that the actions of two radiation fields, the signal and the pumping, can be considered separately. That is, the role of the pumping is only to change the populations of levels, and the signal responds to only the change of population regardless of the pumping mechanism. Further, in an ideal gas system the saturation of one transition does not affect the population of the other levels, because of the equal relaxation times between various levels. Then, the problem may be separated into two parts. The first is the saturation behavior of the pumping transition under Doppler effect, and the second is the one concerned with the signal. Since the latter is essentially the same problem as that in usual spectral lines, the former is considered first.

Suppose that a strong radiation of frequency ν is applied between two levels, 1 and 3, whose separation is ν_0 in frequency. Then the net population change, $\Delta n_3-\Delta n_1=2\Delta n_3$, is given by the theory of saturation effect as

$$2\Delta n_3=(n_1-n_3)\frac{4w_p}{1+4\pi^2(\nu-\nu_0)^2\tau^2+4w_p}\ , \tag{18}$$

$$w_p\equiv\left\{\frac{|\bar{\mu}_{13}|E_p}{2h(\Delta\nu)_p}\right\}^2\ , \qquad (\Delta\nu)_p=\frac{1}{2\pi\tau}\ ,$$

where n_1 and n_3 are the equilibrium population of levels, 1 and 3, $(\Delta\nu)_p$ the half-width due to pressure broadening. Under the presence of Doppler effect, the fractional change of population becomes by using the formula (17)

$$\frac{2\Delta n_3}{n_1-n_3}=\frac{4w_pq}{\sqrt{\pi}}\int_{-\infty}^{\infty}\frac{\exp(-q^2\nu_d^2)d\nu_d}{1+4\pi^2\{\nu_d+(\nu-\nu_0)\}^2\tau^2+4w_p}\ . \tag{19}$$

When $\nu=\nu_0$, it becomes after some change of variables

$$\frac{2\Delta n_3}{n_1-n_3}=\frac{4w_p}{1+4w_p}G(r\sqrt{1+4w_p})\ , \tag{20}$$

where

$$G(x)\equiv\frac{x}{\sqrt{\pi}}\int_{-\infty}^{\infty}\frac{1}{1+\xi^2}e^{-x^2\xi^2}d\xi\ ,^{**}$$

and

$$r\equiv\frac{q}{(2\pi\tau)}=\frac{(\Delta\nu)_p}{(\Delta\nu)_d}\ .$$

Eq. (20) gives general formula of fractional population change between two levels for arbitrary power level and Doppler broadening, and the result of numerical calculation is

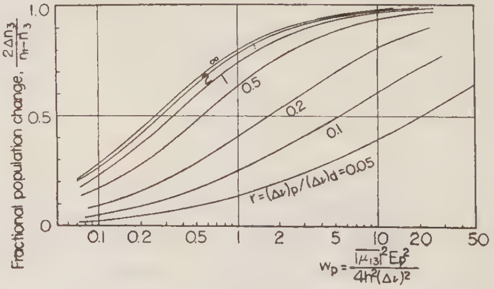

Fig. 4. Fractional population change in a saturation process between two levels under Doppler effect.

---

[*] The relation between $(\Delta\nu)_d$ and the usual half Doppler width $(\Delta\nu)_d^*$ is $(\Delta\nu)_d^*=\sqrt{\ln 2}(\Delta\nu)_d=0.832(\Delta\nu)_d$. Here $(\Delta\nu)$ is used as a Doppler width for convenience.

[**] The function $G(x)$ can be transformed in the form

$$G(x)=xe^{x^2}(\sqrt{\pi}-2\int_0^x e^{-t^2}dt)\ ,$$

whose asymptotic expressions are given by

$$G(x)\sim 1-\frac{1}{2}\frac{1}{x^2}+\frac{3}{4}\frac{1}{x^4}-\cdots \qquad \text{for} \quad x\gg 1$$

$$\sim x(\sqrt{\pi}-2x+\sqrt{\pi}x^2-\cdots) \qquad \text{for} \quad x\ll 1$$

given in Fig. 4.

By a similar approach, the absorption coefficient at the center of a line without saturation effect is given by

$$\alpha=\alpha_0 G(r)\ , \tag{21}$$

where α_0 is the value of α without Doppler effect. Then, a relation

$$G(r)=\frac{(\Delta\nu)_p}{(\Delta\nu)_T}\ , \tag{22}$$

can be obtained, where $(\Delta\nu)_T$ is the total line-width including both pressure-width and Doppler-width.

The Doppler effect at pumping frequency in the three-level gas maser is considered to affect the signal intensity through the population change. When $h\nu_{p0}\ll kT$, the general expression for the absorption coefficient at the center of the signal line including Doppler effects in both signal and pumping frequencies can then be given by

$$\alpha_s=\alpha_{s0}\left\{1-\frac{2w_p RG(r_p\sqrt{1+4w_p})}{1+4w_p}\right\}G(Rr_p)\ , \tag{23}$$

where

$$R\equiv\nu_{p0}/\nu_{s0}\ ,\qquad r_p=(\Delta\nu)_p/(\Delta\nu)_{dp}\ .$$

Here $(\Delta\nu)_{dp}$ is the Doppler-width for the pumping frequency, and α_{s0} the value of α_s without pumping and Doppler effect.

Now, returning to Eq. (20), we consider the physical meaning involved in it by examining some special situations.

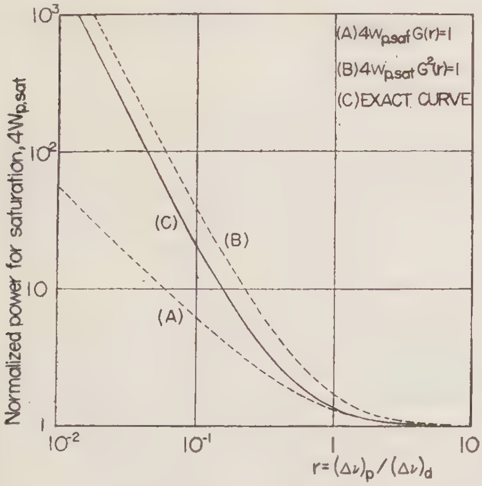

Fig. 5. Normalized power for saturation as a function of $r=(\Delta\nu)_p/(\Delta\nu)_d$. (A) and (B) are the approximate relations, and (C) is the exact curve.

(a) The case of saturation

We choose the value, $2\Delta n_3/(n_1-n_3)=1/2$, as a representative level of saturation, and will then plot a normalized power necessary for saturation, $4w_{p,\mathrm{sat}}$, as a function of $r=(\Delta\nu)_p/(\Delta\nu)_d$. The result is shown in Fig. 5 together with two approximate relations (A) and (B) designated below.

$$\text{(A)}\quad 4w_{p,\mathrm{sat}}G(r)=\frac{|\bar{\mu}_{13}|^2 E_p{}^2}{h^2(\Delta\nu)_p(\Delta\nu)_T}=1 \tag{24}$$

$$\text{(B)}\quad 4w_{p,\mathrm{sat}}G^2(r)=\frac{|\bar{\mu}_{13}|^2 E_p{}^2}{h^2(\Delta\nu)_T{}^2}=1\ . \tag{25}$$

According to a simple saturation theory[14], (A) means that Doppler effect contributes only to line-width, i.e., to transverse relaxation and not to longitudinal rexation, while (B) means that Doppler effect contributes equivalently both to transverse and longitudinal relaxation. At first sight, (A) seems to be a good approximation because Doppler effect is not an energy dissipating process. Fig. 5 indicates, however, that (B) is clearly a better approximation for $r\ll 1$ (Doppler broadening dominant) although (A) is better for $r\gg 1$ (pressure broadening dominant). This fact has already been pointed out by Shimoda[3], but it is proved here more explicitly. The asymptotic forms of the three curves for $r\ll 1$ become

$$\begin{aligned}
&\text{(A)}\quad 4w_{p,\mathrm{sat}}=\frac{1}{\sqrt{\pi}\,r}=0.564\frac{1}{r}\\
&\text{(B)}\quad 4w_{p,\mathrm{sat}}=\frac{1}{\pi r^2}=0.318\frac{1}{r^2}\\
&\text{(C)}\quad 4w_{p,\mathrm{sat}}=\frac{1}{r^2}\left\{G^{-1}\left(\frac{1}{2}\right)\right\}^2=0.187\frac{1}{r^2}\ ,
\end{aligned} \tag{26}$$

The discrepancies of the numerical factors between (B) and (C) varies to some extent depending on the selection of saturation level and the definition of total line-width, and therefore is not essential.

(b) Weak field case

Eq. (20) can be expanded in powers of w_p and by using Eq. (22) it becomes

$$\frac{2\Delta n_3}{n_1-n_3}=4w_pG(r)=4w_p\frac{(\Delta\nu)_p}{(\Delta\nu)_T} \tag{27}$$

This may be interpreted as that Doppler effect behaves in a manner described in the relation (A) at the early stage of saturation.

Semiclassical treatment of Doppler effect in three-level maser action is, of course, a rough approximation in cases of gases, but it will serve as a method of order estimation of the effect.

(ii) *Quantum Mechanical Aspect*

From the quantum mechanical point of view, the actions of signal and pumping radiations in a three-level maser cannot be treated separately, and they must be considered simultaneously.

Consider a three-level system as discussed in § 3. The absorption coefficient (being negative for emission) of the gas at the signal frequency ν_s under the presence of pumping radiation at the frequency ν_p has been given by Eq. (11),

$$\alpha_s=\alpha_{s0}f(\varphi_s,\ \varphi_p,\ w_p,\ R)\ , \tag{11'}$$

The expression of α_s including Doppler shifts of both the signal and the pumping frequencies can be derived in a similar manner as before in the form

$$\alpha_s=\alpha_{s0}\int_{-\infty}^{\infty}f\left(\frac{1}{R}x+\varphi_s,\ x+\varphi_p,\ w_p,\ R\right)\frac{r_p}{\sqrt{\pi}}\exp(-r_p^2x^2)dx\ , \tag{28}$$

where

$$r_p\equiv\frac{c}{\nu_p}\left(\frac{m}{2kT}\right)^{1/2}(\Delta\nu)_p=\frac{(\Delta\nu)_p}{(\Delta\nu)_{dp}}$$

Here $(\Delta\nu)_p$ is the pressure-width, $(\Delta\nu)_{dp}$ the Doppler-width for the pumping frequency. Since Eq. (28) is too complicated to be discussed generally, we shall consider some special cases to clarify the essential features of the effect when the quantum mechanical effects are important.

In the case when $R=\nu_{p0}/\nu_{s0}\gg1$, the Doppler effect at the signal frequency and the terms $(1+a)^2$, $(1-a)^2$, $(1-a^2)$ in the function f can be neglected. Further assume $\nu_p=\nu_{p0}$ (resonant pumping). Then, Eq. (28) becomes

$$\frac{\alpha_s}{\alpha_{s0}}=\int_{-\infty}^{\infty}f(\varphi_s,\ x,\ w_p,\ R)\frac{r_p}{\sqrt{\pi}}\exp(-r_p^2x^2)dx\ . \tag{29}$$

Eq. (29) means that in this case the total shape of the signal line can be given simply by superposing various line components for off-resonant pumping as has been shown in Fig. 3 with a weight factor of Boltzmann distribution. Then, it becomes clear that for large pumping power level Doppler effect at the pumping frequency affects not only the intensity of the signal line, but also have a large influence on the shape of the signal line, due to the double quantum transition which is considerably strong even in the far off-resonant conditions.

For strong pumping, $w_p\gg1$, the third term in the function f can be neglected and Eq. (29) reduces to the form

$$\begin{aligned}\frac{\alpha_s}{\alpha_{s0}}=-\frac{w_pr_p(R-1)}{\sqrt{\pi}\{(1+\varphi_s^2-w_p)^2+4w_p\varphi_s^2\}}\Bigg[&\frac{1}{\sqrt{w_p}}(1+\varphi_s^2-w_p)\int_{-\infty}^{\infty}\frac{1}{1+x^2}\exp(-4r_p^2w_px^2)dx\\&-2\varphi_s\int_{-\infty}^{\infty}\frac{x}{1+x^2}\exp\{-r_p^2N(x+\sigma)^2\}dx+(w_p+\varphi_s^2-1)\int_{-\infty}^{\infty}\frac{1}{1+x^2}\exp\{-r_p^2N(x+\sigma)^2\}dx\Bigg],\end{aligned} \tag{30}$$

where

$$N\equiv\left(1+\frac{w_p}{1+\varphi_s^2}\right)^2,\qquad \sigma\equiv\frac{\varphi_s(1+\varphi_s^2-w_p)}{(1+\varphi_s^2+w_p)}\ .$$

When $r_p\gg1$, it reduces to the equation for no Doppler effect

$$\frac{\alpha_s}{\alpha_{s0}}=-\frac{1}{4}(R-1)\left\{\frac{1}{1+(\sqrt{w_p}+\varphi_s)^2}+\frac{1}{1+(\sqrt{w_p}-\varphi_s)^2}\right\}\ . \tag{31}$$

When $r_p\ll1$, it approaches to the asymptotic formula

$$\frac{\alpha_s}{\alpha_{s0}}=-r_p\sqrt{\pi}(R-1)\frac{\sqrt{w_p}(1-w_p+\varphi_s^2)-w_p(1-w_p-\varphi_s^2)}{(1-w_p+\varphi_s^2)^2+4w_p\varphi_s^2}\ . \tag{32}$$

The solutions, (31) and (32), are compared in Fig. 6 (a), (b).

For $r_p \ll 1$, the doublet structure in the emission line disappears, and it becomes a broader single line having a normalized half-width of about $\Delta\varphi_s \sim \sqrt{w_p}$. This can be interpreted as that the Doppler broadening at the pumping frequency is converted partly into the signal line through the double quantum transitions and hence the broadening of the signal line occurs. This Doppler-broadened signal line will split into doublet again, if the pumping parameter w_p is increased to a larger value. This can be proved from Eq. (30) in a way that, when $w_p \to \infty$, the ratio, α_s/α_{s0} at $\varphi_s=0$, approaches to zero, while α_s/α_{s0} at $\varphi_s=\sqrt{w_p}$ approaches to a finite value of $-(R-1)G(2r_p)/4$

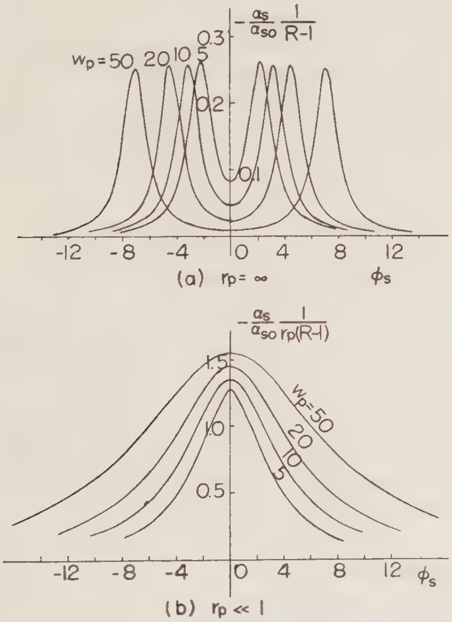

Fig. 6. Comparison of signal line-shape between two cases. (a) no Doppler effect ($r_p \to \infty$) and (b) large Doppler effect ($r_p \ll 1$). $r_p=(\Delta\nu)_p/(\Delta\nu)_{dp}$. $w_p=|\bar{\mu}_{13}|^2E_p^2/[4h^2(\Delta\nu)^2]$. $R=\nu_{p0}/\nu_{s0} \gg 1$.

where G is a function given in Eq. (20).

The Doppler effect is particularly important when the three-level gas masers are applied to the following cases (a) and (b) where Doppler broadening in pumping transition dominates over pressure broadening.

(b) Gas pressure is extremely low as in the case of high resolution radio-frequency spectroscopy of the signal transition[3].

(b) The pumping frequency lies in a shorter wavelength region as in the case of detecting the pumping transition in that frequency[4,5], or in the case of signal amplification by the use of such a pumping frequency.

§ 5. Concluding Remarks

In order to understand the basic characteristics of the three-level gas maser, two problems were theoretically discussed. The one is the multiple quantum process in the off-resonant conditions and the other is the Doppler effect which has a close relation with the former. In conclusion we shall discuss briefly some related problems concerned with the quantum mechanical behavior which have not been mentioned.

An important special case of the off-resonant three-level maser occurs when the separation of the levels 2 and 3 in Fig. 1 becomes so small that a condition, $\nu_{s0} \ll \mathcal{E} \ll \nu_{p0}$, holds. A number of energy level schemes applicable to such situation can be found in the rotational spectrum of slightly asymmetric molecules. This is essentially similar to the two-level Raman-type maser discussed by Javan[15], because the latter requires that at least one of the two levels is degenerate for the case of gas, and indeed it can be considered as a limiting case of the above situation. However, the equations for this case cannot be obtained simply by taking a limit of $\nu_{s0} \to 0$ in the present equations, because various approximations used here become invalid in such a limiting case.

When any energy level of a three-level system has a structure composed of closely spaced levels such as hyperfine levels or accidentally lying near-by levels, a complicated situation will occur. A strong pumping radiation will mix up many such quantum states, and then all these states will interact with the radiation simultaneously.

In the three-level system we can obtain the net induced emission only by a pumping source at the frequency higher than that of the signal, although the quantum mechanical effect widely extends the condition for the occurrence of induced emission. However, it can easily be shown that the net induced emission can be obtained by using lower frequency pumping for a wide range of conditions, if the triple quantum transition in a multi-level system is used. Although it may be hard to obtain a strong emission sufficient for practical use by this process, it will serve as a method of generation or amplification of shorter microwaves in some cases.

The complete understanding of the above problems requires another elaborate analyses starting from fundamental equations. Full discussion on these problems will then be postponed.

Acknowledgement

The author wishes to express his sincere thanks to Prof. K. Shimoda for his kind guidance and continued encouragement throughout this work. He also thanks Mr. H. Takuma for his interest and discussions on the present subject.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN, Vol. 16, No. 8, AUGUST, 1961

Some Optical Properties of Lead Activated Potassium Halide Phosphors

By Yozo KAIFU

Institute of Pelytechnics, Osaka City University

(Received February 16, 1961)

Absorption, emission and excitation spectra of KCl:Pb and KBr:Pb have been measured at various temperatures. These observed spectra are similar to those of KCl:Tl, and the absorption bands seemed to be due to transitions in Pb^{++} ions which occupies the normal positive ion sites. The two principal excited states are $^1P_1$ and $^3P_1$ of Pb^{++} ion. 273 mμ absorption, 345 mμ emission in KCl:Pb and 302 mμ absorption, 365 mμ emission in KBr:Pb are attributed to $^3P_1-{}^1S_0$ transitions perturbed by surrounding host lattice ions. The excitation to $^1P_1$ state does not manifest any distinct emission which is different from the case of Tl activated phosphors. The near ultra-violet emission suffers violent thermal quenching at room temperature, and the activation energies of these non-radiative process are found to be 0.28 eV and 0.18 eV for KCl:Pb and KBr:Pb, respectively.

Several discussions using a single configuration coordinate model are given.

§1. Introduction

It may be considered that the studies of alkali halide phosphors provide several fundamental informations about the luminescence process, since these phosphors have relatively simple structure among the inorganic phosphor. Pohl and his collaborators[1),2)] studied the optical properties of various alkali halides activated by a small amount of heavy metal ions and found the characteristic absorption bands existing on the long wavelength side of the fundamental absorption band of the pure substance.

In most cases, the luminescence can be observed by the excitation of these characteristic bands. However, detailed investigations including emission process about these phosphors have not been carried out except for the thallium activated one. The absorption spectra of lead activated alkali halide phosphors have been investigated by several authors[2)], and the positions of the absorption peaks were summarized in the recent publication[3)]. The emission spectra of these phosphors, on the other hand, have received little attention[4),5)].

The theoretical approach to simple inorganic phosphors has been developed by von Hippel[6)] and Seitz[7)] by introducing a configuration coordinate model. These were applied to thallium activated potassium chloride quantum mechanically[8)], and also semiempirically[9)]. A general interpretation of these luminescence center has been given by these treatments, but several criticisms on these treatments were presented[10)], so further tests of these points are important.

The author made an attempt to investigate the absorption, emission and excitation spectra of lead activated potassium halides, and considered the properties of the luminescence centers in connection with the thallium activated alkali halides.

§2. Experimental Procedures

Single crystals of KCl:Pb were grown from melts of pure alkali halides and lead halides of reagents grade purity, using the Kyropoulos technique. Any special treatment on the exclusion of trace impurities in the pure reagents was not conducted*, and single crystals obtained from the same alkali halide reagents were used as standard substances for optical measurements, and the effects of trace impurities were considered by relative measurements with respect to the standard substance.

Concentrations of lead in the single crystals were analysed by the following chemical method. The lead in the crystals were converted to precipitation of lead chromate, and the quantities of lead ions in the precipitate were volume-metrically determined by means of iodometry. The lead concentrations in the crystal were about one tenth of the lead concentration of the melt, and there were some variation of the concentration affected by the position of same grown crystal.

---

* These metal impurities introduced in single crystals were estimated to be about 10^{-6} mole.

The crystals grown from the high concentration of lead halide, i.e. above 0.3 mole percent $PbCl_2$ melts, were transparent at above 300°C. Cooling to room temperature, however, they became opaque indicating that colloidal aggregates of lead ions were grown in the crystal. As these crystals did not show efficient luminescence, and were considered to have more complex structure of luminescence center than the crystals of low lead concentrations, optical measurements for these crystals of high lead concentrations were not carried out in the present study.

A cryostat was designed to hold a crystal sample at any temperature between about 70°K and 400°K for sufficiently long time for optical measurements (Fig. 1). It has double Dewar containers having radiation shield and a relatively large sample holder made of copper block. The temperature was measured with a copper-constantan thermocouple which was placed close to the sample. The experimental arrangements are shown in Fig. 2 a, b, and detailed explanations are given in the next section.

§ 3. Experimental Results

a) *Absorption spectra*

Absorption spectra of Pb-activated alkali halide single crystals were measured with an automatic recording spectrophotometer at room temperature. The measurements at various temperatures were performed with two monochromators and a cryostat arrangements shown in Fig. 2a. This reduces the error introduced by the fluorescence of the crystal to negligible amount. The absorption curves were measured referring to the non-activated single crystals adjusting the absorption coefficient of each crystals to zero at 400

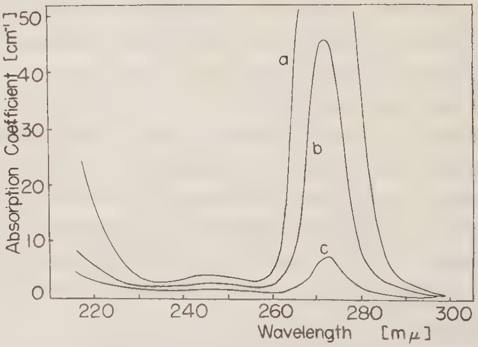

Fig. 3. Absorption spectra of KCl:Pb at room temperature. The concentrations of lead added to the melt are a: 0.1 mole %, b: 0.03 mole % c: 0.005 mole %.

mμ, where they were considered to be transparent.

The observed absorption spectra at room temperature are shown in Fig. 3 and Fig. 4 for various Pb-concentrations. The absorption at 273 mμ (hereafter will be called the A-band), found by previous investigators as a characteristics band of lead activator[2], is also evident in the present figure (Fig. 3). Another band had been found by earlier investigators at 196 mμ (B-band) for KCl:Pb. As our equipment is unreliable below about 220 mμ, we could not study the behavior of this band. But the rise of the absorption curves at the short wavelength region may correspond to this band. A small hump appears at 247 mμ in the KCl:Pb spectra. But as it seems to be independent with the concentration of lead in the crystal, this band may be due to some impurities such as thallium. Increasing the concentration of lead, the absorption coefficients of A-band increase namely proportionally to the lead content, and bands corresponding to paired centers did not appear in the present studies.

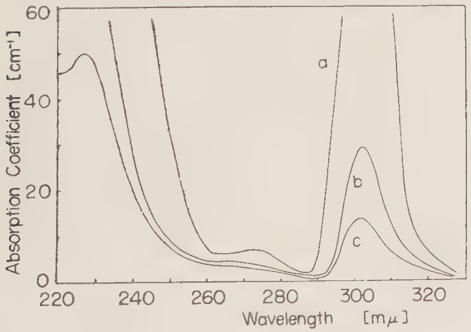

Fig. 4. Absorption spectra of KBr:Pb at room temperature. The concentrations of lead added to the melt are a: 0.1 mole %, b: 0.02 mole %, c: 0.005 mole % (absorption coef. ×2).

The oscillator strength of A-band is calculated with the Smakula's equation[11]:

$$Nf = 0.87 \times 10^{17} \frac{n}{(n^2+2)^2} \alpha_m \cdot W \,\mathrm{cm}^{-3} \qquad (1)$$

where f is the oscillator strength, n: the index of refraction, N: the concentration of the center per unit volume, α_m: the maximum absorption coefficient in reciprocal centimeter, and W: the half width of the band in eV. Using the observed absorption data and the concentration of lead in the crystal, this value is found as 0.075 and is nearly the same as that of 247 mμ band in KCl:Tl[15].

In KBr:Pb, strong two bands appear at about 302 mμ (A-band) and 227 mμ (B-band), and these also agree with the results of earlier measurements. In the present investigation, however, two new bands are observed at longer wavelength side of A-band and at about 272 mμ. As shown in Fig. 4, 302mμ band is asymmetrical, falling off in intensity more sharply at the shorter wavelength side than at the longer wavelength side. This indicates overlapping of another absorption band at the longer wavelength side. By the low temperature measurement, this point was justified, showing a small absorption band appears at 308 mμ at −190°C (Fig. 6).

The asymmetric shape of 302 mμ band is independent of the lead concentration, and found in the crystals even at very low lead content, then the center corresponding to this band may be considered as single Pb ion near a lattice defect rather than pairs of Pb ions. A similar result was found in the excitation spectra of NaCl:Pb showing that the asymmetrical 273 mμ band (may correspond to A-band of NaCl:Pb) was consisted of two excitation bands[4].

Another new observed band around 272 mμ

C; −60°C, D; +80°C

is seen in Fig. 4 in a crystal at higher lead content, and is more sharply resolved by an excitation measurement disclosing this band consists of two band.

Burstein and his associates[12] showed that the absorption spectra of NaCl:Pb are very sensitive to its thermal history. In the present study, however, it is found that A-absorption bands of KCl:Pb and KBr:Pb are not almost altered by thermal treatments. In KBr:Pb, however, the absorption band at 272 mμ and the longer wavelength tail of B-band are fairly sensitive to its thermal treatment or a strain in the crystal. Comparing with the results of Burstein and his associates, it may be considered that the states of lead ion in potassium halide are more stable than that in sodium halide.

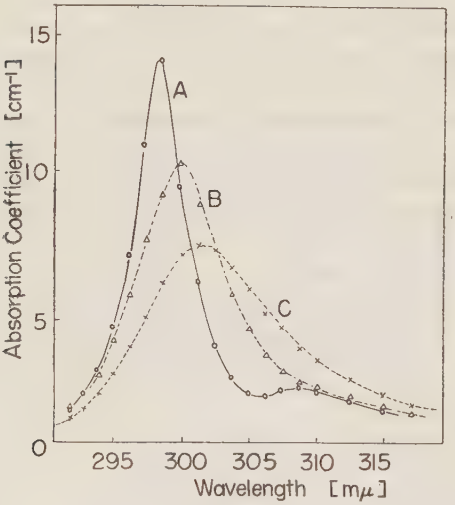

Fig. 6. Absorption spectra of KBr:Pb at various temperatures. The concentration of lead added to the melt is 0.005 mole %.
A: −190°C, B: −100°C, C: +25°C

The temperature variation of the absorption spectra was studied in detail on the A-band, and some of these results are shown in Fig. 5 and 6. In the KCl:Pb, the peak of the absorption band is shifted to the shorter wavelength side, and the band becomes sharper with lowering the temperature, but the integrated absorption area is nearly constant. These behaviors are similar to the F-center in alkali halide crystals. Similar results are obtained in the KBr:Pb, but in this case the band is asymmetric, as stated above, with lowering the temperature this band splits, and additional peak appears at longer wavelength side.

By configuration coordinate (C.C.) model, it is suggested that the absorption and emission band of luminescence center are Gaussian in shape as a first approximation. Hesketh and Schneider[13] discussed the absorption curve of F-center and derived an empirical expression of the absorption curve as follows:

$$\alpha=\alpha_0 \exp[-a(E-E_0)^b] \qquad (2)$$

where α_0 and a are constants, α: the coefficient of absorption, b: a constant which should be 2 for the curve to be Gaussian, E: the photon energy of the light at which α is measured, E_0: the photon energy of the peak of the absorption curve. Fig. 7 shows a plot of $(\ln \alpha_0/\alpha)^{1/2}$ as a function of E under the assumption that the absorption curve is Gaussian, wherein the constant a seems to be of different values in the right and left side of the absorption peak. The constant $|a|$ at higher energy side of E_0 is slightly larger than that of lower energy side at liquid nitrogen temperature. However, at higher temperature these difference is not detected*. In any case it is seen from Fig. 7 that A-

---

* Markham[14] attempted to synthesize more rigorous theory on the band shape and the half width of the absorption band.

absorption band of KCl:Pb is nearly Gaussian in shape above the liquid nitrogen temperature.

The variation of the bandwidth with temperature is shown in Fig. 8 for KCl:Pb, wherein the bandwidth at half maximum, normalized at 300°K, are plotted against $T^{1/2}$ in order to show the approach at high temperature to the $T^{1/2}$ dependence of the width of absorption curve. The C.C. model predicts that the width of absorption band at half maximum, W_a, is given by

$$W_a = A[\coth(h\nu_g/2kT)]^{1/2} \qquad (3)$$

where A is a constant, h: Planck's constant, k: Boltzman's constant, and T: the absolute temperature. In this expression ν_g is a vibrational frequency which influences the center in its ground state. From Fig. 8 it is clearly seen that experimental points best fit the solid curve when Eq. (3) is used by choosing $\nu_g = 3.6 \times 10^{12}$ sec^{-1}.

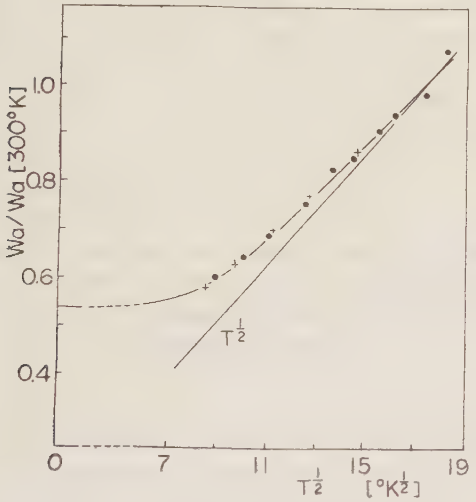

Fig. 8. The temperature variation of the absorption band width at half maximum for KCl:Pb.

● 0.03 mole % Pb
+ 0.005 mole % Pb

In KBr:Pb, these plots are not shown, since the absorption bands are not Gaussian in shape and have overlapping of other band at higher temperature.

b) *Emission spectra*

The apparatus used in this study consists of following arrangement. A monochromator with a hydrogen lamp was used for the irradiation of the sample. The fluorescence of the sample was observed with another monochromator and a 1P28 phtomultiplier in the direction normal to the exciting light (Fig. 2b). The latter monochromator, which has a band

pass of about 5 mμ at 350 mμ, is calibrated for spectral transmission and sensitivity of the phototube, in order to ascertain the real shape of the emission spectra.

The emission spectra were studied under the irradiation of light in the A-absorption band. Typical emission spectra are shown in Fig. 9 and 10 at various temperatures. The emission spectra consist of intense near ultra-violet band and weak visible band. As the visible band is very weak, special care in measurements are necessary for accurate determination of the peak position and the band shape. The peak of the near ultra-violet band lies at 345 mμ for KCl:Pb and 365 mμ for KBr:Pb at room temperature. These peaks shift toward the red in passing from chloride to bromide, in accordance to the general rule of alkali halide phosphors.

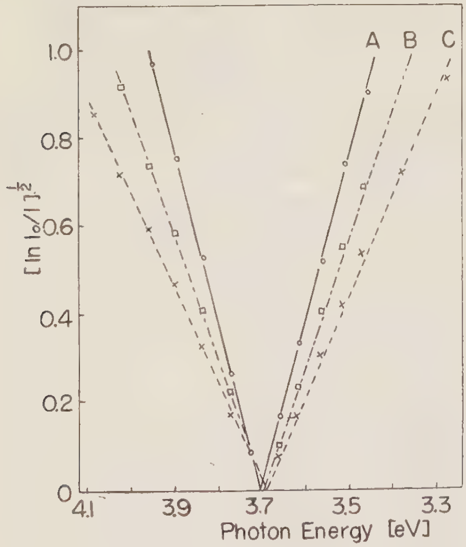

Fig. 11. Gaussian plots of the emission bands for KCl:Pb (0.03 mole % Pb).

A: 193°C, C: −95°C, C: 67°C.

By lowering the temperature, the peak of the emission band also shifts toward the short wavelength. The shape of the emission band is nearly Gaussian as shown by Fig. 11, in which $(\ln I_0/I)^{1/2}$ is plotted as a function of the emission photon energy. Here I_0 and I are the emission intensities at the peak of the band and photon energy E, respectively. These plots fairly well fit into equation similar to (2), showing that the observed near ultra-violet emission band is not a composite band but a single emission band.

Fig. 12 shows a relation between half maximum band width and the temperature. Points indicating the observed values also fit the solid and dotted curves, by assuming ν_e: $4.0\times10^{12}\,\mathrm{sec}^{-1}$. and $3.0\times10^{12}\,\mathrm{sec}^{-1}$. for KCl:Pb and KBr:Pb, respectively. Here ν_g of Eq. (3) is replaced by ν_e which corresponds to a vibrational frequency that influence the luminescence center in its excited state.

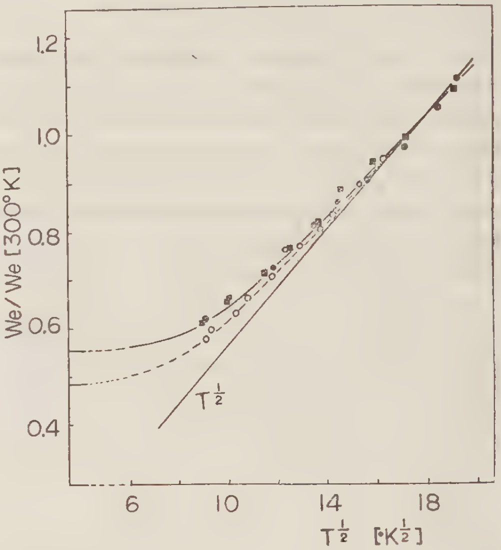

Fig. 12. The temperature variations of the emission band width at half maximum.

KCl:Pb —●— 0.03 mole % Pb
—■— 0.1 mole % Pb
KBr:Pb --○-- 0.02 mole % Pb

Extrapolating these curves, we get the values of half maximum band width at 0°K as 0.26 eV and 0.20 eV for KCl:Pb and KBr:Pb, respectively.

Fig. 9 and 10 also show that the fluorescence of lead activated potassium halides are greatly enhanced at low temperature. By detailed experimental investigation about the temperature variation of the emission intensity, it is justified that the probability of non-radiative transitions to the ground state is appreciably large even at room temperature. At liquid nitrogen temperature, however, it is found that the quantum yields of these emission are nearly unity by relative measurements with KCl:Tl phosphor, which is reported to have a quantum yield of unity for 305 mμ emission band.

Fig. 13 shows the results of these measurements. The probability for these nonradiative transitions may be expressed as

$$P_Q = s\exp(-E_Q/kT)\,, \tag{4}$$

where, E_Q and s are activation energy and frequency factor. It may be considered that the probability of a spontaneous emission, $1/\tau$, is temperature independent as a first approximation, then the luminescence efficiency, η, is given by

$$\eta = [1 + s\tau\exp(-E_Q/kT)]^{-1}\,. \tag{5}$$

In Fig. 13, the luminescence intensity normalized at lowest temperature values is plotted on a logarithmic scale as a function of $1/T$ °K. The quenching rates of the higher temperature portion correspond to the activation energies of 0.28 eV for KCl:Pb and 0.18 eV for KBr:Pb. Assuming τ as 10^{-7} sec., the frequency factor for this process is of the order of the vibrational frequency, i.e. 10^{12} sec^{-1} or greater.

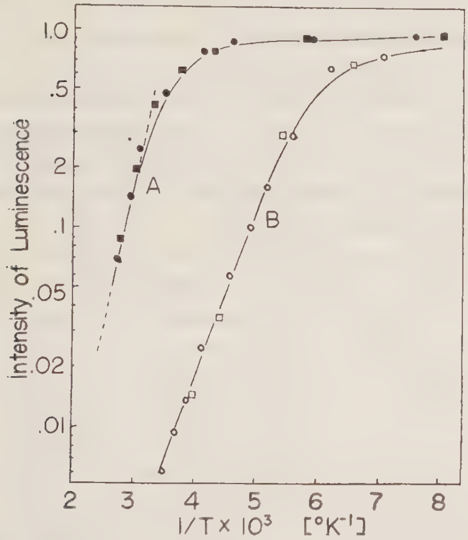

Fig. 13. Temperature variations of the emission intensities for KCl:Pb (A) and KBr:Pb (B).

The emission spectrum of high lead content of KCl:Pb is changed by aging of several weeks at room temperature, where by the near ultra-violet emission band becomes broad, and its maximum is shifted to the red by some ten mμ. By thermal treatment at about 400°C, however, the emission band turns into ordinary single Gaussian band such as in a crystal of low lead concentrations. In the preparation of a crystal, it is found that colloidal aggregates of lead ions are easily produced in alkali halide crystals containing high lead concentrations. These change of emission spectra may be considered due to aggregation of lead ions in the crystals.

c) *Excitation spectra*

The apparatus used in this study is as follow: a monochromator with a Beckmann hydrogen lamp is used to irradiate the sample. The fluorescence of the sample is observed with the 1P28 photomultiplier in the direction normal to the exciting light. A filter is inserted between the sample and the phototube to cut off the reflected exciting light and to transmit the main emitting light of the phosphor. The filter employed is Matsuda UV–D1 which transmits light waves between about 310 mμ and 400 mμ, covering the near ultra-violet emission spectra of KCl:Pb and KBr:Pb. The energy of the exciting light on the specimen is corrected by a 1P28 photomultipler covered with sodium salicylate.

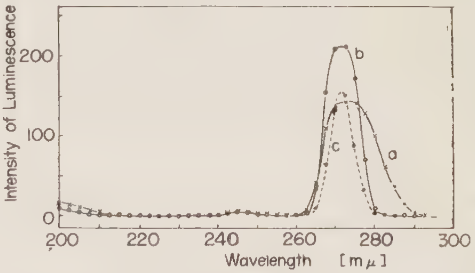

Fig. 14. Excitation spectra of KCl:Pb. The concentration of lead added to the melt are 0.1 mole % (solid line) and 0.005 mole % (dotted line).

a: +27°C, b, c: −193°C.

Typical excitation spectra of KCl:Pb and KBr:Pb are shown in Figs. 14 and 15. In KCl:Pb, the near ultra-violet emission band is favored by the excitation of A-absorption band. Especially with specimen of low lead concentration, the excitation band coincides very well with the absorption band at 273mμ with respect to band shape and temperature variation of the peak position. In the case of high lead content, the excitation peak is flat owing to the saturated absorption of the exciting light. Appearance of the near ultra-violet emission under the excitation of B-band was not ascertained, as our equipment could not give reliable results below 220 mμ. Comparing with the absorption spectra, however, it may be considered that B-band is not very effective in stimulation the near ultra-violet emission.

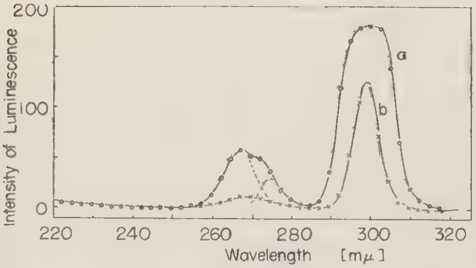

Fig. 15. Excitation spectra of KBr:Pb at −196°C. a: 0.1 mole %, b: 0.02 mole %.

In KBr:Pb, the near ultra-violet emission is also favored by the excitation of A-band, but is not favored by the excitation of B-band peaked at 227 mμ. The new absorption band around 272 mμ is also found in this excitation spectra. Excitation intensity of this band gradually increases with the same rate as A-band by lowering the temperature. Accordingly, these excitation and absorption bands are considered due to some composite lead centers. As in the absorption spectra, the intensity of this band is changed by the thermal history of the specimen. It may be clear by Fig. 15 that this band consists of two bands peaking at about 268 mμ and 275 mμ at liquid nitrogen temperature.

§ 4. Computation of Configuration Coordinate Curve

The continuous dielectric model is inadequate to describe the optical properties of the Pb-center, since the experimentally derived ground state frequency ν_g is fairly small compared with the longitudinal optical vibration frequency ν_0 of the host crystal ($\nu_0=6.3\times 10^{12}\,\mathrm{sec}^{-1}$ for KCl[9]). Therefore, the C.C. model will be applied to the Pb-center to compute the ground and excited state energy curves.

The evaluation of C.C. curves are carried out in accordance to the method described by Klick[16]. In these treatments, it is assumed that; (1) the predominant vibrational mode of the center is the breathing mode, so that a single coordinate may be used, (2) the energy curves are parabolic so that the center acts as a simple harmonic oscillator in both states, (3) the initial state of the center is treated by quantum mechanical method whereas the final state curve is treated classically, (4) the slope of the final state curve is taken to be a constant value over the range of transition coordinates.

The above mentioned single coordinate is taken as the distance from the center to the nearest neighboring halogen ion assuming that lead ions replace the potassium ions in the cubic lattice, being surrounded by six halogen ions.

To describe the C.C. curves, four constants are necessary. K_g and K_e are force constants for the ground and excited states, X_0 and E_0 are the displacement of the minimum of the excited state from the ground state minimum along the coordinate axis and energy axis, respectively. In addition, the mass of the oscillator system, M, is needed. Williams had shown that the effective mass of a Tl-center in KCl is the sum of the masses of the six nearest halogen ions multiplied by a factor of 1.2, considring the effect of other host lattice ions[17]. The specific assumption on the mass is not critical in most applications of these curves. Thus the mass of the oscillator will be assumed in the manners described above.

Using these constants, experimental data

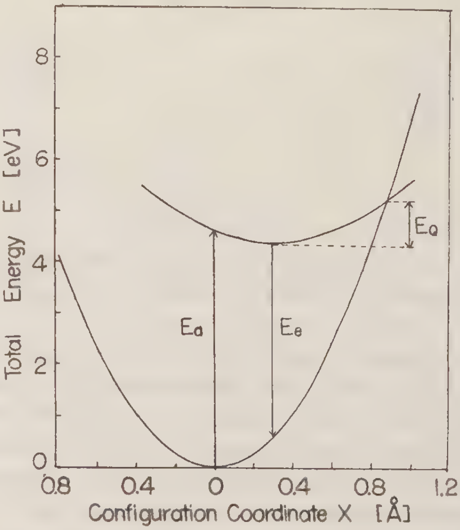

Fig. 16. Calculated configuration coordinate curves for the ground and lowest excited states of Pb-center in KCl.

may be expressed by the following equations: ν_g may be represented in terms of the forgoing constants as

$$\nu_g \fallingdotseq (2\pi)^{-1}(K_g/M)^{1/2}\ . \qquad (6)$$

Energies at the peaks of the absorption and emission bands are expressed as

$$E_a = E_0 + K_e X_0^2/2 \qquad (7)$$

$$E_e = E_0 - K_g X_0^2/2 \qquad (8)$$

in these expression, where the zero point energy (in the order of 0.01 eV) is neglected. The width of the absorption band at half maximum is given by

$$W_a \fallingdotseq 1.355\times10^{-13} K_e X_0(\nu_g/K_g)^{1/2} \qquad (9)$$

in ergs. at the low temperature limit.

Eqs. (6), (7), (8) and (9) were used to compute the C.C. curves for the Pb-center in KCl. The experimental values used are the following: $M=4.16\times10^{-22}$ gr., $\nu_g=3.6\times10^{12}$ sec^{-1}, $E_a=4.59$ eV, $E_e=3.71$ eV and $W_a=0.089$ eV. The resultant curves are illustrated in Fig. 16, and calculated constants are shown in Table I. The calculated values for KCl:Tl by Klick are also found in Table I[18].

Table I. The Calculated and Observed Constants of the Configuration Coordinate Curves.

	K_g ev/A^2	K_e eV/A^2	X_0 Å	E_0 eV	ν_{ec} $\times10^{12}$ sec^{-1}	ν_{eo} $\times10^{12}$ sec^{-1}	W_{ec} eV	W_{eo} eV
KCl:Pb	13.4	5.6	0.30	4.35	2.3	4.0	0.28	0.26
KCl:Tl[18]	16.8	6.4	0.36	5.05	2.5	5.6	0.26	0.32

With these constants and equations for the excited state similar to Eqs. (6) and (9), it becomes possible to predict the vibrational frequency at the excited state and the width of the emission band at the low temperature limit, assuming that the mass of the oscillator is identical for the system in its ground and excited states. These values are also shown as ν_{ec} and W_{ec} in Table I together with the corresponding observed values, ν_{eo} and W_{eo}.

From these values in Table I, it is clear that the force constant for the excited state is smaller than that of the ground state. This is also presumed from the difference of the band width between the emission and absorption spectra, and indicates that the excited state has more diffuse charge distributions than the ground state. This conclusion seems to be a character of the impurity center, in which the impurity is a positive ion in ionic crystals. The calculated value of the emission band width coincides farely well with the observed value, but some discrepancy is found in the excited frequency.

The height of the intersection of the ground and excited state curves above the minimum of the excited state curve corresponds to the activation energy, E_Q, of the non-radiative transition of the luminescence center. This value is found to be about 0.9 eV. In this calculation, it is assumed that the ground state curve is parabolic at even higer energy. It may be considered that the potential curve rises more rapidly than a parabola at these large amplitude of the oscillation owing to the repulsive force. Thus calculation gives somewhat larger value of the activation energy. Even if these effects are considered, it seems to be too large compared with the observed value, namely 0.28 eV.

§ 5. Discussion

It may be considered that the luminescence centers of these lead activated alkali halide phosphors are composed of Pb-ion surrounded by the negative ions of the host crystals. Hence the electronic configurations of the central ion may be described as $5d^{10}\ 6s^2$ for the ground state and $5d^{10}\ 6s6p$ for the excited state, similar to the case of Tl-activated one. KCl:Tl is the most widely studied phosphor both side in experiment and theory. Therefore Pb-phosphors are considered here in connection with Tl-phosphors.

The observed absorption spectra of Pb-phosphors are remarkably similar to those of Tl-phosphors. Two strong absorption bands (A- and B-band) may be considered as corresponding to the transitions for two excited states, $^1P_1$ and $^3P_1$, from the ground state, $^1S_0$, of Pb-ion perturbed by the surrounding host lattice ions. In KCl:Pb, the $^1P_1$ absorption band (B-band) occurs at 196 mμ whose energy is almost the same as that of KCl:Tl, but the $^3P_1$ absorption band (A-band) is shifted to the longer wavelength side than in KCl:Tl. Similar results are also found in KBr case, accordingly the separations between the $^1P_1$ and $^3P_1$ states are larger in Pb-phosphors than Tl-phosphors. These are expected from the fact that a larger spin-orbit interaction exists for the Pb-centers.

The near ultra-violet emission band may be regarded as the reverse process of A-absorption by the results of the excitation measurements, therefore these transitions are attributed to $^3P_1 \rightarrow {}^1S_0$, which appears at longer wavelength than Tl-phosphors. The photon energies at the peaks of the emission bands are found to be 3.71 eV and 3.14 eV for KCl:Pb and KBr:Pb, respectively. The Stockes' shifts of these $^1S_0 \rightarrow {}^3P_1$ transitions, however, have the same values within experimental error in both Pb- and Tl-phosphors but are changed by the different host lattices, namely, 0.87 eV for KCl and 0.76 eV for KBr. These Stockes' shifts are originated from the energy dissipation in the lattice after an optical transition. It is therefore not surprising that these values are more intimately related to the host lattice than the center ion, and the unique values for each host crystals may be accidental.

In the excitation spectra, the light in $^1P_1$-absorption band does not excite emission so intensely as the excitation of $^3P_1$ band. In Tl-phosphors, the excitation of $^1P_1$ band yields emission in both near ultra-violet and visible bands, which correspond to the transitions of $^3P_1 \rightarrow {}^1S_0$ and $^1P_1 \rightarrow {}^1S_0$, respectively[19).* If we consider the present results in connection with those of Tl-phosphors, the weak visible emission may be considered as corresponding to the transition of $^1P_1 \rightarrow {}^1S_0$. However, the visible emission here is too weak to carry out reliable excitation measurements. The light in $^1P_1$-absorption band does not stimulate the near ultra-violet emission. The situation is different in the case of Tl-phosphors. These indicate that the internal conversion between $^1P_1$ and $^3P_1$ states does not take place effectively in Pb-phosphrs. In either case, the reverse process of $^1S_0 \rightarrow {}^1P_1$ absorption is not observed as effective photoluminescence process. Hence the author considers that $^1P_1$ state is susceptible to non-radiative transition.

Similar phenomena are also found for $^3P_1$-state by the temperature variation of the near ultra-violet emission. As it is shown in Fig. 13, Pb-phosphors do not show so efficient a luminescence as Tl-phosphors above room temperature. At liquid nitrogen temperature, these efficiencies are increased up to that of Tl-phosphors which is considered to be nearly unity. The above phenomena indicate that the $^3P_1$-state also suffers non-radiative transition at room temperature. The activation energies of this process are found to be 0.28 eV for KCl:Pb and 0.18 eV for KBr:Pb, therefore the non-radiative process operate more effectively in KBr lattice than KCl lattice.

In the C.C. model, the activation energy E_Q corresponds to the height of the intersection of the ground $^1S_0$ and excited $^3P_1$ energy curves above the minimum of $^3P_1$ state. The smallness of E_Q may be expected as a result from the diffuseness of the excited state, thus $^3P_1$ states of Pb centers in both alkali halides interact more strongly with the states of the host lattice ions than Tl-centers.

On the other hand, a positive ion vacancy is introduced in the neighbourhood of Pb-ions owing to the charge compensation of the host lattice. If these positive ion vacancies occupy a neighboring site of the luminescence center as observed in NaCl:Mn[20), it may be presumed that these vacancies play an important part in the above non-radiative process.

Fredericks and Scott[21) have shown that Pb-centers in KCl at high temperature migrate as if they were negative ions such as $PbCl_6^{4-}$ by measurements of the ionic conductivity. Several questions are presented whether these complex ions exist in the crystals at lower temperature[3). However, it may be seen that Pb-ions in alkali halides are more intimately mixed with the negative ions of the host lattice than for the case of Tl-ions. The present results favor the view that these interactions are more strong in KBr than in KCl lattice.

The one dimentional C.C. model interpretes fairly well the observed results for the shape and the band width of the spectra in Pb-phosphors. The temperature variations of the band width are also well interpreted by this model. However, calculation on this model with observed absorption data does not bring reasonable results for the emission data. This model also does not elucidate the difference of the non-radiative process between Pb- and Tl-phosphors, since the calculated value of the activation energy in Pb-phosphor is greater than the Tl-phosphor, which is opposite direction to the experimental results.

---

* Recently, several question are presented against this old interpretation of the visible emission in KCl:Tl.

These indicates the possibility of the application of one dimentional C.C. model. Namely, this model describes the optical properties related to a single state fairly well, but it does not present satisfactory results for the process related to both the ground and excited states such as non-radiative transition. The author supposes that these limitation come from the simplified assumption adopted in this model where the breathing mode of vibration is always effective in both states. If another mode of vibration is broken out after optical transition, the values of the final state calculated by this model with the data of initial state will not give satisfactory results.

Recently, Karo, McComble and Murray[22] found that main contribution to the breadth of F-band come from modes in fairly small range of frequencies in which the empirical configuration frequency is included. Therefore, the present results obtained for the ground and excited frequencies, ν_{g0} and ν_{e0}, may be considered to have close resemblance to real frequencies.

To make more advanced treatments of Pb-center including non-radiative process, it may be necessary to use of a multidimensional C.C. treatment, developed and applied by Kamimura and Sugano[23] for KCl:Tl, considering the effects of the all excited level such as $^1P_1$, $^3P_2$, $^3P_1$ and $^3P_0$ states of Pb-ions.

§ 6. Summary

1) Absorption spectra of lead activated phosphors are nearly the same as the results of earlier investigations. Two intense bands (A- and B-bands) are considered as transitions of $^1S_0 \to {}^3P_1$ and $^1S_0 \to {}^1P_1$ in Pb^{++} ion perturbed by host lattice ions.

2) Emission band observed in near-ultraviolet region may be ascribed to $^3P_1 \to {}^1S_0$ transition.

3) The excitation of $^1P_1$ state does not result in any distinct emission different from the case of Tl-phosphors. This indicates that $^1P_1$-state of Pb-center is susceptible to non-radiative transition.

4) $^3P_1$-state also suffers non-radiative transition at room temperature. The activation energies of this process are found as 0.28 eV and 0.18 eV for KCl:Pb and KBr:Pb, respectively.

5) These results favor the view that Pb-ions in alkali halide are intimately mixed with the negative ions of the host lattice, but is not well interpreted by the use of a semiempirical C.C. treatment.

6) The temperature variations of the absorption and emission band width are fairly well interpreted by a simple C.C. model, and the C.C. frequencies of the luminescence center in KCl:Pb are found as 3.6×10^{-12} sec^{-1} and 4.0×10^{12} sec^{-1} for the ground and excited states, respectively.

7) C.C. curves for KCl:Pb are calculated by a semiempirical method. Some results expected from these curves are compared with the observed data; the agreement in emission band width and disagreements in the activation energy for non-radiative process and the effective vibrational frequency of the center at excited state are obtained.

Acknowledgements

The author would like to express his thanks to Prof. T. Okuda for his guidance during the course of this study, and also to Prof. M. Sawada and Prof. T. Nagamiya of Osaka University for their kind advice and comments on this manuscript. His thanks are also due to Mr. T. Miwa for his assistance in the process of chemical analysis of the specimen.

Local Description of the Flow behind a Steady, Two-Dimensional, Curved Shock Wave*

By Zirō Hasimoto and Shigeki Morioka

Department of Mathematics and Physics, Faculty of Science and Engineering, Ritumeikan University, Kyoto

(Received February 16, 1961)

The local properties of the rotational flow field behind a steady, two-dimensional, curved shock wave which occurs in a supersonic uniform flow of a perfect gas are considered. The states of flow field in the vicinity of a point on a shock wave are described as a power series about this point under the assumption that the shape of the shock wave is regular. The hodograph transformation of such a field becomes singular at the points where Jacobian relating to the transformation vanishes. The fields in the vicinity of such singular points are discussed in detail.

§ 1. Introduction

We shall consider the flow behind a steady, two-dimensional, curved shock wave which occurs in a supersonic uniform flow of a perfect gas. We assume that the viscosity and thermal conductivity of the gas can be neglected. In general, however, the flow field behind the shock wave is rotational. When the shape of the shock wave is given as a regular curve, the flow field immediately behind the shock can be determined by the shock conditions. It is the purpose of the present paper to describe the local field behind a shock wave as the series expansion about the field value immediately behind the shock, and to transform such a local field to the hodograph plane. First, in Section 2, we give the expressions for the derivatives of the velocity components immediately behind the shock wave. These derivatives are necessary for the determination of the coefficients in the expansion formulas for the various quantities of flow as seen in the following sections. These derivatives enable us to determine the directions and curvatures of the lines of constant speed, deflection, pressure, and density immediately behind the shock wave (Section 3). The pressure distribution on a streamline behind a shock wave is formulated in Section 4. The formula thus obtained seems to be useful to find the pressure distribution over the surface of a curved airfoil in the neighbourhood of its leading edge when a shock wave is attached to the edge.

---

* The results in §§ 4, 5, 6 of this paper have been reported in part by one of the authors (Z.H.) (Ref. 1).

In the transformation of such local field onto the hodograph plane, we find that there occur certain cases when the Jacobian defined by Eq. (31) vanishes. This is the case, for example, when the shock spine coincides with the shock polar in the hodograph plane, or when the shock wave has an inflection point. The singularity at such points and the flow fields in the vicinity of those point are discussed in Sections 5 and 6.

§ 2. Derivatives of the Velocity Components Immediately behind a Shock Wave

We choose the origin of the coodinate system at a point of interest on a shock wave, and take the x_1-axis in the direction of the velocity vector immediately behind the shock wave and the x_2-axis perpendicularly to it (see Fig. 1). The shock conditions can be expressed as follows,

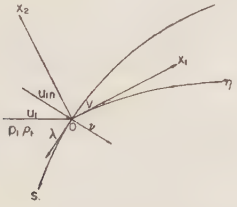

Fig. 1.

$$\left.\begin{aligned} u_\alpha &= u_{1\alpha} - \frac{2(\rho_1 u_{1n}{}^2 - \gamma p_1)\nu_\alpha}{(\gamma-1)\rho_1 u_{1n}} \qquad (\alpha=1,2) \\ p &= p_1 + \frac{2}{\gamma+1}(\rho_1 u_{1n}{}^2 - \gamma p_1) \\ \rho &= \rho_1 + \frac{2\rho_1(\rho_1 u_{1n}{}^2 - \gamma p_1)}{2\gamma p_1 + (\gamma+1)\rho_1 u_{1n}{}^2}\,, \end{aligned}\right\} \tag{1}$$

where u_α, p and ρ are the velocity components, the pressure, and the density immediately behind the shock wave; those with the subscript 1 denote the values in front of the shock wave; ν_α are the components of the normal unit vector to the shock line; $u_{1n} = u_{1\alpha}\nu_\alpha$; and γ is the ratio of the specific heats. Differentiating Eq. 1 with respect to the arc-length along the shock line, we obtain[2]

$$\left.\begin{aligned} u_{\alpha,\beta}\lambda_\beta &= A_\alpha \kappa \\ p_{,\beta}\lambda_\beta &= B\kappa \\ \rho_{,\beta}\lambda_\beta &= C\kappa\,, \end{aligned}\right\} \tag{2}$$

where λ_β denote the components of the tangential unit vector to the shock line, the subscript, β denote $\partial/\partial x_\beta$ and κ is the curvature of the shock line. The curvature of the shock line is assumed to be positive for the shock wave convex to the x_2-axis. In the above equations the summation convention is used and this convention will be used throughout this paper. A_α, B and C are given as

$$\left.\begin{aligned} A_1 &= -\lambda_1\lambda_2\left(\frac{4}{\gamma+1} + \frac{[\rho]^2}{\rho\rho_1}\right)v \\ A_2 &= \left\{\frac{4}{\gamma+1}\lambda_1{}^2 - \frac{[\rho]}{\rho}\left(\lambda_1{}^2 + \frac{\rho}{\rho_1}\lambda_2{}^2\right)\right\}v \\ B &= \frac{4}{\gamma+1}\lambda_1\lambda_2\rho v^2 \\ C &= 2\frac{\lambda_1}{\lambda_2}\left(\rho_1 - \frac{\gamma-1}{\gamma+1}\rho\right)\,, \end{aligned}\right\} \tag{3}$$

where $[\rho] = \rho - \rho_1$ and v is the speed of flow immediately behind the shock wave. On the other hand, the flow behind a shock is governed by the following equations

$$\left.\begin{aligned} &p_{,\alpha} + \rho u_\sigma u_{\alpha,\sigma} = 0 && \text{(Equation of motion)} \\ &\rho_{,\alpha} + \rho u_{\sigma,\sigma} = 0 && \text{(Equation of continuity)} \\ &\rho u_{\alpha,\beta} u_\alpha u_\beta - \gamma p u_{\sigma,\sigma} = 0 && \text{(Entropy is constant along each streamline)}\,. \end{aligned}\right\} \tag{4}$$

Solving Eqs. (2) and (4) simultaneously, the first derivatives $u_{\alpha,\beta}$ of the velocity components u_α immediately behind a shock wave are obtained in the form

$$u_{\alpha,\beta} = F_{\alpha\beta}\kappa\,, \tag{5}$$

where

$$\left.\begin{aligned} F_{11}&=\frac{1}{m^2\lambda_2^2-1}\left(\lambda_1\frac{B}{\rho v}+\lambda_2A_2\right)\\ F_{12}&=\frac{1}{\lambda_2}(A_1-\lambda_1F_{11})\\ F_{21}&=-\frac{1}{m^2\lambda_2^2-1}\left\{\lambda_1A_2+\lambda_2(m^2-1)\frac{B}{\rho v}\right\}\\ F_{22}&=(m^2-1)F_{11}\ , \end{aligned}\right\} \tag{6}$$

and m denotes the Mach number immediately behind a shock wave. Further differentiation of the first two of Eq. (2) with respect to the arc-length s along the shock line yields

$$\left.\begin{aligned} u_{\alpha,\beta\gamma}\lambda_\beta\lambda_\gamma&=-u_{\alpha,\beta}\lambda_{\beta,\gamma}\lambda_\gamma+\frac{dA_\alpha}{ds}\kappa+A_\alpha\frac{d\kappa}{ds}\\ p_{,\beta\gamma}\lambda_\beta\lambda_\gamma&=-p_{,\beta}\lambda_{\beta,\gamma}\lambda_\gamma+\frac{dB}{ds}\kappa+B\frac{d\kappa}{ds}\ , \end{aligned}\right\} \tag{7}$$

where

$$\left.\begin{aligned} \frac{dA_1}{ds}&=-\frac{4}{\gamma+1}\left(\lambda_1^2-\frac{\rho}{\rho_1}\lambda_2^2\right)v\kappa-\lambda_1\lambda_2\left(1-\frac{\rho_1}{\rho}\right)v\frac{C\kappa}{\rho}\\ \frac{dA_2}{ds}&=-\frac{4}{\gamma+1}\lambda_1\lambda_2\left(1+\frac{\rho}{\rho_1}\right)v\kappa-\left(\lambda_1^2\frac{\rho_1}{\rho}+\lambda_2^2\right)v\frac{C\kappa}{\rho}\\ \frac{dB}{ds}&=\frac{4}{\gamma+1}\left(\lambda_1^2-\frac{\rho^2}{\rho_1^2}\lambda_2^2\right)\rho_1v^2\kappa\ . \end{aligned}\right\} \tag{8}$$

Differentiating, on the other hand, the first and the third of Eq. (4) along the axes of the coordinate system, we get

$$\left.\begin{aligned} &\rho u_\sigma u_{\alpha,\sigma\gamma}+p_{,\alpha\gamma}=-(\rho_{,\gamma}u_\sigma u_{\alpha,\sigma}+\rho u_{\sigma,\gamma}u_{\alpha,\sigma})\\ &\rho u_\alpha u_\beta u_{\alpha,\beta\gamma}-\gamma p u_{\sigma,\sigma\gamma}=-(\rho_{,\gamma}u_{\alpha,\beta}u_\alpha u_\beta+\rho u_{\alpha,\beta}u_{\alpha,\gamma}u_\beta+\rho u_{\alpha,\beta}u_\alpha u_{\beta,\gamma}-\gamma p_{,\gamma}u_{\sigma,\sigma})\ . \end{aligned}\right\} \tag{9}$$

The respective terms on the right hand sides of Eqs. (7) and (9) can be determined by using the preceding results. Solving Eqs. (7) and (9) simultaneously, these second derivatives of the velocity components immediately behind the shock wave are obtained as follows:

$$u_{\alpha,\beta\gamma}=G_{\alpha\beta\gamma}\frac{d\kappa}{ds}+H_{\alpha\beta\gamma}\kappa^2\ , \tag{10}$$

where

$$\left.\begin{aligned} G_{111}&=-\frac{1}{(m^2\lambda_2^2-1)^2}\left\{2\lambda_1\lambda_2A_2+[\lambda_1^2+(m^2-1)\lambda_2^2]\frac{B}{\rho v}\right\}\\ G_{112}&=\frac{1}{(m^2\lambda_2^2-1)^2}\left\{[\lambda_1^2+(m^2-1)\lambda_2^2]A_2+2(m^2-1)\lambda_1\lambda_2\frac{B}{\rho v}\right\}\\ G_{122}&=\frac{1}{\lambda_2^2}\{-\lambda_1^2G_{111}-2\lambda_1\lambda_2G_{112}+A_1\}\\ G_{211}&=G_{112}\ ,\qquad G_{212}=(m^2-1)G_{111}\ ,\qquad G_{222}=(m^2-1)G_{112} \end{aligned}\right\} \tag{11}$$

$$\left.\begin{aligned} H_{111}&=\frac{1}{(m^2\lambda_2^2-1)^2}\{2(m^2-1)\lambda_1\lambda_2^3L_0-[3\lambda_1^2-(m^2-1)\lambda_2^2]\lambda_2^2L_1\\ &\qquad-2\lambda_1\lambda_2^3L_2+[\lambda_1^2+(m^2-1)\lambda_2^2]L_3-2\lambda_1\lambda_2L_4\}\\ H_{112}&=\frac{1}{(m^2\lambda_2^2-1)^2}\{[\lambda_1^2-3(m^2-1)\lambda_2^2]\lambda_1^2L_0+2\lambda_1^3\lambda_2L_1\\ &\qquad+[\lambda_1^2+(m^2-1)\lambda_2^2]\lambda_2^2L_2-2(m^2-1)\lambda_1\lambda_2L_3+[\lambda_1^2+(m^2-1)\lambda_2^2]L_4\}\\ H_{122}&=\frac{1}{\lambda_2^2}\{-\lambda_1^2H_{111}-2\lambda_1\lambda_2H_{112}+L_5\}\\ H_{211}&=H_{112}-L_0\ ,\qquad H_{212}=(m^2-1)H_{111}-L_1\ ,\qquad H_{222}=(m^2-1)H_{112}-L_2 \end{aligned}\right\} \tag{12}$$

$$\left.\begin{aligned}
L_0&=-\frac{m^2}{v}\left(\frac{\lambda_1}{\lambda_2}F_{11}+F_{12}\right)F_{11}-\frac{1}{\lambda_2}\frac{C}{\rho}F_{11}\\
L_1&=-\frac{m^2}{v}\{[(\gamma-1)m^2+2]F_{11}{}^2+(F_{12}+F_{21})F_{21}\}\\
L_2&=-\frac{m^2}{v}\left\{\frac{\lambda_1}{\lambda_2}m^2F_{11}+(m^2+1)F_{12}+[(\gamma+1)m^2-1]F_{21}\right\}F_{11}-\frac{1}{\lambda_2}\frac{C}{\rho}m^2F_{11}\\
L_3&=-\frac{1}{v}\{-\lambda_1{}^2F_{11}F_{22}+F_{12}F_{21}+\lambda_1\lambda_2m^2F_{11}F_{21}+\lambda_2{}^2F_{22}{}^2\}\\
&\quad-\lambda_2\frac{C}{\rho}F_{21}-\lambda_1F_{21}+\lambda_2F_{11}-\frac{1}{\rho v\kappa}\frac{dB}{ds}\\
L_4&=-\lambda_1F_{22}+\lambda_2F_{21}+\frac{1}{\kappa}\frac{dA_2}{ds}\\
L_5&=-\lambda_1F_{12}+\lambda_2F_{11}+\frac{1}{\kappa}\frac{dA_1}{ds}\ .
\end{aligned}\right\}\qquad(13)$$

§ 3. Directions and Curvatures of the Lines of Constant Speed, Deflection, Pressure, and Density Immediately behind a Shock Wave

Consider the line of constant speed passing through a point on a shock wave. Let l_1 denote the arc length measured from the shock wave along the line (see Fig. 2). Let ψ_1 denote the angle of inclination of this line (say l_1-line) refered to stream-lines. ψ_1 is measured positively counterclockwise. Then,

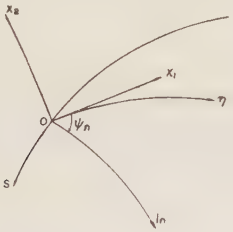

Fig. 2.

$$\frac{dw}{dl_1}=\frac{\partial w}{\partial x_1}\cos\psi_1+\frac{\partial w}{\partial x_2}\sin\psi_1=0$$

since the flow speed $w=\sqrt{u_\sigma u_\sigma}$ is constant along the l_1-line. Hence,

$$\tan\psi_1=-\frac{u_\sigma u_{\sigma,1}}{u_\sigma u_{\sigma,2}}\ . \qquad (14)$$

Evaluating Eq. (14) at the point immediately behind the shock wave, we get

$$\tan\psi_1=-\frac{u_{1,1}}{u_{1,2}} \qquad (15)$$

because of $u_1=v$ and $u_2=0$. Differentiating Eq. (14) along l_1-line and using Eq. (15), we get the expression for the curvature of the line of constant speed immediately behind the shock wave:

$$\frac{d\psi_1}{dl_1}=-\frac{\cos^3\psi_1}{u_{1,2}}\left\{u_{1,11}+2u_{1,12}\tan\psi_1+u_{1,22}\tan^2\psi_1+\frac{1}{v}(u_{2,1}+u_{2,2}\tan\psi_1)^2\right\}\ . \qquad (16)$$

As to the directions and curvatures of the lines of constant deflection, pressure, and density, we can obtain, by the same procedure as above, the following expressions:

$$\left.\begin{aligned}
\tan\psi_2&=-\frac{u_{2,1}}{u_{2,2}}\\
\frac{d\psi_2}{dl_2}&=-\frac{\cos^3\psi_2}{u_{2,2}}\{u_{2,11}+2u_{2,12}\tan\psi_2+u_{2,22}\tan^2\psi_2\}
\end{aligned}\right\}\qquad(17)$$

$$\left.\begin{aligned}
\tan\psi_3&=-\frac{u_{1,1}}{u_{2,1}}\\
\frac{d\psi_3}{dl_3}&=-\frac{\cos^3\psi_3}{u_{2,1}}\Big\{u_{1,11}+(u_{1,12}+u_{2,11})\tan\psi_3+u_{2,12}\tan^2\psi_3\\
&\qquad+\frac{1}{v}(u_{1,2}+u_{2,2}\tan\psi_3)(u_{2,1}+u_{2,2}\tan\psi_3)\Big\}
\end{aligned}\right\}\qquad(18)$$

$$\left.\begin{aligned} \tan\psi_4 &= -\frac{u_{1,1}}{u_{1,2}+\gamma(u_{2,1}-u_{1,2})} \\ \frac{d\psi_4}{dl_4} &= -\frac{\cos^3\psi_4}{\rho_{,2}}\{\rho_{,11}+2\rho_{,12}\tan\psi_4+\rho_{,22}\tan^2\psi_4\}\,, \end{aligned}\right\} \tag{19}$$

where

$$\frac{\rho_{,11}}{\rho_{,2}} = -\frac{u_{\sigma,\sigma1}}{u_{\sigma,\sigma}}\tan\psi_4 - \frac{1}{v}\{u_{2,1}-(u_{\sigma,\sigma}+u_{1,1})\tan\psi_4\}$$

$$\frac{\rho_{,12}}{\rho_{,2}} = -\frac{u_{\sigma,\sigma2}}{u_{\sigma,\sigma}}\tan\psi_4 - \frac{1}{v}\{u_{\sigma,\sigma}+u_{2,2}-u_{1,2}\tan\psi_4\}$$

$$\begin{aligned} \frac{\rho_{,22}}{\rho_{,2}} = &-\frac{\gamma(u_{2,12}-u_{1,22})+u_{1,22}}{u_{1,1}}\tan\psi_4 \\ &+\frac{1}{v}\left\{\frac{u_{\sigma,\sigma}}{\tan\psi_4}+(\gamma u_{\sigma,\sigma}-u_{2,2})\frac{u_{1,2}}{u_{1,1}}-\frac{u_{2,2}{}^2}{u_{1,1}}\tan\psi_4\right\}. \end{aligned}$$

Here, ψ_2, ψ_3, and ψ_4 denote respectively the inclinations of the lines of constant deflection, pressure, and density (say l_2-, l_3-, and l_4-line respectively) against the streamline (see Fig. 2). In general, the differential coefficient of a certain quantity Q along a certain l_n-line is given by

$$\frac{dQ}{dl_n} = Q_{,1}\cos\psi_n + Q_{,2}\sin\psi_n\,.$$

Hence, the differential ratio of any quantities Q and Q' along any l_n-line is given by

$$\left(\frac{\partial Q}{\partial Q'}\right)_{l_n} = \frac{Q_{,1}+Q_{,2}\tan\psi_n}{Q'_{,1}+Q'_{,2}\tan\psi_n}\,, \tag{20}$$

where $Q_{,\beta}$, $Q'_{,\beta}$ and $\tan\psi_n$ all can be expressed with $u_{\alpha,\beta}$.

§4. Pressure Distribution on a Streamline behind a Shock Wave

The pressure distribution on the streamline through the origin of the coordinate system can be expressed in the expansion form:

$$P = p + p'\eta + \frac{1}{2}p''\eta^2 + \cdots\,, \tag{21}$$

where η is the distance measured from the shock wave along the streamline; p is the pressure at the origin and has been given in Eq. (1); p' and p'' are the first and the second derivatives of the pressure with respect to η at the origin, and are deduced from Eqs. (4) and (9) as follows

$$\left.\begin{aligned} p' &= -\rho v u_{1,1} \\ p'' &= -\rho v u_{1,11} + \rho(u_{1,1}u_{1,2} - u_{1,2}u_{2,1} - u_{2,1}{}^2)\,. \end{aligned}\right\} \tag{22}$$

On the other hand, the curvature of the streamline and its variation along the streamline can be expressed at the origin as

$$\left.\begin{aligned} K &= \frac{u_{2,1}}{v} \\ \frac{dK}{d\eta} &= \frac{1}{v}u_{2,11} - \frac{2}{v^2}u_{2,1}u_{1,1} + \frac{1}{v^2}u_{2,1}u_{2,2}\,, \end{aligned}\right\} \tag{23}$$

where K is assumed to be positive when the streamline is concave toward the positive direction of the x_2-axis. Elimination of κ and $d\kappa/d\eta$ from Eqs. (22) and (23) (see Eqs. (5) and (10)) yields

$$\left.\begin{aligned} p' &= -\rho v^2 \frac{F_{11}}{F_{21}} K \\ p'' &= -\rho v^2 \left\{ \frac{G_{111}}{G_{211}} \frac{dK}{d\eta} + \left[\frac{G_{111}}{G_{211}} (-vH_{211} + 2F_{11}F_{21} - F_{21}F_{22}) \right.\right. \\ &\qquad \left.\left. + vH_{111} - F_{11}F_{22} + F_{12}F_{21} + F_{21}^2 \right] \frac{K^2}{F_{21}^2} \right\} . \end{aligned}\right\} \tag{24}$$

As an example of applying Eq. (24) to a practical problem, we shall obtain the pressure distribution near the leading edge along the surface of a circular-arc profile with an attached shock wave (see Fig. 3). For a circular-arc profile,

$$\frac{dK}{d\eta} = 0 \qquad \text{and} \qquad \eta = -\frac{1}{K}(\omega - \theta) ,$$

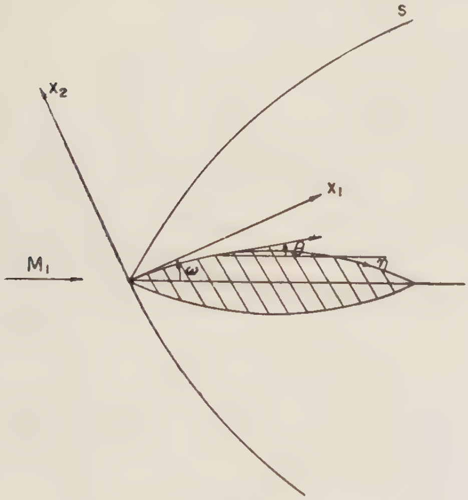

Fig. 3.

where θ denotes the angle which the tangent to the profile makes with the direction of the uniform flow in front of the shock wave and ω denotes the direction of x_1-axis refered to the uniform flow. In Fig. 4, the values $\frac{1}{K}\frac{p'}{p}$ and $\frac{1}{K^2}\frac{p''}{p}$ are shown against the Mach number M_1 associated with the uniform flow in front of the shock wave for $\omega = 10°$, 20°, and 30°. The pressure distribution in the neighbourhood of the leading edge of the circular-arc profile in the uniform stream of $M_1 = 3$ and 4, respectively, is shown in Fig. 5 for the case $\omega = 30°$. For comparison, Thomas' result is plotted in Fig. 5 too.[3] His method is, by considering pressure as a function of θ and entropy S, to derive the pressure over the surface of the profile from the pressure immediately behind the shock wave. He gives the following formula which is correct to the first order in the entropy change.

$$P = p + \left(\frac{\partial p}{\partial S}\right)_\theta \Delta S . \tag{25}$$

The coefficient $(\partial p/\partial S)_\theta$ can be obtained by taking $Q = p$, $Q' = S$, and $n = 2$ in Eq. (20) as

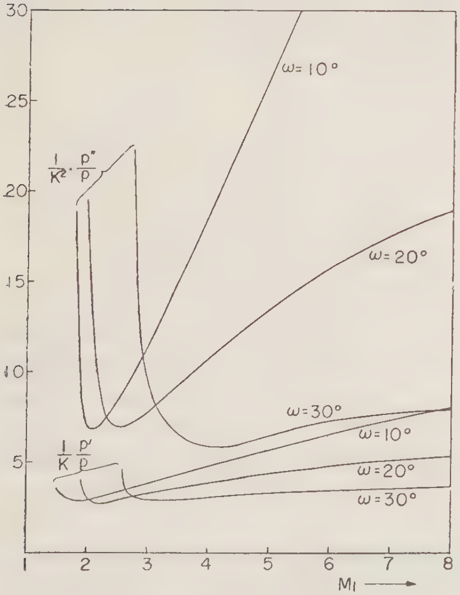

Fig. 4. Values $\frac{1}{K}\frac{p'}{p}$ and $\frac{1}{K^2}\frac{p''}{p}$ for the circular-arc profile at $\omega = 10°$, 20°, and 30°.

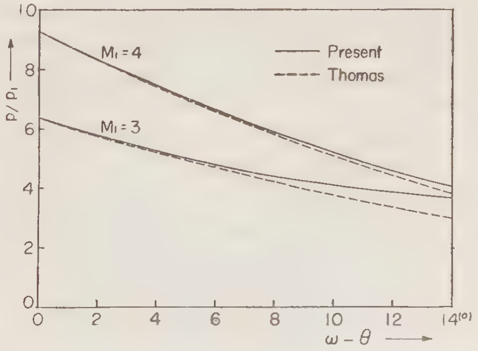

Fig. 5. Pressure distribution near the leading edge of the circular-arc profile (for $M_1 = 3$ and 4; $\omega = 30°$).

follows:

$$\left(\frac{\partial p}{\partial S}\right)_\theta=\frac{p}{R}\frac{u_{1,1}u_{2,2}-u_{2,1}{}^2}{u_{2,1}(u_{2,1}-u_{1,2})}. \tag{26}$$

And

$$\Delta S=\frac{R}{\gamma-1}\left\{\ln\frac{p}{p_1}\left(\frac{\rho_1}{\rho}\right)^\gamma-\ln\frac{p_0}{p_1}\left(\frac{\rho_1}{\rho_0}\right)^\gamma\right\}, \tag{27}$$

where p_0 and ρ_0 denote the values of p and ρ immediately behind the shock wave at the leading edge, and R is the gas constant.

§ 5. Flow in the Vicinity of the Point at which the Spine Coincides with the Shock Polar

The directions of the spine and shock polar in the hodograph plane are given, respectively, by

$$\frac{u_{2,1}}{u_{1,1}} \quad \text{and} \quad \frac{u_{2,\sigma}\lambda_\sigma}{u_{1,\sigma}\lambda_\sigma}. \tag{28}$$

Hence, the condition that these two coincide is

$$\frac{u_{2,1}}{u_{1,1}}-\frac{u_{2,\sigma}\lambda_\sigma}{u_{1,\sigma}\lambda_\sigma}=0. \tag{29}$$

Using Eqs. (2), (3), (5) and (6), the above condition can be transformed as

$$\begin{aligned}(M_1{}^2\sin^2\alpha_c-1)\{&4\gamma^2(\gamma-1)M_1{}^6\sin^6\alpha_c\\&-[2\gamma(\gamma^2-1)M_1{}^2-2(9\gamma^2-4\gamma-1)]M_1{}^4\sin^4\alpha_c\\&-[(\gamma+1)(\gamma^2+6\gamma-3)M_1{}^2\\&+2(\gamma^2-12\gamma-1)]M_1{}^2\sin^2\alpha_c\\&-[2(\gamma+1)(\gamma+3)M_1{}^2+4(\gamma-1)]\}=0,\end{aligned} \tag{30}$$

where α_c is the shock angle at the point where the directions of the spine and shock polar coincide in the hodograph plane. Fig. 6 shows the M_1-α_c curve. Since we assume the uniform flow ahead of the shock front in the present paper, the portion of the α_c-curve for $M_1<(2/\sqrt{3})$ must be left out of consideration, except for the case $M_1\sin\alpha_c-1=0$ when the shock wave degenerates into a Mach line. Thus, the directions of the spine and shock polar coincide at the point in the supersonic region for $(2/\sqrt{3})<M_1<\sqrt{(\gamma^2+4\gamma-5)/(\gamma+3)}$ ($=1.69$ for $\gamma=1.4$), whilst at the point in the subsonic region between the sonic point and the maximum deflection point for $M_1>\sqrt{(\gamma^2+4\gamma-5)/(\gamma+3)}$ (see Fig. 7).

By introducing a Jacobian J such that

$$J=\frac{\partial(u_1,u_2)}{\partial(x_1,x_2)}=u_{1,1}u_{2,2}-u_{2,1}u_{2,1}, \tag{31}$$

the condition (29) can be rewritten as

$$J=0.$$

This shows that the Jacobian defined as above vanishes at the point where the directions of the spine and shock polar coincide. Since $J_{,\alpha}$ does not vanish in general, this is the singular point of first order and there exists the singular line starting from this point[4].

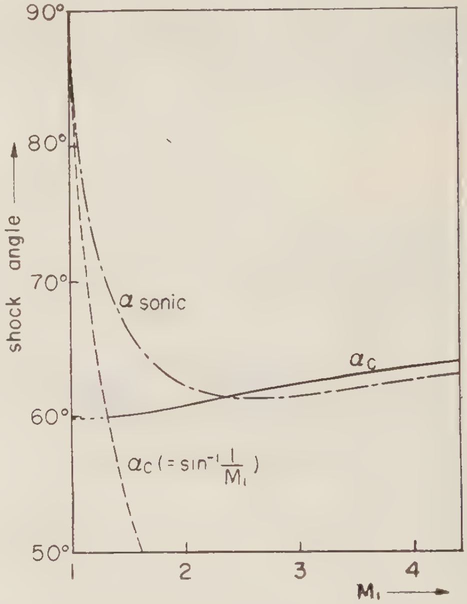

Fig. 6. Curves α_c versus M_1. α_c denotes the shock angle when the directions of the spine and shock polar coincide; α_{sonic} denotes the shock angle at which the velocity immediately behind the shock is sonic.

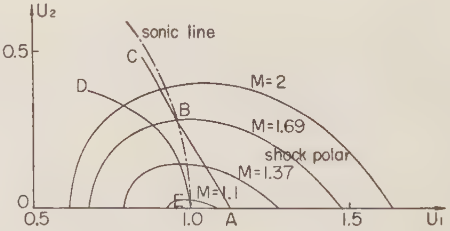

Fig. 7. Hodograph plane; curve ABC is the locus of the point where the spine coincides with the shock polar. In the right hand side of curve DE, there occurs multiplicity of the flow pattern for the inflected shock wave.

Let us assume the singular line to be expressed in the form

$$x_2=bx_1+\cdots. \tag{32}$$

Then, the coefficient b can be determined by inserting Eq. (32) into

$$J=\frac{\partial U_1}{\partial x_1}\frac{\partial U_2}{\partial x_2}-\frac{\partial U_1}{\partial x_2}\frac{\partial U_2}{\partial x_1}=0\,, \tag{33}$$

where

$$\frac{\partial U_\alpha}{\partial x_\beta}=u_{\alpha.\beta}+u_{\alpha,\beta\gamma}x_\gamma+\cdots\ .$$

The streamlines in the vicinity of the origin satisfy the equation

$$\frac{dx_2}{dx_1}=\frac{u_{2,\sigma}x_\sigma+\frac{1}{2}u_{2,\alpha\beta}x_\alpha x_\beta+\cdots}{v+u_{1,\sigma}x_\sigma+\frac{1}{2}u_{1,\alpha\beta}x_\alpha x_\beta+\cdots}\ . \tag{34}$$

We assume that the streamlines in the neighbourhood of the origin are expressed in the form

$$x_2=a_0+a_1x_1+\tfrac{1}{2}a_2x_1^2+\cdots\ . \tag{35}$$

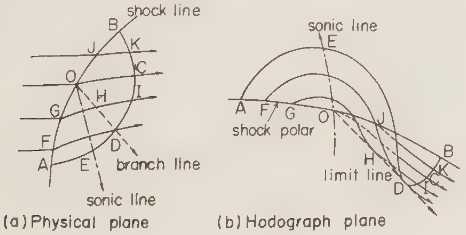
Then the coefficients a_1 and a_2 can be expressed with a_0 by inserting Eq. (35) into Eq. (34) and by equating the terms of same order in x_1 on the both sides. The transformation from the physical plane to the hodograph plane is performed by

$$U_\alpha=u_\alpha+u_{\alpha,\beta}x_\beta+\tfrac{1}{2}u_{\alpha,\beta\gamma}x_\beta x_\gamma+\cdots\ . \tag{36}$$

In the special case where

$$M_1=\sqrt{(\gamma^2+4\gamma-5)/(\gamma+3)}\ ,$$

the spine coincides with the shock polar at the sonic point. In this case, the calculation is simplified since $u_{1,2}=u_{2,2}=u_{2,22}=0$ and hence $a_1=0$. Fig. 8-a shows the streamlines and the branch line in the physical plane for $\kappa=1$, $d\kappa/ds=0$. Fig. 8-b shows schematically the image of these in the hodograph plane.



(a) Physical plane (b) Hodograph plane

Fig. 8. Flow pattern in the vicinity of the point at which shock spine coincides with shock polar ($M_1=1.69$, $\kappa=1$ and $d\kappa/ds=0$).

§6. Flow in the Vicinity of an Inflection Point

If a shock wave has an inflection point, as in the case of a detached shock wave which lies upstream in a wind tunnel at a low supersonic choked state[5)], $u_{\alpha,\beta}=0$ since $\kappa=0$ at that point. Hence, in such a case

$$J=J_{,\alpha}=0 \tag{37}$$

at this points. Thus, this is a singular point of the second order[4)], and is isolated only for

$$\begin{aligned}D\equiv&(u_{1,11}u_{2,22}-u_{1,22}u_{2,11})^2\\&-4(u_{1,12}u_{2,22}-u_{1,22}u_{2,12})\\&\times(u_{1,11}u_{2,12}-u_{1,12}u_{2,11})<0\ .\end{aligned} \tag{38}$$

When the shock angle at the inflection point is less than a certain value, the flow behind it has a multiplicity in the hodograph plane. Such a state occurs at the points in the subsonic region (see Fig. 7). The streamlines and the branch lines in the vicinity of an inflection point and their corresponding hodograph images can be obtained by the same way as in the preceding section. In Fig. 9, the directions of the branch lines, the shock line, and the streamline passing through the inflection point are shown as the functions of the shock angle α_i for $M_1=2$. In this case, the singular point is isolated for $\alpha_i>68.9°$, while there exist two branch lines for $\alpha_i<68.9°$. For $68.9°>\alpha_i>62.3°$, only the streamlines through the shock segment concave to the flow behind it traverse the two branch lines. Fig. 10 shows the streamlines and the

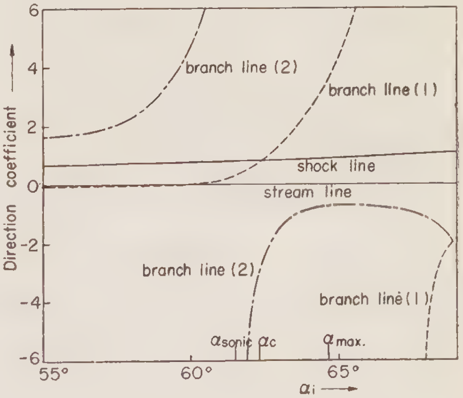


Fig. 9. Directions of the branch lines, the shock line, and the streamline passing through the inflection point for the case $M_1=2$.

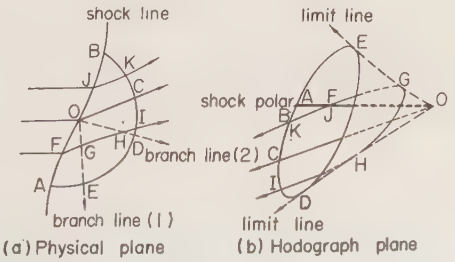
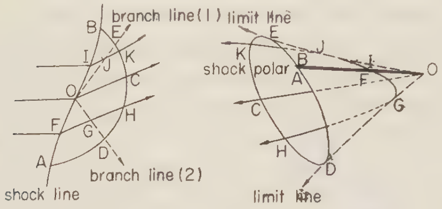


(a) Physical plane (b) Hodograph plane

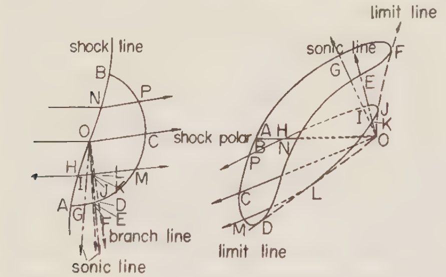
Fig. 10. Flow pattern in the vicinity of the inflection point. ($M_1=2$; $\alpha_i=64.7°$)

branch lines for $\alpha_i=64.7°$ in the physical plane and the corresponding schematic pattern in the hodograph plane. The value $\alpha_i=64.7°$ is the shock angle at the maximum deflection point for case $M_1=2$. For $62.3°>\alpha_i>59.6°$ every streamline traverses one branch line. Here, $\alpha_i=59.6°$ corresponds to the case when one of the branch lines coincides with the streamline. Fig. 11 shows the streamlines and the branch lines in the physical plane and the corresponding schematic hodograph pattern for $\alpha_i=62°$. For $\alpha_i<59.6°$, the two branch lines are traversed only by the streamlines through the shock segment concave to the flow behind it.



(a) Physical plane (b) Hodograph plane

Fig. 11. Flow pattern in the vicinity of the inflection point. ($M_1=2$; $\alpha_i=62°$)



(a) Physical plane (b) Hodograph plane

Fig. 12. Flow pattern in the vicinity of the inflection point. ($M_1=1.3$; $\alpha_i=65°7'$ sonic point))

Let us consider the case when the inflection occurs at the sonic point. If the sonic lines starting from this point are assumed to be expressed in the form,

$$x_2=cx_1+\cdots\ , \tag{39}$$

c can be determined by inserting above expression into

$$\left.\begin{aligned} &U_\alpha U_\alpha=a_*^2\\ &U_1=a_*+\tfrac{1}{2}u_{1,\alpha\beta}x_\alpha x_\beta+\cdots\\ &U_2=\tfrac{1}{2}u_{2,\alpha\beta}x_\alpha x_\beta+\cdots\ , \end{aligned}\right\} \tag{40}$$

where a_* denotes the sonic speed. Thus, there exist the real values of c for

$$u_{1,12}{}^2-u_{1,11}u_{2,11}\geqq 0\ . \tag{41}$$

So that, it is possible that there exists a local supersonic region behind the inflection point. This is the case, in fact, when the Mach number is less than 1.37. Fig. 12 shows the streamlines, the branch lines, and the sonic lines in the physical plane for $M_1=1.3$ together with the corresponding schematic hodograph pattern.

Two-Dimensional Supersonic Jet of a Conducting Inviscid Gas in the Presence of a Uniform Magnetic Field

By Shigeki MORIOKA

Department of Physics and Mathematics, Faculty of Science and Engineering, Ritumeikan University, Kyoto

(Received February 20, 1961)

The behaviour of the two-dimensional supersonic jet of an ideal gas with weak electric conductivity in the presence of a uniform magnetic field is considered on the basis of the linearized theory. In general, the boundary of the jet can be expressed by the formula which contains the terms yielding the monotonic change of the width of the jet and its deflection due to the inclination of the lines of force in addition to the term in the ordinary gasdynamics. The expressions for these terms are shown explicitly.

§1. Introduction

The problems of jet in the ordinary gasdynamics have been investigated in detail by S. I. Pai, D. C. Pack, and others[1,2]. On the other hand, the behaviour of the jet of a perfectly conducting gas in the presence of a magnetic field parallel to the stream can be obtained by making suitable substitution of the parameters in the known results of the linearized theory for the ordinary gasdynamic case[3]. In this paper, we consider the behaviour of the two-dimensional supersonic jet of an ideal gas with weak conductivity in the presence of a uniform magnetic field.

Let a jet issue as a uniform, supersonic stream of an ideal gas from a nozzle of a semi-width L, with velocity U_1, pressure p_1, density ρ_1, ratio of the specific heats γ_1, and electric conductivity σ into a conducting ideal gas with pressure p_2, density ρ_2, ratio of the specific heats γ_2. (The electric conductivity of the surrounding fluid may be arbitrary in Secs. 2 and 4 since we assume that $\boldsymbol{E}+\mu\boldsymbol{v}\times\boldsymbol{H}=0$. On the other hand, in Sec. 3 it must be so small that $\boldsymbol{j}=\sigma(\boldsymbol{E}+\mu\boldsymbol{v}\times\boldsymbol{H})$ is negligible for the value $\boldsymbol{E}+\mu\boldsymbol{v}\times\boldsymbol{H}$ assumed to be sufficiently small. Here, μ, $\boldsymbol{v}$, $\boldsymbol{H}$ and $\boldsymbol{E}$ denote permeability, velocity, magnetic- and electric-field intensity respectively.) The heat-conductivity and viscosity are neglected. We assume that the difference of the pressures p_1-p_2 is small compared with p_1 and that the interaction between the magnetic field and the conducting stream is sufficiently small. Therefore, the problem can be linearized. In the following, we consider three cases: (1) the surrounding fluid is at rest, a uniform magnetic field exists, and N, $Rm\ll 1$; (2) the surrounding fluid moves with a supersonic velocity $\boldsymbol{U}_2$ to the same direction as the jet, a uniform magnetic field $\boldsymbol{H}$ and a uniform electric field $\boldsymbol{E}=-\mu(\boldsymbol{U}_2\times\boldsymbol{H})$ exist, and N, $Rm\ll 1$; (3) the surrounding fluid is at rest, a strong magnetic field parallel to the jet exists, and $N\simeq 1$ though $Rm\ll 1$. Here, $N=RmS$; $Rm=\sigma\mu U_1L$ and $S=\mu H^2/\rho_1U_1^2$ are respectively the magnetic Reynolds number and the pressure number in the jet; and μ is assumed to be constant everywhere. These cases will be formulated as the boundary value problems and will be solved by using Laplace transformation in Sections 2, 3 and 4, respectively.

The fundamental relations necessary in the following are

$$\left.\begin{aligned}
&\operatorname{div}(\rho\boldsymbol{v})=0\,,\\
&\rho(\boldsymbol{v}\operatorname{grad})\boldsymbol{v}=-\operatorname{grad}p+\mu(\boldsymbol{j}\times\boldsymbol{H})\\
&\operatorname{div}\boldsymbol{H}=0\,,\\
&\operatorname{rot}\boldsymbol{H}=\boldsymbol{j}\,,\\
&\boldsymbol{j}=\sigma(\boldsymbol{E}+\mu\boldsymbol{v}\times\boldsymbol{H})\,,\\
&\rho(\boldsymbol{v}\operatorname{grad})p-\gamma p(\boldsymbol{v}\operatorname{grad})\rho=(\gamma-1)\rho(\boldsymbol{j}^2/\sigma)\,.
\end{aligned}\right\} \tag{1}$$

The electric field $\boldsymbol{E}$ is constant for two-dimensional motion and it is assumed to be zero in Cases 1 and 3 and to be $-\mu(\boldsymbol{U}_2\times\boldsymbol{H})$ in Case 2.

§2. Jet Issuing into a Fluid at Rest

In this section, we consider the two-dimensional supersonic jet of a conducting gas issuing into a fluid at rest in the presence of a uniform magnetic field. We choose the origin of the coordinate system at the middle of the exit, and we take the x-axis parallel to the direction of the velocity at the exit and the y-axis perpendiculary to it. The inclination of the magnetic field is assumed to be α with respect to the x-axis. Then, we can put as follows,

$$\left.\begin{aligned} &\boldsymbol{v}=U_1(1+u')\boldsymbol{e}_1+U_1v'\boldsymbol{e}_2\ ,\\ &\boldsymbol{H}=\lambda_1H(1+h_x')\boldsymbol{e}_1+\lambda_2H(1+h_y)\boldsymbol{e}_2\ ,\\ &\boldsymbol{E}=0\ ,\ p=p_1(1+p')\ ,\ \rho=\rho_1(1+\rho')\ ,\end{aligned}\right\} \qquad (2)$$

where $\boldsymbol{e}_1$ and $\boldsymbol{e}_2$ denote the fundamental unit vectors; $\lambda_1=\cos\alpha$; $\lambda_2=\sin\alpha$; and u', v', h_x', h_y', p' and ρ' are dimensionless small quantities. The space coordinates are made non-dimensional with L. Substituting Eq. (2) into Eq. (1) and neglecting higher order terms, we obtain

$$\left.\begin{aligned} &\frac{\partial v'}{\partial x}-\frac{\partial u'}{\partial y}=N\lambda_1\lambda_2\ ,\\ &-(M_1^2-1)\frac{\partial u'}{\partial x}+\frac{\partial v'}{\partial y}=\gamma_1M_1^2N\lambda_2^2\ ,\\ &\lambda_1\frac{\partial h_x'}{\partial x}+\lambda_2\frac{\partial h_y'}{\partial y}=0\ ,\\ &\lambda_2\frac{\partial h_y'}{\partial x}-\lambda_1\frac{\partial h_x'}{\partial y}=Rm\lambda_2\ ,\\ &p'=-\gamma_1M_1^2(u'+N\lambda_2^2x)\ ,\\ &\rho'=-M_1^2(u'+\gamma_1N\lambda_2^2x)\ ,\end{aligned}\right\} \qquad (3)$$

where $M_1=U_1/\sqrt{\gamma_1p_1/\rho_1}$ is the Mach number and N, Rm are assumed to be sufficiently small. We introduce the velocity potential defined by

$$u'=\frac{\partial\phi}{\partial x}\ ,\qquad v'=\frac{\partial\phi}{\partial y}+N\lambda_1\lambda_2x\ . \qquad (4)$$

Then, it satisfies the equation

$$-(M_1^2-1)\frac{\partial^2\phi}{\partial x^2}+\frac{\partial^2\phi}{\partial y^2}=\gamma_1M_1^2N\lambda_2^2\ . \qquad (5)$$

On the other hand, multiplying the element ds of a streamline by the modified momentum equation;

$$\frac{1}{2}\ \mathrm{grad}\ \boldsymbol{v}^2-\boldsymbol{v}\times\mathrm{rot}\ \boldsymbol{v}+\frac{1}{\rho}\mathrm{grad}\ p$$

$$-\frac{\mu}{\rho}(\boldsymbol{j}\times\boldsymbol{H})=0\ ,$$

and integrating it along a streamline under the approximation of Eq. 2, we get the relation

$$p=p_1-\rho_1U_1^2u'-\sigma\mu^2U_1H^2\lambda_2^2x\ .$$

Then, the condition that the pressure is constant on the boundary of the jet can be expressed as

$$\frac{\partial\phi}{\partial x}=\varepsilon-N\lambda_2^2x\quad \text{for}\quad x>0\ ,\quad |y|=1\ , \qquad (6)$$

where $\varepsilon=(p_1-p_2)/\rho_1U_1^2$. As the condition at the exit, we assume a uniform flow; that is,

$$\phi=\frac{\partial\phi}{\partial x}=0\qquad \text{for}\quad x=0\ ,\quad |y|<1\ . \qquad (7)$$

If we assume $\sigma\neq0$ for $x<0$ and $\lambda_1\lambda_2\neq0$, the flow is rotational upstream of the exit ($x<0$) as is seen from Eq. 3. Therefore, in order that this condition (7) is valid for the given shape of the nozzle in the presence of a uniform magnetic field and is consistent with the basic equations, we must assume that the flow of the jet has no conductivity upstream of the exit, i.e., for $x<0$, except for the case $\lambda_1\lambda_2=0$. This assumption means the abrupt rising of the temperature leading to the ionization of the gas at the exit. It, however, may be permissible as a model of practical jet exhausts. The Laplace transformation of Eqs. (5) and (6) leads to

$$\frac{\partial^2\overline{\phi}}{\partial y^2}-(M_1^2-1)s^2\overline{\phi}=\frac{\gamma_1M_1^2N\lambda_2^2}{s}\ , \qquad (8)$$

$$\overline{\phi}=\frac{\varepsilon}{s^2}-\frac{N\lambda_2^2}{s^3}\quad \text{for}\quad x<0\ ,\quad |y|=1\ , \qquad (9)$$

where $\overline{\phi}=\int_0^x e^{-sx}\phi(x,y)dx$ and Eq. (7) has been used. The solution of Eq. (8) which satisfies Eq. (9) can be found as

$$\overline{\phi}=\frac{(\varepsilon/s^2)+(\delta/s^3)}{e^{m_1s}+e^{-m_1s}}(e^{m_1sy}+e^{-m_1sy})-\frac{\gamma_1M_1^2N\lambda_2^2}{m_2^2s^3}\ , \qquad (10)$$

where

$$\delta=\frac{[(\gamma_1-1)M_1^2+1]N\lambda_2^2}{m_1^2}\quad \text{and}\quad m_1^2=M_1^2-1\ .$$

If we assume the boundary of the jet in the form $y=\pm1+F(x)_\pm$, then

$$F(x)_\pm=\int_0^x\left[\frac{\partial\phi}{\partial y}\right]_{y=\pm1}dx+\frac{1}{2}N\lambda_1\lambda_2x^2\ .$$

Hence, the Laplace transformation yields

$$\overline{F}(s)_\pm=\pm\left(\frac{m_1\varepsilon}{s^2}+\frac{m_1\delta}{s^3}\right)\tanh m_1s+N\lambda_1\lambda_2\frac{1}{s^3}\ .$$

By making the inverse transformation, the boundary of the jet can be found as

$$\begin{aligned} F(x)_\pm=&\pm m_1\varepsilon H(x,4m_1)\\ &\pm m_1\delta\int_0^x H(x,4m_1)dx+\frac{1}{2}N\lambda_1\lambda_2x^2\ , \end{aligned} \qquad (11)$$

where $H(x, 4m_1)=\begin{cases} x \ (0\leq x\leq 2m_1) \\ 4m_1-x \ (2m_1\leq x\leq 4m_1) \end{cases}$ is a triangular wave function. The first term is the same as that in the gasdynamic case; the second term, which has the integrated form of the function in the first term, expresses the monotonic spreading of the width of the jet; and the third term expresses the deflection of the whole jet due to the inclination of the lines of force.

§ 3. Jet Issuing into a Uniform Supersonic Stream

We consider, in this section, the two-dimensional supersonic jet of a conducting gas issuing into a uniform supersonic stream with a velocity U_2 parallel to the jet in the presence of a uniform magnetic field $\boldsymbol{H}$ and a uniform electric field $\boldsymbol{E}=-\mu(\boldsymbol{U}_2\times\boldsymbol{H})$. This corresponds to the case in which we observe the jet that issues with velocity U_1 relative to the moving nozzle with velocity U_2, in the coordinate system moving with the velocity U_2. Introducing the velocity potentials ϕ_1, ϕ_2 defined by

$$\left.\begin{aligned} u_1'&=\frac{\partial\phi_1}{\partial x}, & v_1'&=\frac{\partial\phi_1}{\partial y}+\eta N\lambda_1\lambda_2 x, \\ u_2'&=\frac{\partial\phi_2}{\partial x}, & v_2'&=\frac{\partial\phi_2}{\partial y}, \end{aligned}\right\} \qquad (12)$$

(where, suffices 1 and 2 refer respectively to the jet and to the surrounding fluid), by the procedure similar to that in the preceding section, we can obtain the following boundary value problem for the present case;

$$\left.\begin{aligned} &-(M_1^2-1)\frac{\partial^2\phi_1}{\partial x^2}+\frac{\partial^2\phi_1}{\partial y^2}=[(\gamma_1-1)\eta+1]\eta M_1^2 N\lambda_2^2 \quad \text{(for jet)}, \\ &-(M_2^2-1)\frac{\partial^2\phi_2}{\partial x^2}+\frac{\partial^2\phi_2}{\partial y^2}=0 \quad \text{(for surrounding stream)}, \end{aligned}\right\} \qquad (13)$$

$$\left.\begin{aligned} &\phi_1=\frac{\partial\phi_1}{\partial x}=0 \quad \text{for} \quad x=0, \quad |y|<1, \\ &\phi_2=\frac{\partial\phi_2}{\partial x}=0 \quad \text{for} \quad x=0, \quad |y|>1, \\ &\phi_2<\infty \qquad \text{at} \quad |y|\to\infty, \\ &\left.\begin{aligned} &\frac{\partial\phi_1}{\partial x}-\beta\frac{\partial\phi_2}{\partial x}=\varepsilon-\eta N\lambda_2^2 x \\ &\frac{\partial\phi_1}{\partial y}-\frac{\partial\phi_2}{\partial y}=-\eta N\lambda_1\lambda_2 x \end{aligned}\right\} \quad \text{for} \quad x>0, \quad |y|=1, \end{aligned}\right\} \qquad (14)$$

where $\eta=1-\dfrac{U_2}{U_1}$ and $\beta=\dfrac{\rho_2 U_2^2}{\rho_1 U_1^2}=\dfrac{\gamma_1 M_1^2}{\gamma_2 M_2^2}$. Here, for the condition at the exit of the nozzle, we must again make the same assumption as that in the preceding section; that is, it must be assumed that the flow of the jet has the conductivity only for $x>0$, except for the case $\lambda_1\lambda_2=0$. The Laplace transformations of Eqs. (13) and (14) yield

$$\left.\begin{aligned} &\frac{\partial^2\phi_1}{\partial y^2}-m_1^2 s^2\overline{\phi_1}=[(\gamma_1-1)\eta+1]\eta M_1^2 N\lambda_2^2/s, \\ &\frac{\partial\overline{\phi_2}}{\partial y^2}-m_2^2 s^2\overline{\phi_2}=0, \end{aligned}\right\} \qquad (15)$$

$$\left.\begin{aligned} &\overline{\phi_2}<\infty \quad \text{at} \quad |y|\to\infty, \\ &\left.\begin{aligned} &\overline{\phi_1}-\beta\overline{\phi_2}=\frac{\varepsilon}{s^2}-\frac{\eta N\lambda_2^2}{s^3} \\ &\frac{\partial\overline{\phi_1}}{\partial y}-\frac{\partial\overline{\phi_2}}{\partial y}=-\frac{\eta N\lambda_1\lambda_2}{s^2} \end{aligned}\right\} \quad \text{for} \quad x>0, \quad |y|=1. \end{aligned}\right\} \qquad (16)$$

The solution of Eq. (15) which satisfies the conditions of Eq. (16) is found as

$$\overline{\phi_1}=\frac{m\mathcal{E}}{m+\beta}\frac{1}{s^2}\frac{e^{m_1sy}+e^{-m_1sy}}{e^{m_1s}+\nu e^{-m_1s}}+\frac{m\delta'}{m+\beta}\frac{1}{s^3}\frac{e^{m_1sy}+e^{-m_1sy}}{e^{m_1s}+\nu e^{-m_1s}}-\frac{\beta\zeta}{m+\beta}\frac{1}{s^3}\frac{e^{m_1sy}-e^{-m_1sy}}{e^{m_1s}-\nu e^{-m_1s}}$$
$$-\frac{[(\gamma_1-1)\eta+1]\eta M_1{}^2N\lambda_2{}^2}{m_1{}^2s^3}, \tag{17}$$

where

$$\left.\begin{aligned}&m=\frac{m_2}{m_1}=\frac{\sqrt{M_2{}^2-1}}{\sqrt{M_1{}^2-1}}, \qquad \nu=\frac{m-\beta}{m+\beta},\\ &\delta'=[(\gamma_1-1)M_1{}^2\eta+1]\eta N\lambda_2{}^2/m_1{}^2,\\ &\zeta=\eta N\lambda_1\lambda_2/m_1{}^2.\end{aligned}\right\} \tag{18}$$

Hence

$$\overline{F}(s)_\pm=\frac{1}{s}\left[\frac{\partial\overline{\phi_1}}{\partial y}\right]_{y=\pm1}+\eta N\lambda_1\lambda_2\frac{1}{s^3}=\pm\frac{m_2\mathcal{E}}{m+\beta}\frac{1}{s^2}\frac{1-e^{-2m_1s}}{1+\nu e^{-2m_1s}}\pm\frac{m_2\delta'}{m+\beta}\frac{1}{s^3}\frac{1-e^{-2m_1s}}{1+\nu e^{-2m_1s}}$$
$$-\frac{m_1\beta\zeta}{m+\beta}\frac{1}{s^3}\frac{1+e^{-2m_1s}}{1+\nu e^{-2m_1s}}+\eta N\lambda_1\lambda_2\frac{1}{s^3}.$$

The inverse transformation yields the following expression for the boundary of the jet in the neighbourhood of the exit.

$$F(x)_\pm=\pm\frac{m_2\mathcal{E}}{m+\beta}\left\{x-(1+\nu)\sum_{n=1}^{\infty}(-\nu)^{n-1}(x-2n\cdot m_1)\cdot u(x-2n\cdot m_1)\right\}$$
$$\pm\frac{m_2\delta'}{m+\beta}\int_0^x\left\{x-(1+\nu)\sum_{n=1}^{\infty}(-\nu)^{n-1}(x-2n\cdot m_1)\cdot u(x-2n\cdot m_1)\right\}dx$$
$$-\frac{m_1\beta\zeta}{m+\beta}\int_0^x\left\{x+(1+\nu)\sum_{n=1}^{\infty}\nu^{n-1}(x-2n\cdot m_1)\cdot u(x-2n\cdot m_1)\right\}dx+\frac{1}{2}\eta N\lambda_1\lambda_2x^2, \tag{19}$$

where $u(x-x_0)=\begin{cases}0 & (x<x_0)\\ 1 & (x>x_0)\end{cases}$ is a unit step function. The first term is the same as that in the gasdynamic case; the second term, which has the integrated form of the function in the first term, expresses the monotonic spreading or contracting of the width of the jet due to the magnetic field according as $\delta'>0$ $\left(0<\frac{U_2}{U_1}<1 \text{ or } \frac{U_2}{U_1}>1+\frac{1}{(\gamma_1-1)M_1{}^2}\right)$ or $\delta'<0$ $\left(1<\frac{U_2}{U_1}<1+\frac{1}{(\gamma_1-1)M_1{}^2}\right)$; and the third and the fourth terms express as a whole the deflection of the jet due to the inclination of the lines of force. Here it should be noticed that the direction of the deflection changes at $U_2=U_1$. On the other hand, the stream line through the origin is expressed by

$$F(x)_{y=0}=-\frac{2m_1\beta\zeta}{m+\beta}\int_0^x\left\{\sum_{n=1}^{\infty}\nu^{n-1}[x-(2n-1)m_1]\cdot u[x-(2n-1)m_1]\right\}dx+\frac{1}{2}\eta N\lambda_1\lambda_2x^2. \tag{20}$$

§ 4. Jet of a Weakly Conducting Gas Issuing into the Fluid at Rest in the Presence of a Strong Magnetic Field Parallel to the *x*-Axis

In this case, we can put as follows,

$$\left.\begin{aligned}&\boldsymbol{v}=U_1(1+u')\boldsymbol{e}_1+U_1v'\boldsymbol{e}_2,\\ &\boldsymbol{H}=H(1+h_x')\boldsymbol{e}_1+Hh_y'\boldsymbol{e}_2,\\ &\boldsymbol{E}=0, \quad p=p_1(1+p'), \quad \rho=\rho_1(1+\rho').\end{aligned}\right\} \tag{21}$$

Then, Eq. (1) reduces to

$$\left.\begin{aligned}
&\frac{\partial u'}{\partial x}+\frac{\partial v'}{\partial y}+\frac{\partial \rho'}{\partial x}=0\,,\\
&\frac{\partial u'}{\partial x}=-\frac{1}{\gamma_1 M_1^2}\frac{\partial p'}{\partial x}\,,\\
&\frac{\partial v'}{\partial x}=-\frac{1}{\gamma_1 M_1^2}\frac{\partial p'}{\partial y}+N(h'-v')\,,\\
&\frac{\partial h_x'}{\partial x}+\frac{\partial h_y'}{\partial y}=0\,,\\
&\frac{\partial h_y'}{\partial x}-\frac{\partial h_x'}{\partial y}=Rm(h_y'-v')\,,\\
&\frac{\partial p'}{\partial x}-\gamma_1\frac{\partial \rho'}{\partial x}=0\,.
\end{aligned}\right\}\tag{22}$$

We assume that $N=RmS\simeq 1$ though $Rm\ll 1$ and we neglect the deviation of the magnetic field due to the interaction. Then, the stream function ψ defined by

$$u'=-\frac{1}{M_1^2-1}\frac{\partial\psi}{\partial y}\,,\qquad v'=-\frac{\partial\psi}{\partial x}\,,\tag{23}$$

satisfies the equation

$$\frac{\partial^2\psi}{\partial x^2}-(M_1^2-1)\frac{\partial^2\psi}{\partial y^2}+N\frac{\partial\psi}{\partial x}=0\,.\tag{24}$$

The boundary conditions for ψ are given as follows

$$\left.\begin{aligned}
&\psi=\frac{\partial\psi}{\partial x}=0 && \text{for } x=0,\ 1>y>0\,,\\
&\frac{\partial\psi}{\partial x}=0 && \text{for } x>0,\ y=0\,,\\
&\frac{\partial\psi}{\partial y}=-(M_1^2-1)\mathcal{E} && \text{for } x>0,\ y=1\,.
\end{aligned}\right\}\tag{25}$$

The Laplace transformations of Eqs. (24) and (25) yield

$$\frac{\partial^2\bar{\psi}}{\partial y^2}-m_1^2(s^2+Ns)\bar{\psi}=0\,,\tag{26}$$

$$\left.\begin{aligned}
&\psi=0 && \text{for}\quad y=0,\quad x>0\,,\\
&\frac{\partial\bar{\psi}}{\partial y}=-\frac{m_1^2\mathcal{E}}{s} && \text{for}\quad y=1,\quad x>0\,.
\end{aligned}\right\}\tag{27}$$

The solution of Eq. (26) which satisfies the condition (27) is

$$\bar{\psi}=-\frac{m_1\mathcal{E}\{\exp(m_1\sqrt{s^2+Ns}\,y)-\exp(-m_1\sqrt{s^2+Ns}\,y)\}}{s\sqrt{s^2+Ns}\,\{\exp(m_1\sqrt{s^2+Ns})+\exp(-m_1\sqrt{s^2+Ns})\}}\,.\tag{28}$$

The boundary of the jet is given by $F(x)=-[\psi]_{y=1}$ for this case. Then,

$$\bar{F}(s)=\frac{m_1\mathcal{E}}{s\sqrt{s^2+Ns}}\,\frac{1-\exp(-2m_1\sqrt{s^2+Ns})}{1+\exp(-2m_1\sqrt{s^2+Ns})}\,.\tag{29}$$

If we consider the region where N/s is sufficiently small and adopt the first two terms in the expansion with respect to it, we obtain

$$\bar{F}(s)=m_1\mathcal{E}\frac{1}{s^2}\,\frac{1-\nu' e^{-2m_1 s}}{1+\nu' e^{-2m_1 s}}-\frac{m_1 N\mathcal{E}}{2}\,\frac{1}{s^3}\,\frac{1-\nu' e^{-2m_1 s}}{1+\nu' e^{-2m_1 s}}\,,\tag{30}$$

where

$$\nu' = e^{-m_1 N} . \tag{31}$$

The boundary of the jet in the neighbourhood of the exit can be expressed as follows, by taking the inverse transformation,

$$F(x) = m_1 \varepsilon \left\{ x + 2 \sum_{n=1}^{\infty} (-\nu')^n (x - 2n \cdot m_1) \cdot u(x - 2n \cdot m_1) \right\} - \frac{1}{2} m_1 N \varepsilon \int_0^x \left\{ x + 2 \sum_{n=1}^{\infty} (-\nu')^n (x - 2n \cdot m_1) \cdot u(x - 2n \cdot m_1) \right\} dx . \tag{32}$$

This expression reduces to that in the gas-dynamic case as $N \to 0$. The interaction between the magnetic field and the conducting stream has an influence such as to reduce the deviation of the width of the jet from that at the exit as well as the amplitude, as should be expected.

The writer wishes to express his hearty thanks to Prof. Z. Hasimoto for valuable discussion and to Dr. T. Sakurai for kind inspection of the manuscript.

Steady Temperature in a Composite Elliptic Cylinder

By Václav VODIČKA
Plzeň, Czechoslovakia

(Received April 27, 1961)

Classical methods are used to determine the steady temperature distribution in a finite elliptic cylinder consisting of any number of plane-parallel layers. As illustration of the general procedure, the case of a homogeneous isotropic elliptic cylinder is treated in some detail.

§ 1. Description of the Problem

The cylindrical body

$$b^2x^2 + a^2y^2 - a^2b^2 \leq 0 , \qquad 0 \leq z \leq z_n$$

is made of n homogeneous and isotropic parts

$$b^2x^2 + a^2y^2 - a^2b^2 \leq 0 , \qquad z_{k-1} \leq z \leq z_k , \qquad 1 \leq k \leq n , \qquad z_0 = 0 ,$$

with the conductivities λ_k, respectively. The problem in question is that of finding the steady temperature field in the solid provided that its curved surface $b^2x^2 + a^2y^2 - a^2b^2 = 0$ has steadily the temperature zero, whereas the other surfaces $z = 0$, $z = z_n$ are kept at two temperatures given in functions $f(\xi, \eta)$, $g(\xi, \eta)$ of the elliptic coordinates ξ, η to be introduced later-see (2.1). In addition to this we shall consider such a tight contact between adjacent layers of the body that it is possible to calculate with a continuous variation of the temperature within the whole cylinder.

§ 2. Mathematical Statement

Introducing the coordinates ξ, η, z of the elliptic cylinder by

$$x=c\,\mathrm{ch}\,\xi\cos\eta\,,\qquad y=c\,\mathrm{sh}\,\xi\sin\eta\,,\qquad z=z\,,\qquad c=\sqrt{a^2-b^2}\,, \tag{2.1}$$

our problem reduces to determining the solution $u_k=u_k(\xi,\eta,z)$ of the familiar equations

$$\left.\begin{aligned}&\frac{1}{c^2(\mathrm{ch}^2\xi-\cos^2\eta)}\left(\frac{\partial^2 u_k}{\partial\xi^2}+\frac{\partial^2 u_k}{\partial\eta^2}\right)+\frac{\partial^2 u_k}{\partial z^2}=0\,,\\ &\qquad 0\leq\xi<\xi_0\,,\quad 0\leq\eta\leq 2\pi\,,\quad z_{k-1}<z<z_k\,,\quad 1\leq k\leq n\,,\quad \xi_0=\lg\frac{a+b}{c}\end{aligned}\right\} \tag{2.2}$$

$$u_1(\xi,\eta,0)=f(\xi,\eta)\,,\qquad u_n(\xi,\eta,z_n)=g(\xi,\eta)\,,\qquad 0\leq\xi<\xi_0\,,\quad 0\leq\eta\leq 2\pi \tag{2.3}$$

$$\left.\begin{aligned}&u_{k+1}(\xi,\eta,z_k)=u_k(\xi,\eta,z_k)\,,\qquad 0\leq\xi<\xi_0\,,\quad 0\leq\eta\leq 2\pi\\ &\frac{\partial u_{k+1}}{\partial z}=\Lambda_k\frac{\partial u_k}{\partial z}\,,\qquad \Lambda_k=\frac{\lambda_k}{\lambda_{k+1}}\,,\\ &\qquad 0\leq\xi<\xi_0\,,\quad 0\leq\eta\leq 2\pi\,,\quad z=z_k\,,\quad 1\leq k\leq n-1\end{aligned}\right\} \tag{2.4}$$

$$u_k(\xi_0,\eta,z)=0\,,\qquad 0\leq\eta\leq 2\pi\,,\quad z_{k-1}<z<z_k\,,\quad 1\leq k\leq n\,. \tag{2.5}$$

§ 3. Particular Integrals

Assuming the integrals of (2.2) in the form

$$v_k(\xi,\eta,z)=X(\xi)Y(\eta)Z_k(z)\,,\qquad 1\leq k\leq n \tag{3.1}$$

one finds with a free parameter ω on one hand

$$Z_k(z)=A_k\,\mathrm{ch}\,\omega(z-z_{k-1})+B_k\,\mathrm{sh}\,\omega(z-z_{k-1})\,,\qquad 1\leq k\leq n \tag{3.2}$$

and on the other

$$\frac{d^2X}{d\xi^2}-(\rho-2q\,\mathrm{ch}\,2\xi)X=0\,,\qquad \frac{d^2Y}{d\eta^2}+(\rho-2q\cos 2\eta)Y=0\,; \tag{3.3}$$

ρ is another free parameter and q depends upon ω through the relation

$$q=\frac{1}{4}c^2\omega^2 \tag{3.4}$$

Using Whittaker's notation and taking into account the obvious periodicity of the required temperature functions with regard to η, we have to consider only the particular integrals[1]

$$ce_m(\eta,q)\,,\quad m=0,1,2,\cdots,\qquad se_m(\eta,q)\,,\quad m=1,2,3,\cdots \tag{3.5}$$

of the second equation (3.3). It should be remarked that it belongs to every term $ce_m(\eta,q)$ of the first sequence (3.5) the well-known expression $\rho=\rho_m^{(1)}(q)$ of ρ in terms of the only free parameter q and similarly one has another known form $\rho=\rho_m^{(2)}(q)$ of ρ for every $se_m(\eta,q)$.

As for the first equation (3.3), its particular integrals are the modified functions $Ce_m(\xi,q)$, $Fe_m(\xi,q)$ for $\rho=\rho_m^{(1)}(q)$ and $Se_m(\xi,q)$, $Ge_m(\xi,q)$ for $\rho=\rho_m^{(2)}(q)$. Hence, taking $\rho=\rho_m^{(1)}(q)$, the above formulae (3.1), (3.2) yield two infinite sets

$$\left.\begin{aligned}&v_{km}(\xi,\eta,z)=Ce_m(\xi,q)ce_m(\eta,q)Z_k(z,q)\,,\\ &w_{km}(\xi,\eta,z)=Fe_m(\xi,q)ce_m(\eta,q)Z_k(z,q)\,,\\ &\qquad\qquad 1\leq k\leq n\,,\quad m=0,1,2,\cdots\end{aligned}\right\} \tag{3.6}$$

of particular solutions of the equations (2.2) and similarly we obtain

$$\left.\begin{aligned} V_{km}(\xi, \eta, z) &= Se_m(\xi, q)se_m(\eta, q)Z_k(z, q) , \\ W_{km}(\xi, \eta, z) &= Ge_m(\xi, q)se_m(\eta, q)Z_k(z, q) , \\ & 1 \leq k \leq n , \quad m=1, 2, 3, \cdots \end{aligned}\right\} \tag{3.7}$$

by putting $\rho=\rho_m^{(2)}(q)$ in the above Mathieu equations (3.3). Here

$$Z_k(z, q) = A_k \operatorname{ch} \omega(z-z_{k-1}) + B_k \operatorname{sh} \omega(z-z_{k-1}) , \qquad 1 \leq k \leq n \tag{3.8}$$

the constants A_k, B_k of integration depending in general upon the parameter q; the same holds by virtue of (3.4) also in the case of ω.

But considering the continuity of the required temperature and of the heat flux in the plane $\xi=0$ passing through the both foci of the base of our cylindrical body and using the elementary properties of Mathieu functions entering in (3.6) and (3.7), there remain only the sets $v_{km}(\xi, \eta, z)$, $V_{km}(\xi, \eta, z)$ of particular integrals suitable for dealing with our problem.

As for the only free parameter q, it is to be found according to the conditions (2.5), i.e. from the equations

$$\left.\begin{aligned} Ce_m(\xi_0, q) &= 0 , \qquad m=0, 1, 2, \cdots, \quad \text{if } \rho=\rho_m^{(1)}(q) \\ Se_m(\xi_0, q) &= 0 , \qquad m=1, 2, 3, \cdots, \quad \text{if } \rho=\rho_m^{(2)}(q) . \end{aligned}\right\} \tag{3.9}$$

There corresponds, to each value of m, an infinite set

$$q_{mr} , \qquad r=1, 2, 3, \cdots$$

of positive roots $q=q_{mr}$ of the equation $Ce_m(\xi_0, q)=0$ and another set

$$Q_{mr} , \qquad r=1, 2, 3, \cdots$$

of positive numbers, each satisfying the condition $Se_m(\xi_0, Q)=0$. These roots q_{mr}, Q_{mr} are known as the parametric zeros of belonging modified functions $Ce_m(\xi, q)$, $Se_m(\xi, q)$ at $\xi=\xi_0$.

In this way we find two doubly infinite systems

$$\left.\begin{aligned} & v_{kmr}(\xi, \eta, z) = Ce_m(\xi, q_{mr})ce_m(\eta, q_{mr})Z^{(1)}_{kmr}(z) , \\ & \quad Z^{(1)}_{kmr}(z) = A_{kmr} \operatorname{ch} \omega_{mr}(z-z_{k-1}) + B_{kmr} \operatorname{sh} \omega_{mr}(z-z_{k-1}) , \\ & \quad \omega_{mr} = \frac{2}{c}\sqrt{q_{mr}} , \qquad 1 \leq k \leq n , \quad m=0, 1, 2, \cdots, \quad r=1, 2, 3, \cdots \\ & V_{kmr}(\xi, \eta, z) = Se_m(\xi, Q_{mr})se_m(\eta, Q_{mr})Z^{(2)}_{kmr}(z) , \\ & \quad Z^{(2)}_{kmr}(z) = C_{kmr} \operatorname{ch} \Omega_{mr}(z-z_{k-1}) + D_{kmr} \operatorname{sh} \Omega_{mr}(z-z_{k-1}) , \\ & \quad \Omega_{mr} = \frac{2}{c}\sqrt{Q_{mr}} , \qquad 1 \leq k \leq n , \quad m=1, 2, 3, \cdots, \quad r=1, 2, 3, \cdots \end{aligned}\right\} \tag{3.10}$$

of particular solutions of the set of equations (2.2), each satisfying, besides, the boundary condition (2.5).

It is an easy matter to subject the coefficients $A_{kmr}, \cdots, D_{kmr}$ to such relations, that the above systems (3.10) satisfy also the conditions (2.4) at the surfaces of separation between neighbouring layers of the body. This will be so, if and only if

$$\begin{aligned} & A_{k+1,mr} = A_{kmr} \operatorname{ch} \omega_{mr} l_k + B_{kmr} \operatorname{sh} \omega_{mr} l_k , \\ & B_{k+1,mr} = \Lambda_k(A_{kmr} \operatorname{sh} \omega_{mr} l_k + B_{kmr} \operatorname{ch} \omega_{mr} l_k) , \\ & \quad l_k = z_k - z_{k-1} , \quad 1 \leq k \leq n-1 , \quad m=0, 1, 2, \cdots, \quad r=1, 2, 3, \cdots \end{aligned}$$

$$\begin{aligned} & C_{k+1,mr} = C_{kmr} \operatorname{ch} \Omega_{mr} l_k + D_{kmr} \operatorname{sh} \Omega_{mr} l_k , \\ & D_{k+1,mr} = \Lambda_k(C_{kmr} \operatorname{sh} \Omega_{mr} l_k + D_{kmr} \operatorname{ch} \Omega_{mr} l_k) , \\ & \quad l_k = z_k - z_{k-1} , \quad 1 \leq k \leq n-1 , \quad m=1, 2, 3, \cdots, \quad r=1, 2, 3, \cdots . \end{aligned}$$

Writing these equations in the matrix form[2)]

$$\left.\begin{aligned}
&K_{k+1,mr}=M_k(q_{mr})K_{kmr}\,, \qquad 1\leq k\leq n-1\,,\quad m\geq 0\,,\quad r\geq 1\,,\\
&\quad K_{kmr}=\left\|\begin{matrix}A_{kmr}\\ B_{kmr}\end{matrix}\right\|\,, \qquad 1\leq k\leq n\,,\\
&\quad M_k(q_{mr})=\left\|\begin{matrix}\operatorname{ch}\omega_{mr}l_k\,, & \operatorname{sh}\omega_{mr}l_k\\ \Lambda_k\operatorname{sh}\omega_{mr}l_k\,, & \Lambda_k\operatorname{ch}\omega_{mr}l_k\end{matrix}\right\|\,, \qquad 1\leq k\leq n-1\,,\quad m\geq 0\,,\quad r\geq 1
\end{aligned}\right\}\tag{3.11}$$

$$\left.\begin{aligned}
&L_{k+1,mr}=N_k(Q_{mr})L_{kmr}\,, \qquad 1\leq k\leq n-1\,,\quad m\geq 1\,,\quad r\geq 1\,,\\
&\quad L_{kmr}=\left\|\begin{matrix}C_{kmr}\\ D_{kmr}\end{matrix}\right\|\,, \qquad 1\leq k\leq n\,,\\
&\quad N_k(Q_{mr})=\left\|\begin{matrix}\operatorname{ch}\Omega_{mr}l_k\,, & \operatorname{sh}\Omega_{mr}l_k\,,\\ \Lambda_k\operatorname{sh}\Omega_{mr}l_k\,, & \Lambda_k\operatorname{ch}\Omega_{mr}l_k\end{matrix}\right\|\,, \qquad 1\leq k\leq n-1\,,\quad m\geq 1\,,\quad r\geq 1\,,
\end{aligned}\right\}\tag{3.12}$$

we readily obtain the expression

$$\left.\begin{aligned}
&K_{k+1,mr}=R_k(q_{mr})\left\|\begin{matrix}A_{1mr}\\ B_{1mr}\end{matrix}\right\|\,, \qquad 1\leq k\leq n-1\,,\quad m\geq 0\,,\quad r\geq 1\,,\\
&L_{k+1,mr}=S_k(Q_{mr})\left\|\begin{matrix}C_{1mr}\\ D_{1mr}\end{matrix}\right\|\,, \qquad 1\leq k\leq n-1\,,\quad m\geq 1\,,\quad r\geq 1\,,\\
&\qquad R_k(q_{mr})=M_k(q_{mr})M_{k-1}(q_{mr})\cdots M_1(q_{mr})\,,\\
&\qquad S_k(Q_{mr})=N_k(Q_{mr})N_{k-1}(Q_{mr})\cdots N_1(Q_{mr})
\end{aligned}\right\}\tag{3.13}$$

of all the unknown coefficients $A_{kmr},\cdots,D_{kmr}$ $(1\leq k\leq n)$ in terms of the undetermined $A_{1mr},\cdots,D_{1mr}$.

Writing

$$R_k(q_{mr})=\|\kappa_{kmr}^{(\alpha,\beta)}\|\,,\qquad S_k(Q_{mr})=\|\lambda_{kmr}^{(\alpha,\beta)}\|\,,\qquad \alpha,\beta=1,2$$

and using the relations (3.13), our expressions $Z_{kmr}^{(1)}(z)$ and $Z_{kmr}^{(2)}(z)$ from (3.10) become

$$\left.\begin{aligned}
&Z_{1mr}^{(1)}(z)=A_{1mr}\operatorname{ch}\omega_{mr}z+B_{1mr}\operatorname{sh}\omega_{mr}z\,,\\
&Z_{k+1,mr}^{(1)}(z)=A_{1mr}[\kappa_{kmr}^{(11)}\operatorname{ch}\omega_{mr}(z-z_k)+\kappa_{kmr}^{(21)}\operatorname{sh}\omega_{mr}(z-z_k)]\\
&\qquad +B_{1mr}[\kappa_{kmr}^{(12)}\operatorname{ch}\omega_{mr}(z-z_k)+\kappa_{kmr}^{(22)}\operatorname{sh}\omega_{mr}(z-z_k)]\,,\\
&\qquad\qquad 1\leq k\leq n-1\,,\quad m\geq 0\,,\quad r\geq 1\\
&Z_{1mr}^{(2)}(z)=C_{1mr}\operatorname{ch}\Omega_{mr}z+D_{1mr}\operatorname{sh}\Omega_{mr}z\,,\\
&Z_{k+1,mr}^{(2)}(z)=C_{1mr}[\lambda_{kmr}^{(11)}\operatorname{ch}\Omega_{mr}(z-z_k)+\lambda_{kmr}^{(21)}\operatorname{sh}\Omega_{mr}(z-z_k)]\\
&\qquad +D_{1mr}[\lambda_{kmr}^{(12)}\operatorname{ch}\Omega_{mr}(z-z_k)+\lambda_{kmr}^{(22)}\operatorname{sh}\Omega_{mr}(z-z_k)]\,,\\
&\qquad\qquad 1\leq k\leq n-1\,,\quad m\geq 1\,,\quad r\geq 1\,.
\end{aligned}\right\}\tag{3.14}$$

Recapitulating, we see that the relations (3.10) and (3.14) define two doubly infinite systems

$$v_{kmr}(\xi,\eta,z)\,,\quad V_{kmr}(\xi,\eta,z)\,,\qquad 1\leq k\leq n,\ r\geq 1,\ m\geq 0 \text{ for } v_{kmr} \text{ and } m\geq 1 \text{ for } V_{kmr}$$

of particular integrals, each group satisfying not only the equations (2.2), but also the additional conditions (2.4) and (2.5). Our problem reduces then to determining the coefficients $A_{1mr},\cdots,D_{1mr}$ entering in (3.14).

§ 4. Determination of $A_{1mr},\cdots,D_{1mr}$

Let $h(\xi,\eta)$ be a continuous single-valued function within the region $0\leq\xi<\xi_0$, $0\leq\eta\leq 2\pi$ and let $h(\xi_0,\eta)=0$ for $0\leq\eta\leq 2\pi$. Such a function can be represented by the well-known series

$$
\begin{aligned}
&h(\xi,\eta)=\sum_{m=0}^{\infty}\sum_{r=1}^{\infty}h_{mr}^{(c)}Ce_m(\xi,q_{mr})ce_m(\eta,q_{mr})+\sum_{m=1}^{\infty}\sum_{r=1}^{\infty}h_{mr}^{(s)}Se_m(\xi,Q_{mr})se_m(\eta,Q_{mr})\,,\\
&h_{mr}^{(c)}=\frac{\int_0^{\xi_0}\int_0^{2\pi}(\operatorname{ch}2\xi-\cos 2\eta)h(\xi,\eta)Ce_m(\xi,q_{mr})ce_m(\eta,q_{mr})d\xi d\eta}{\pi\int_0^{\xi_0}(\operatorname{ch}2\xi-\Theta_{mr})Ce_m^2(\xi,q_{mr})d\xi}\,,\\
&h_{mr}^{s}=\frac{\int_0^{\xi_0}\int_0^{2\pi}(\operatorname{ch}2\xi-\cos 2\eta)h(\xi,\eta)Se_m(\xi,Q_{mr})se_m(\eta,Q_{mr})d\xi d\eta}{\pi\int_0^{\xi_0}(\operatorname{ch}2\xi-\Psi_{mr})Se_m^2(\xi,Q_{mr})d\xi}\,,\\
&\begin{matrix}\Theta_{mr}\\ \Psi_{mr}\end{matrix}=\frac{1}{\pi}\int_0^{2\pi}\begin{matrix}ce_m^2(\eta,q_{mr})\\ se_m^2(\eta,Q_{mr})\end{matrix}\cos 2\eta d\eta\,,
\end{aligned}
\tag{4.1}
$$

this expansion being valid in the whole extent $0\leq\xi\leq\xi_0$, $0\leq\eta\leq 2\pi$.

Let us assume, that the given functions $f(\xi,\eta)$, $g(\xi,\eta)$ from (2.3) have the properties just imposed on $h(\xi,\eta)$ and let us assume the required solution $u_k(\xi,\eta,z)$ of our original problem (2.2)-(2.5) in the form

$$u_k(\xi,\eta,z)=\sum_{m=0}^{\infty}\sum_{r=1}^{\infty}v_{kmr}(\xi,\eta,z)+\sum_{m=1}^{\infty}\sum_{r=1}^{\infty}V_{kmr}(\xi,\eta,z)\,,\qquad 1\leq k\leq n\,,\tag{4.2}$$

the eigenfunctions $v_{kmr}(\xi,\eta,z)$, $V_{kmr}(\xi,\eta,z)$ being defined by the relations (3.10), (3.14).

Then the only pair of unsatisfied conditions (2.3) appears in the form of two requirements

$$f(\xi,\eta)=\sum_{m=0}^{\infty}\sum_{r=1}^{\infty}Z_{1mr}^{(1)}(0)Ce_m(\xi,q_{mr})ce_m(\eta,q_{mr})+\sum_{m=1}^{\infty}\sum_{r=1}^{\infty}Z_{1mr}^{(2)}(0)Se_m(\xi,Q_{mr})se_m(\eta,Q_{mr})\,,$$

$$g(\xi,\eta)=\sum_{m=0}^{\infty}\sum_{r=1}^{\infty}Z_{nmr}^{(1)}(z_n)Ce_m(\xi,q_{mr})ce_m(\eta,q_{mr})+\sum_{m=1}^{\infty}\sum_{r=1}^{\infty}Z_{nmr}^{(2)}(z_n)Se_m(\xi,Q_{mr})se_m(\eta,Q_{mr})\,,$$

$$0\leq\xi<\xi_0\,,\quad 0\leq\eta\leq 2\pi\,.$$

Equating this with (4.1) and using (3.14) gives the set of equations

$$
\left.
\begin{aligned}
&Z_{1mr}^{(1)}(0)=A_{1mr}=f_{mr}^{(c)}\,,\qquad Z_{1mr}^{(2)}(0)=C_{1mr}=f_{mr}^{(s)}\,,\\
&Z_{nmr}^{(1)}(z_n)=A_{1mr}(\kappa_{n-1,mr}^{(11)}\operatorname{ch}\omega_{mr}l_n+\kappa_{n-1,mr}^{(21)}\operatorname{sh}\omega_{mr}l_n)\\
&\qquad+B_{1mr}(\kappa_{n-1,mr}^{(12)}\operatorname{ch}\omega_{mr}l_n+\kappa_{n-1,mr}^{(22)}\operatorname{sh}\omega_{mr}l_n)=g_{mr}^{(c)}\,,\\
&Z_{nmr}^{(2)}(z_n)=C_{1mr}(\lambda_{n-1,mr}^{(11)}\operatorname{ch}\Omega_{mr}l_n+\lambda_{n-1,mr}^{(21)}\operatorname{sh}\Omega_{mr}l_n)\\
&\qquad+D_{1mr}(\lambda_{n-1,mr}^{(12)}\operatorname{ch}\Omega_{mr}l_n+\lambda_{n-1,mr}^{(22)}\operatorname{sh}\Omega_{mr}l_n)=g_{mr}^{(s)}
\end{aligned}
\right\}
\tag{4.3}
$$

for the undetermined values $A_{1mr},\cdots,D_{1mr}$. The Fourier coefficients $f_{mr}^{(c)},\cdots,g_{mr}^{(s)}$ entering in the system (4.3) are to be calculated according to (4.1).

§ 5. Recapitulation and Solution of the Original Problem

Solving the above equations (4.3) and substituting the resulting values $A_{1mr},\cdots,D_{1mr}$ into (3.14) gives us the expressions $Z_{kmr}^{(1)}(z)$, $Z_{kmr}^{(2)}(z)$ needed in (3.10). Nevertheless, detailed calculation does not lead to any simple formulae and so we shall break our considerations at the present stage. Instead of continuing the laborious calculations it will prove useful to give a brief summary of all the preceding results and to show, in what a way they enable us to obtain the solution of our original problem (2.2)-(2.5).

1. Using the given constants

$$a,\ b,\ 0=z_0<z_1<z_2<\cdots<z_n\,,\quad \lambda_1,\ \lambda_2,\ \cdots,\ \lambda_n\,,$$

we first calculate the auxiliary values

$$c=\sqrt{a^2-b^2}\,,\quad \xi_0=\lg\frac{a+b}{c}\,,\quad l_k=z_k-z_{k-1}\,,\quad 1\le k\le n\,,\qquad \Lambda_k=\frac{\lambda_k}{\lambda_{k+1}}\,,\quad 1\le k\le n-1\,. \tag{5.1}$$

2. Solving the equations (3.9) gives us the parametric zeros q_{mr}, Q_{mr} of the modified functions $Ce_m(\xi, q)$, $Se_m(\xi, q)$ at $\xi=\xi_0$.

3. Using the given functions $f(\xi, \eta)$, $g(\xi, \eta)$, we calculate their Fourier coefficients $f_{mr}^{(c)}$, $f_{mr}^{(s)}$, $g_{mr}^{(c)}$, $g_{mr}^{(s)}$ by means of (4.1).

4. Having used (3.10) to find the values ω_{mr}, Ω_{mr}, it is an easy matter to write down the matrices $M_k(q_{mr})$, $N_k(Q_{mr})$, as defined in (3.11) and (3.12).

5. The essence and the most difficult part of the problem lie in constructing the matrices $R_k(q_{mr})$, $S_k(Q_{mr})$, as given by the two last formulae (3.13).

6. Knowing the elements $\kappa_{kmr}^{(\alpha,\beta)}$, $\lambda_{kmr}^{(\alpha,\beta)}$, $\alpha, \beta=1, 2$ of $R_k(q_{mr})$ and $S_k(Q_{mr})$, we can proceed to establish the equations (4.3). Solving them gives the coefficients $A_{1mr}, \cdots, D_{1mr}$.

7. Using (3.14) yields the expressions $Z_{kmr}^{(1)}(z)$, $Z_{kmr}^{(2)}(z)$ and herewith we obtain by (3.10) the particular integrals $v_{kmr}(\xi, \eta, z)$, $V_{kmr}(\xi, \eta, z)$.

Having performed all the operations indicated in the preceding seven stages, we can write down the final solution of the original problem, according to the formula (4.2).

§ 6. A Homogeneous Cylinder

To illustrate our general deductions by at least one example, let us treat the case

$$\Lambda_1=\Lambda_2=\cdots=\Lambda_{n-1}=1$$

corresponding to a homogeneous isotropic cylinder.

A simple calculation gives

$$R_k(q_{mr})=\begin{Vmatrix}\operatorname{ch}\omega_{mr}z_k\,, & \operatorname{sh}\omega_{mr}z_k\\ \operatorname{sh}\omega_{mr}z_k\,, & \operatorname{ch}\omega_{mr}z_k\end{Vmatrix}\,,\qquad S_k(Q_{mr})=\begin{Vmatrix}\operatorname{ch}\Omega_{mr}z_k\,, & \operatorname{sh}\Omega_{mr}z_k\\ \operatorname{sh}\Omega_{mr}z_k\,, & \operatorname{ch}\Omega_{mr}z_k\end{Vmatrix}\,,\qquad 1\le k\le n-1\,,$$

and the equations (4.3) become

$$A_{1mr}=f_{mr}^{(c)}\,,\qquad C_{1mr}=f_{mr}^{(s)}\,,$$

$$A_{1mr}\operatorname{ch}\omega_{mr}z_n+B_{1mr}\operatorname{sh}\omega_{mr}z_n=g_{mr}^{(c)}\,,$$

$$C_{1mr}\operatorname{ch}\Omega_{mr}z_n+D_{1mr}\operatorname{sh}\Omega_{mr}z_n=g_{mr}^{(s)}\,.$$

Solving with respect to $A_{1mr}, \cdots, D_{1mr}$ and substituting into (3.14) leads to the common expressions

$$Z_{kmr}^{(1)}(z)=\frac{1}{\operatorname{sh}\omega_{mr}z_n}[f_{mr}^{(c)}\operatorname{sh}\omega_{mr}(z_n-z)+g_{mr}^{(c)}\operatorname{sh}\omega_{mr}z]\,,$$

$$Z_{kmr}^{(2)}(z)=\frac{1}{\operatorname{sh}\Omega_{mr}z_n}[f_{mr}^{(s)}\operatorname{sh}\Omega_{mr}(z_n-z)+g_{mr}^{(s)}\operatorname{sh}\Omega_{mr}z]$$

holding for all $1\le k\le n$.

Using (3.10) and (4.2) gives us the final solution in the form

$$\begin{aligned}u(\xi, \eta, z)=&\sum_{m=0}^{\infty}\sum_{r=1}^{\infty}\frac{Ce_m(\xi, q_{mr})ce_m(\eta, q_{mr})}{\operatorname{sh}\omega_{mr}z_n}[f_{mr}^{(c)}\operatorname{sh}\omega_{mr}(z_n-z)+g_{mr}^{(c)}\operatorname{sh}\omega_{mr}z]\\ &+\sum_{m=1}^{\infty}\sum_{r=1}^{\infty}\frac{Se_m(\xi, Q_{mr})se_m(\eta, Q_{mr})}{\operatorname{sh}\Omega_{mr}z_n}[f_{mr}^{(s)}\operatorname{sh}\Omega_{mr}(z_n-z)+g_{mr}^{(s)}\operatorname{sh}\Omega_{mr}z];\end{aligned} \tag{6.1}$$

the meaning of all the abbreviations is explained in § 5.

§7. Final Remarks

1. The above expansion (4.1) can be deduced under more general conditions than those cited at the beginning of § 4. Thus, it would be possible to moderate in some measure the requirements imposed upon the given functions $f(\xi, \eta)$, $g(\xi, \eta)$ entering in (2.3).

2. It may be reasoned that the solution of many problems like that treated above would be greatly simplified by building up a theory of Mathieu transforms. This can be done in quite an analogous manner to, for instance, the case of the familiar Hankel transforms. The outlines of such a theory and a number of applications to mathematical physics will be the object of separate papers.

Ultrasonic Dispersion in Acetone

C. Raghupathi RAO

Department of Physics, Nizam College, Hyderabad-Dn. India

(Received March 13, 1961)

The study of dispersion of acoustic velocity in acetone employing ultrasonic waves of very high frequencies up to 180 Mc/s has been made for the first time and no positive evidence of dispersion could be established. It is shown that the angular distribution of high frequency diffraction is less in acetone than that in water, as this depends only on the parameter $\pi L/\lambda^*$ where L corresponds to the length of the sound path traversed by the light beam and λ^* corresponds to the sound wavelength in the medium.

§ 1. Introduction

The study of dispersion in liquids has been carried out by many workers[1)-3)] but dispersion has not been positively established in many cases. Raghavendra Rao[4)] observed definite evidence of dispersion of acoustic velocity in liquids. He determined the hypersonic velocities in a number of organic liquids by a study of the fine structure of monochromatic radiations scattered by liquids. He reported a decrease of acoustic velocity by about 225 m/sec in acetone. Venkateswaran[5)] reported a decrease of acoustic velocity in acetone by about 20 m/sec at 28°C, while Fabelinskii[6)] observed no change. Rank, Shull and Axford[7)] observed an increase of 125 m/sec at −78°C. The accuracy of hypersonic measurements, however, is comparatively small. So, it is interesting and useful to perform the measurements by using ultrasonic waves of very high frequencies in liquids to detect or disprove dispersion positively.

§ 2. Method

Ultrasonic velocities have been measured using the usual Debye and Sears'[8)] optical diffraction method at low frequencies up to 80 Mc/s and the simultaneous excitation method[9)] at high frequencies upto 180 Mc/s. It is possible to excite the first order diffraction lines symmetrically on either side of zero order up to 80 Mc/s in the normal incidence position of the crystal holder but at higher frequencies, the crystal holder is to be tilted to the appropriate Bragg angle[10)] so that a single diffraction order makes its appearance. The fringe width of the high frequency diffraction order is computed by measuring its distance on a comparator from the low frequency diffraction lines.

§ 3. Results and Discussion

The ultrasonic velocities measured in this way are given in Table I for various frequencies from 28 to 180 Mc/s. The study of dispersion of acoustic velocity in acetone employing ultrasonic waves of very high frequencies up to 180 Mc/s is made for the first time and Table I clearly shows the absence of dispersion at these frequencies.

Table I.

λ=5893 A.U. Temperature=28°C.

Frequency in Mc/s v^*	Fringe width 'd' in cms	v^*/d	Velocity in metres/sec
28.19	0.4678	60.27	1184
48.73	0.8122	59.99	1179
73.08	1.2120	60.30	1184
149.80	2.4901	60.17	1182
180.25	2.9900	60.26	1184

§ 4. Angular Distribution of High Frequency Diffraction

The high frequency diffraction order generally persists in the field of view over an angle on either side of its Bragg position. This angular width over which the diffraction order appears is termed as "the angular distribution of high frequency diffraction". In order to find the variation of this distribution of diffraction with increasing frequencies in acetone, this investigation is undertaken.

The expression[11)] $I_{+1}=I_m\left\{\frac{\sin(\pi L/\lambda^*)\phi}{(\pi L/\lambda^*)\phi}\right\}^2$ is useful in this study. I_{+1} denotes the intensity of the first order, L represents the length of the ultrasonic path travelled by the light beam, λ^* corresponds to the sound wavelength in the medium and ϕ shows the angle of deviation of the sound wave-front from the Bragg position. It can be seen by differentiating the above expression that the angular distribution of high frequency diffraction depends only on the value of the parameter $\pi L/\lambda^*$. At higher frequencies this parameter increases, making the high frequency diffraction order appear over a very small angle. That is to say, for very high frequencies and large lengths of the sound field, the phenomenon of characteristic reflection of light gains importance.

With the help of the Photo-tube, the intensity of the first order of diffraction is measured and plotted against the tilt of the crystal holder. The theoretical curves and the experimental ones obtained by the Photo-

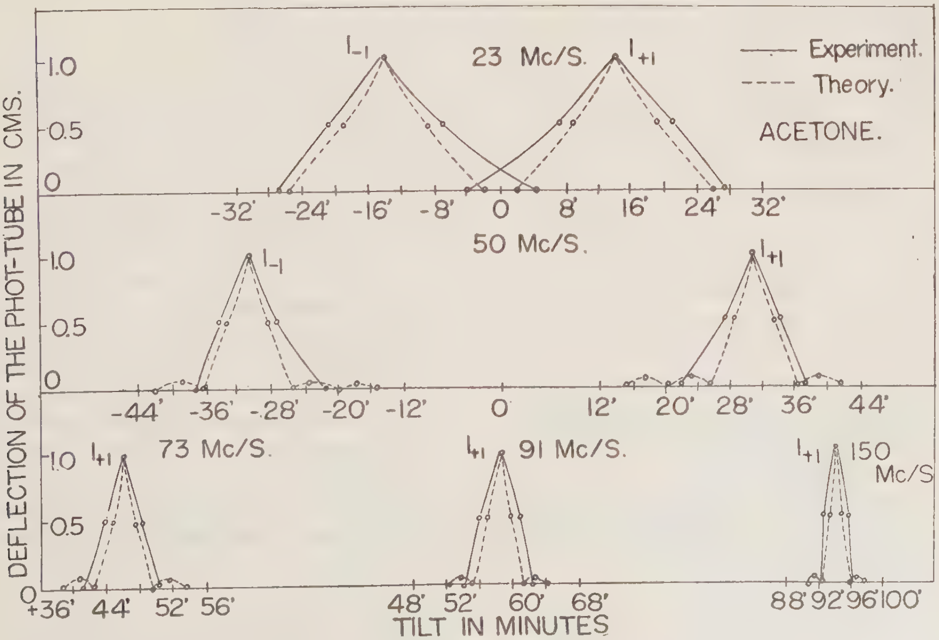

Fig. 1. Angular distribution of high frequency diffraction in acetone. Comparison between theory and experiment.

tube are shown in Fig. 1 to facilitate comparision. For all the frequencies employed in this study, the maximum intensity of the first order of diffraction is adjusted to be the same and the effect of tilt studied by the Photo-tube. It will be noticed, firstly, that the curves become narrower as one approaches higher frequencies, showing their dependence on the parameter $\pi L/\lambda^*$; secondly, that the theoretical curves are always bound within the experimental curves and thirdly, that the theoretical curves show a sharp fall in intensity while the fall in the experimental curves is very gradual. These deviations in intensity can, however, be explained as mainly due to the fact that the sound field is not the ideal plane wave with un-damped amplitude as assumed in the theory.

A comparision of the angular distribution of high frequency diffraction in water and acetone is very instructive. At 50 Mc/s both the diffraction orders on either side of the zero order persist through a large angle, though faintly, in water; while a single diffraction order appears over a small angle in respect of acetone. This behaviour of the diffraction pattern at this frequency in the two liquids is shown in Fig. 2. The angular distribution of high frequency diffraction is less in acetone than that in water[12] This is due to the small wave-length of sound in acetone, its ultrasonic velocity being smaller than that in water.

In conclusion, the author's thanks are due to Dr. S. Bhagavantam for his keen interest in this work.

Paramagnetic Resonance of Cobalt in Cadmium Chloride and Cadmium Bromide

By Kazuo Morigaki*

Department of Physics,
Osaka University, Osaka

(Received May 17, 1961)

Paramagnetic resonance of Co^{2+} ions present as substitutional impurities in single crystals of cadmium chloride and cadmium bromide has been observed below about 40°K using the frequency of 9300 Mc/sec.

The orbital ground state of Co^{2+} ion in the cubic crystalline field has a threefold degeneracy, which is split into a singlet and a doublet if the trigonal field acts on the ion in addition to the cubic field. Each Co^{2+} ion substituting cadmium ion is subjected to a crystalline field of approximately cubic symmetry with a trigonal component in the $CdCl_2$-type lattice. The observed spectra of Co^{2+} ions in cadmium chloride can be described by the following spin Hamiltonian,

$$\mathscr{H}=g_{/\!/}\beta H_zS_z'+g_{\perp}\beta(H_xS_x'+H_yS_y')$$
$$+AI_zS_z'+B(I_xS_x'+I_yS_y')$$

with effective electron spin $S'=1/2$, nuclear spin $I=7/2$, $g_{/\!/}=3.04\pm0.02$, $g_{\perp}=4.95\pm0.02$, $A=(36\pm6)\times10^{-4}\,\mathrm{cm}^{-1}$, $B=(169\pm9)\times10^{-4}\,\mathrm{cm}^{-1}$ at 4.2°K, and $g_{/\!/}=3.03\pm0.02$, $g_{\perp}=4.95\pm0.02$, $A=(36\pm6)\times10^{-4}\,\mathrm{cm}^{-1}$, $B=(167\pm9)\times10^{-4}\,\mathrm{cm}^{-1}$ at 1.4°K, where the z direction is chosen to coincide with the c axis of the crystal.** The above spin Hamiltonian indicates that the lowest level of Co^{2+} ions in the cadmium chloride crystal is an orbital singlet. The observed values of $g_{/\!/}$ and $g_{\perp}$ can be explained by the theory of Abragam and Pryce[1)].

The paramagnetic resonance spectrum of Co^{2+} ions in cadmium bromide at about 10°K can be fitted with the above spin Hamiltonian with the following values of the parameters; $g_{/\!/}=2.71\pm0.05$, $g_{\perp}=4.99\pm0.05$, $A=(32\pm8)\times10^{-4}\,\mathrm{cm}^{-1}$, $B=(175\pm10)\times10^{-4}\,\mathrm{cm}^{-1}$, $S'=1/2$, and $I=7/2$.

The resonance lines of Co^{2+} ions in cadmium chloride and cadmium bromide can be saturated at relatively small power (below half a milliwatt) of the microwave at liquid helium temperature. The measurement of saturation of the resonance lines of Co^{2+} ions in cadmium chloride was done at 4.2°K and 1.4°K in the case of the static magnetic field perpendicular to the c axis in which eight h.f.s. lines could be observed. The saturation behaviour is an inhomogeneous type at both temperatures and the products of T_1 and T_2 are given as follows: $T_1\cdot T_2=6.6\times10^{-12}\,\mathrm{sec}^2$ at 4.2°K and $T_1\cdot T_2=3.1\times10^{-11}\,\mathrm{sec}^2$ at 1.4°K.

As the measuring temperature is increased above 4.2°K, the resonance lines are broadened gradually and above about 40°K they become unobservable because of the too short spin—lattice relaxation time. The spin—lattice relaxation time at about 40°K estimated from the line width is 1.4×10^{-9} sec. The temperature dependence of the spin—lattice relaxation time is understood by the direct process in the interaction between phonons and spins in the temperature range from 1.4°K to 4.2°K and by the Raman process in the temperature range from 20°K to 40°K.

Besides the allowed transitions described above the forbidden transitions which correspond to a simultaneous flipping of electron and nuclear spins in the same and opposite directions are observed at 4.2°K in the case of cadmium chloride crystal when the oscillating magnetic field has a component parallel to the static magnetic field. In the static magnetic field perpendicular to the c-axis, each line of seven forbidden h.f.s. lines is located in the middle between every eight allowed h.f.s. lines. The relative intensities of the forbidden lines in themselves are in good agreement with those calculated from the formula of the transition probability given by Jeffries[2)] using the above parameters of the spin Hamiltonian, but the ratio of the intensity of the forbidden lines to that of the allowed lines is five times as large as that expected from the theory of Jeffries.

The full accounts of this report will be published in a near future. The author would like to thank Professor J. Itoh for his helpful discussions.

Oscillator Strength of I⁻-Absorption Band in KCl Crystal

By Takehiko ISHII

Department of Physics, The Faculty of Science, Tohoku University

(Received June 5, 1961)

A KCl crystal containing a small amount of KI shows an absorption band due to the presence of I⁻ ions[1]. The absorption peak of this band appears at the wavelength of 188 mμ at room temperature. If the concentration of I⁻ ions in the crystal is known and the absorption curve is precisely measured, one can calculate the oscillator strength of this band using Smakula's formula. The oscillator strength of the I⁻-absorption band has been determined by this principle.

Five KCl single crystals containing different amounts of KI were grown from the melt in air by Kyropoulos method. The absorption spectrum of each crystal was measured at room temperature with a vacuum spectrophotometer constructed in our laboratory[2]. The resolving power of the spectrophotometer was set to give $\Delta\lambda \sim 0.5$ mμ in the present case. The absorption spectra are shown in Fig. 1. The absorption peak was located at 188.5 mμ and the half width of the band was 0.31 ev. The optical density at the band peak of specimen No. 5, in which the concentration of I⁻ ions is 1.17×10^{19} cm⁻³, is too large to be directly measured and was estimated from the band tail.

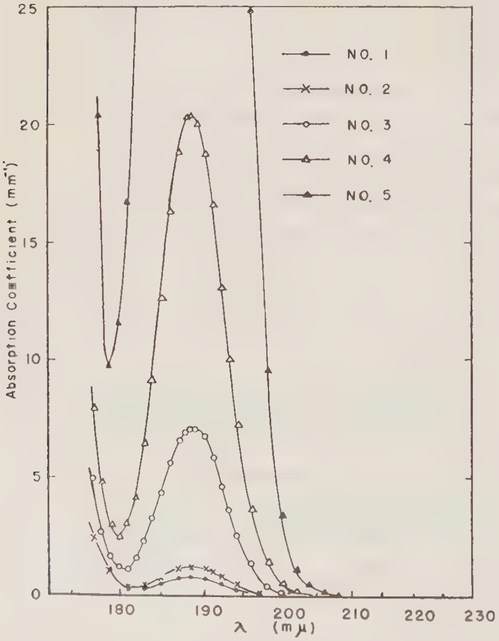

Fig. 1. Absorption spectra of KCl crystal containing various amounts of KI.

The concentrations of I⁻ ions in the crystals were determined by chemical anylysis. Potassium iodide in specimen was oxidized to give IO_3^- with potassium permanganate, and liberation of iodine from IO_3^- was made by adding KI. The concentration of freed iodine was determined by photocolorimetric iodimetry using starch. In KCl crystal Br⁻ ions are usually contained as an impurity. In the present chemical analysis, a procedure which is not affected by the presence of Br⁻ ions is employed. The result of this colorimetric analysis is tabulated in Table I.

Table I. Concentration of I⁻ ions and calculated oscillator strength.

Specimen	α_m (cm⁻¹)	n_0 (cm⁻³)	f
No. 1	7.77	7.25×10^{16}	0.29
No. 2	12.4	1.21×10^{17}	0.27
No. 3	70.7	5.90×10^{17}	0.32
No. 4	204	1.70×10^{18}	0.32
No. 5	1450	1.17×10^{19}	0.33

The height of the absorption maximum is not proportional to the concentration of KI added before melting, but seems to be proportional to that in the crystal. The oscillator strength is calculated with Smakula's formula

$$n_0 f = 1.31\times10^{17}\times\frac{n}{(n^2+2)^2}\alpha_m W\,,$$

where n_0 is the concentration of I⁻ ions in cm⁻³; n is the refractive index of the crystal at 188.5 mμ, α_m is the absorption coefficient in cm⁻¹ at 188.5 mμ and W is the half width of the band in ev. In the present case, the value of $n=1.796$ is adopted which is obtained with appropriate interpolation of the data measured by Martens and Gyulai[3]. The oscillator strength is given as $f=0.30\pm0.04$ by taking the mean of the values in the Table I.

The author expresses his cordial thanks to Mr. S. Tamura, the Institute for Solid State Physics, University of Tokyo, for his guidance in chemical analysis. He also appreciates Professors M. Ueta and K. Kobayashi for their kind interests and useful discussions throughout this work.

Magnetic After Effects in Manganese Zinc Ferrites

By Tsuneo AKASHI and Takashi OKADA

Research Laboratory, Nippon Electric Company, Limited, Tokyo

(Received March 2, 1961)

Co-existence of the Richter Type after effect and the time decrease of initial permeability has been observed in many ferro- and ferri-magnetic materials such as iron-steel[1),2)], Mn-Zn ferrites[3),4)], Ni-Zn ferrites[5)] and Mn-ferrites[6)]. Snoek has proposed the theory[1),2)] that the two effects are caused by the impurity atoms in ferro magnetic materials. In ferrites, it has been assumed by many authors[3),5)] that the transition $Fe^{++} \rightleftarrows Fe^{+++}$ is responsible for the two effects.

In this short note, we report the influence of partial oxygen pressure of the atmosphere (PO_2) during sitering process (1200C° 4 hr) on the two effects, observed for several Mn-Zn ferrites whose composition are given in Table I.

Table I.

Sample No	Fe_2O_3 (mol %)	MnO (mol %)	ZnO (mol %)
1	48	33.2	18.8
2	49	32.6	18.5
3	51	32.3	17.7
4	53	30.1	16.9
5	55	28.7	16.3

Richter Type after effects observed in the samples having the same composition and being sintered in various atmospheres are shown in Fig. 1. The peak values of tan δ increased with the decreas of PO_2. The temperatures at which the peaks occured, were found to be dependent on the composition of the ferrite but not on PO_2. As is usually accepted, the Richter type after Effects, observed in the samples having excess Fe_2O_3 (before sintering) is caused by the transition of electrons between Fe^{++} and Fe^{+++}. Thus the present results indicate that Fe^{++} content in the Mn-Zn ferrite would be decreased with the increase of PO_2.

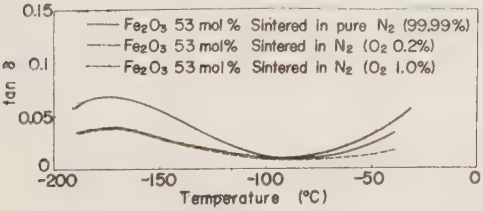

Fig. 1. Richter type after effects in Mn-Zn ferrites.

Time decrease of initial permeability obtained can be expressed by

$$\Delta\mu/\mu=(\alpha/\mu)\log(t/t_0) \qquad (1)$$

where $\Delta\mu$ is the decrease of initial permeability after $t=t_0$. The observed relations between α/μ and composition of the ferrites are shown in Fig. 2 as a function of PO_2. α/μ are sensitive to the compositions as well as PO_2. It is interesting to note that the assumptions that the transition of electrons between Fe^{++} and Fe^{+++} is also responsible for the time decrease of initial permeability may not be valid, because the increase of PO_2, i.e., decrease of Fe^{++}, gave rise to the increase of α/μ.

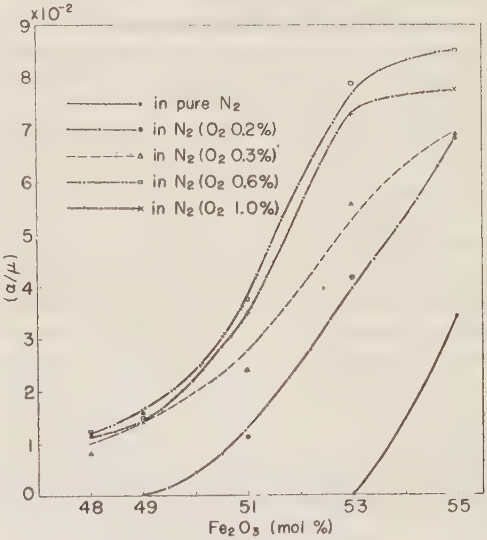

Fig. 2. The decrease of initial permeability in Mn-Zn ferrites after sintering.

The authors wish to express their sincere thanks to Dr. M. Kobayashi rnd Dr. Y. Ishikawa for their kind guidance.

Some Properties of Complex Oxides $AB_{0.5}B'_{0.5}O_3$ of Perovskite Type

By Shoichiro NOMURA and Tatsuyuki KAWAKUBO

Physics Department,
Tokyo Institute of Technology,
O-okayama, Meguro-ku, Tokyo

(Received May 9, 1961)

Recently it has been reported by Brixner[1] that several oxides of $AB_{0.5}B'_{0.5}O_3$ type (A=Ba, Sr: B=W, Mo: B'=Ni, Co) show the perovskite structure, cubic for the oxide of barium and tetragonal for the oxide of strontium. We have made x-ray measurements on the oxides in which Ba and Sr atoms are mixed at various ratio in the position of A, and also measurements of electric conductivity on Sr oxides.

The specimens were prepared by the method of two successive solid-state reactions at 1250~1350°C and 1 atom pressure of air. The crystal structure at room temperature was determined from the powder diffraction patterns, using CuK_α radiation, and it was ascertained that all of these oxides are of perovskite type and further that the dimensions of the unit cell a and c can be represented as $a=2a_0$, $c=2c_0$, where a_0 and c_0 are those of the unit cell of typical perovskite structure containing one molecule in it. This fact suggests us that the rock-salt type ordered arrangement of B and B' ions is realized in the crystal. The values of the cell dimensions are in good agreement with Brixner's data[1]. The ordered arrangement was not broken by quenching from temperature as high as 1250°C.

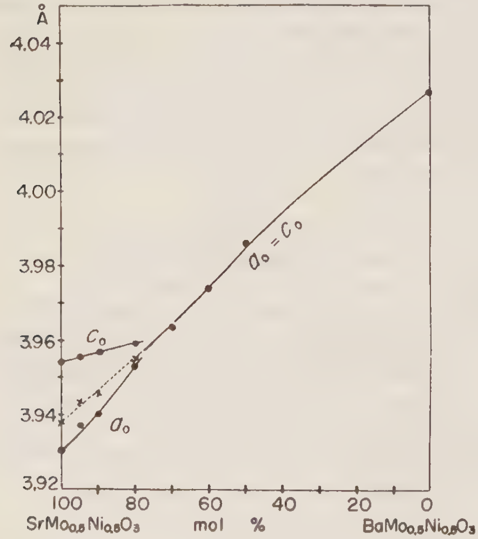

Fig. 1. Cell dimensions for the system of $BaMo_{0.5}Ni_{0.5}O_3$-$SrMo_{0.5}Ni_{0.5}O_3$. The crosses represent the values of $\sqrt[3]{a_0^2c_0}$.

By replacing some of Sr ions with Ba ions, the unit cell volume of the oxides of strontium increased and the tetragonality decreased with the increasing content of Ba ions until it became 1. As an example, the result for $BaMo_{0.5}Ni_{0.5}O_3-SrMo_{0.5}Ni_{0.5}O_3$ system is shown in Fig. 1, where the cell volume varies almost continuously with the content of Ba ions, passing through the transition from the tetragonal- to cubic-phase.

The electrical conductivities of these samples in the temperature range from r.t. to 300°C were measured by the two terminal method and an anomaly was found for each oxide of strontium. The results obtained are exhibited in Fig. 2. The

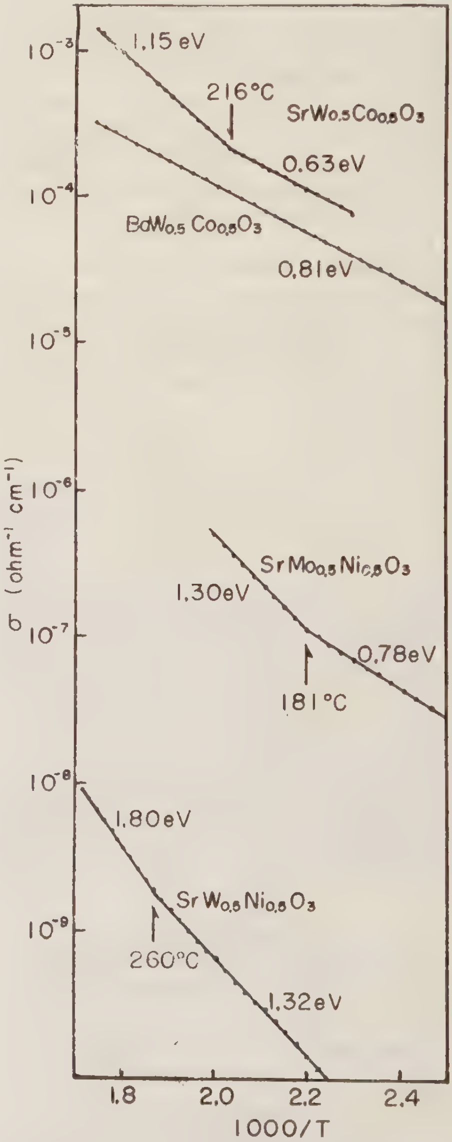

Fig. 2. Electrical conductivity *vs* temperature characteristics.

logarithmic law of conductivity holds for all samples. It is to be noted that for each oxide of strontium the activation energy abruptly changes its value at a certain temperature, while for oxide of barium it remains constant in the temperature range concerned. The anomaly observed in the electrical conductivity-temperature characteristics is considered to be due to the crystal deformation accompanied by the polymorphic transition from the tetragonal- to cubic-phase.

We may conclude from these measured results that the transformation from the tetragonal- to cubic-phase can be induced in the oxides of strontium by raising the temperature as well as by replacing Sr ions partly with Ba ions. The detailed investigations are now in progress.

The authors wish to express their thanks to Mr. H. Machino for his helps in the experimental procedures.

Cross Modulation Line Profiles in Cyclotron Resonance Experiments

By Louis GOLD

Radiation Laboratory and Department of
Nuclear Engineering University of
Michigan, Ann Arbor, Michigan

(Received May 10, 1961)

Work is in progress to characterize the line profiles associated with d.c. cross modulation signals recorded in cyclotron resonance experiments with semiconductors. For a many-valley semiconductor, rather complicated algebraic expressions need to be elaborated for this purpose. It will thus be possible in the future to investigate scattering processes and related phenomena directly from cross modulation data.

The theory differs substantially from conventional treatment of cyclotron resonance, incorporating fully the dispersive behavior of the free carriers; the cross modulation effect is intimately connected with the role of the magnetoplasma. Hence delineation of the cross modulation response requires identification of the appropriate dispersion relation which is embodied in the following finding for the effective conductivity σ in the circumstance of zero bias voltage.

$$\sigma_{\text{eff}}=-i\omega\left\{\frac{-f_2\pm\sqrt{f_2^2-4f_1\left(a_{11}-\frac{\omega_p^2}{\omega^2}\right)\frac{\omega_p^4}{\omega^4}}}{2f_1}\right\}. \qquad (1)$$

For the collision-free limit, the functions $f_{1,2}$ take on the values

$$\left.\begin{aligned} f_1&=f(a_{jl})-\frac{\omega_p^2}{\omega^2}(a_{22}a_{33}-a_{23}^2)-\frac{\omega_c^2}{\omega^2}a_{33}\,,\\ f_2&=\frac{\omega_p^2}{\omega^2}(a_{12}^2-a_{11}a_{22})+(a_{22}+a_{33})\frac{\omega_p^4}{\omega^4}+\frac{\omega_c^2\omega_p^2}{\omega^4}\,,\end{aligned}\right\} \qquad (2)$$

where a_{jl} are the dimensionless components of the mass tensor $\overleftrightarrow{m}$ (whose longitudinal and transverse components are reprectively m_1 and m_2)

$$\overleftrightarrow{m}=\frac{m_2}{3}((a_{jl}))\,, \qquad (3)$$

as dictated by orientation of the electric vector and the d.c. magnetic field $\vec{H}$ relative to the crystal axes; the other quantities are:

$$\left.\begin{aligned} f(a_{jl})&=a_{11}a_{22}a_{33}+2a_{12}a_{13}a_{23}\\ &\quad-(a_{11}a_{23}^2+a_{22}a_{13}^2+a_{33}a_{12}^2)\,,\\ \omega_p^2&=\frac{3Nq^2}{m_2}\,,\qquad \omega_c=\frac{3qH}{m_2}\,,\end{aligned}\right\} \qquad (4)$$

where N is the electron density (charge q).

The foregoing supposes strict alignment of the external magnetic field normal to the direction of the electromagnetic wave. The cross modulation resonances in this circumstance, originating when $f_1=0$, are given by

$$\omega_{\text{res}}^2=\frac{\omega_p^2(a_{22}a_{33}-a_{23}^3)+\omega_c^2a_{33}}{f(a_{jl})}\,. \qquad (5)$$

It may be recognized that this corresponds to the coupled plasma and cyclotron oscillations in the scalar mass limit, $\omega^2=\omega_p^2+\omega_c^2$. In the limit where $\omega_p\ll\omega_c\sim\omega$, the usual cyclotron resonances arise[2].... a result which is independent of the orientation of the fluctuating fields and the wave front itself.

Now, unlike the ordinary cyclotron resonance situation where the number of lines depends only upon the direction of the externally applied magnetic field, additional lines may appear if the perturbing fields shift direction as can arise in a dispersive medium. The nature of these lines was described some time ago[3] and the present analysis has strengthened the suspicion that the origin of ghost-lines[4] may indeed be linked to coupling of plasma and cyclotron modes.

A more complete understanding of this phenomenon (strange sensitivity of the cross modulation spectra to various conditions such as changes in light intensity[4]) should emerge upon a detailed examination of the line shapes where expression (1) is properly modified to include the role of collisions and realignment of the wave normal.

Temperature Distribution around the Rest or Moving Solid-Liquid Interface in a Rod

By Mikio YAMAMOTO

The Research Institute for Iron, Steel and Other Metals, Tôhoku University, Sendai

(Received March 20, 1961)

It has already been known that a high yield percentage in growing single crystals from the melt is obtained by the high purity of the material used, low velocity of crystallization, and high temperature gradient in the specimen[1]. It has also been found that the orientation distribution of single crystals grown at high rates from the melt shows a remarkable anisotropy[2]. The interpretation of these facts requires the clarification of the process of solidification and of the associated factors.

We have considered the temperature distribution around the solid-liquid interface as one of such factors and calculated it as a function of the temperature gradient in the furnace and of the moving velocity of the interface or the velocity of crystallization for the case of an infinitely long rod which is either at rest or moving at a constant velocity, R, in an infinitely long cylindrical vacuum furnace having a uniform temperature gradient, G_f (>0). It is assumed that the solid-liquid interface is planar and that the temperature distribution in the normal cross-section of the rod is uniform so that the heat convection does not occur in the liquid.

Let us denote the temperature of the furnace as T_f, the cross-sectional area of the rod as A, its circumference as S, its density as ρ, its specific heat as c, its thermal conductivity as k, its emissivity as σ, its temperature as T, its temperature gradient as G, its melting point as T_E, its latent heat of solidification as L, the positional coordinate along the rod axis as x, and the time as t. We indicate quantities associated with solid and with liquid, respectively, by putting the subscripts s and l. Taking $x=0$ at the interface separating the solid portion $(x<0)$ and the liquid one $(x>0)$ and denoting the moving velocity of the interface as R_i, we have, at the interface,

$$k_sA_sG_{so}-k_lA_lG_{lo}=\rho_sA_sL_iR\ , \tag{1}$$

which was already obtained by Goss[3], and, for the solid and liquid portions,

$$-R_i(\partial T/\partial\xi)_t=\alpha(\partial^2T/\partial\xi^2)_t+(S/A)\beta(T_f^4-T^4)\ , \tag{2}$$

where

$$\xi=x+R_it\ , \tag{3}$$

$$\alpha=k/\rho c \qquad \text{and} \qquad \beta=\sigma/\rho c\ .$$

From Eqs. (2) and (1), we get an equation

$$\begin{aligned}&(1/2)(T_o-T_{fo})[(\rho_lc_lA_l-\rho_sc_sA_s)R_i+k_lA_l\{(R_i^2/\alpha_l^2)-4(R_i/\alpha_l)G_f/(T_o-T_{fo})\\&\quad+4K_l(T_o+T_{fo})(T_o^2+T_{fo}^2)\}^{1/2}+k_sA_s\{(R_i^2/\alpha_s^2)-4(R_i/\alpha_s)G_f/(T_o-T_{fo})\\&\quad+4K_s(T_o+T_{fo})(T_o^2+T_{fo}^2)\}^{1/2}]=(k_lA_l-k_sA_s)G_f+\rho_sA_sLR_i\ ,\end{aligned} \tag{4}$$

where

$$K=(S/A)(\sigma/k)\ .$$

Eq. (4) yields, for small G_f and R_i,

$$T_{fo}=T_E-\{(BG_f+DR_i)/2T_E^{3/2}\}\ , \tag{5}$$

$$\left.\begin{aligned}G_{lo}&=G_f-K_l^{1/2}(BG_f+DR_i)\ ,\\G_{so}&=G_f+K_s^{1/2}(BG_f+DR_i)\ ,\end{aligned}\right\} \tag{6}$$

and

$$\left.\begin{aligned}T_l&=T_f+\{(BG_f+DR_i)/2T_E^{3/2}\}\exp[-(R_i/2\alpha_l)-2K_l^{1/2}T_E^{3/2}\{1-(3/8)(BG_f+DR_i)/T_E^{3/2}\}]x\ ,\\T_s&=T_f+\{(BG_f+DR_i)/2T_E^{3/2}\}\exp[-(R_i/2\alpha_s)+2K_s^{1/2}T_E^{3/2}\{1-(3/8)(BG_f+DR_i)/T_E^{3/2}\}]x\ ,\end{aligned}\right\} \tag{7}$$

where

$$B=(k_lA_l-k_sA_s)/\{(S_lA_lk_l\sigma_l)^{1/2}+(S_sA_sk_s\sigma_s)^{1/2}\}$$

and

$$D=\rho_sA_sL/\{(S_lA_lk_l\sigma_l)^{1/2}+(S_sA_sk_s\sigma_s)^{1/2}\}\ .$$

These equations indicate that, for the rest interface $(R_i=0)$, $T_E \gtrless T_{fo}$, $G_{lo} \gtrless G_f$, and $G_{so} \gtrless G_f$ according as $k_lA_l \gtrless k_sA_s$ as for usual metals or for bismuth[3], and that, for the moving interface during solidification $(R_i>0)$, as R_i increases, eventually T_E becomes larger than T_{fo}, G_{lo} becomes negative, and G_{so} becomes greater than G_f, even in the case $k_lA_l<k_sA_s$.

These results of calculation are found to accord well with the results of Goss and Weintroub's[3),4)] experiments with moving rod in a fixed furnace, which measured $\partial T/\partial t=R_iG$. The detail will be published elsewhere soon.

Electron Spin Resonance in Neutron-Irradiated LiF

By Kazuo MORIGAKI*

Department of Physics,
Osaka University, Osaka

(Received June 1, 1961)

Electron spin resonance in neutron-irradiated LiF has been studied at 4.2°K and 1.4°K with various power levels of the microwave to examine whether the resonance line is due to more than one magnetic centers. Single crystals of LiF obtained from Harshaw were exposed at room temperature to thermal neutron with neutron doses of 2×10^{16} nvt and 1×10^{16} nvt. The partially resolved h.f.s. with $g=2.002\pm0.002$ were observed in these crystals. The spacings between neighboring h.f.s. lines are given for some orientations of the magnetic field as follows: 14.7 G for [111], 14.4 G for [001], 12.0 G for [110], and 6.8 G for the direction making the angle of 70° with the [001] axis in a (110) plane. It was found that the entire line shape which is Gaussian at the small rf field depends strongly on the intensity of the rf field. The line width (ΔH_{ms}) decreases and partially resolved structures become less emphasized with increase of the intensity of the rf field as shown in Fig. 1. On the other hand, the spacing between h.f.s. lines does not change with the intensity of the rf field and as to the line widths of resolved h.f.s. lines little change is observed over the power range of the microwave available in this experiment, but a slight increase is recognized at the maximum microwave power.

A sample with 2×10^{16} nvt irradiation was kept at 290°C for 15 minutes, followed by quenching to room temperature.** By this heat treatment the line shape was transformed into Lorentzian. In the magnetic field parallel to [111] partially resolved h.f.s. lines were observed with spacing of 14.9 G. The line width of the broad line is almost isotropic to be given as 77 G at the small rf field. The decrease in the line width and the ratio of h_2 to h_1 with increasing intensity of the rf field was observed in a manner similar to that in the case of the sample before heat treatment. The resonance line saturates in smaller rf field than that on the samples before heat treatment.

A possible explanation for the above experimental results is given as follows: Two distinct types of magnetic centers contribute to the resonance spectrum, one of which is responsible for the resolved h.f.s. and the other gives a broad line superposed on the resolved h.f.s.. A broad line of Lorentzian shape appears with increase of the intensity of the rf field owing to a difference of saturation behavior between both magnetic centers. The former is the F center distributed isolately over the crystal, and the latter may be the aggregate F centers which interact each other to narrow the resonance line owing to the exchange interaction among them, but are not so aggregate that they form a colloid. Transformation of the line shape associated with heat treatment indicates that isolated F centers diffuse to form aggregate states.

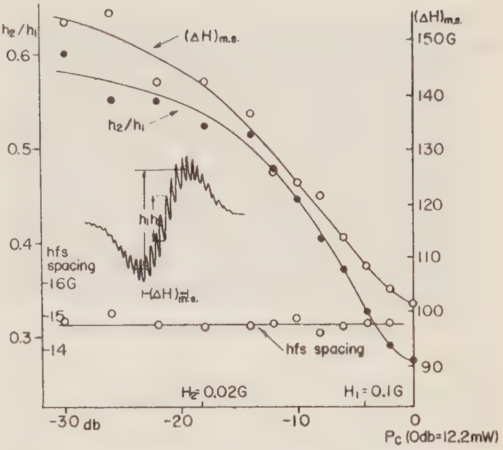

Fig. 1. Dependence of the ratio of h_2 to h_1, the line width, and the spacing of neighboring h.f.s. lines on the microwave power inside the cavity, P_c, in the magnetic field parallel to [111] at 1.4°K. The spectrum observed at 1.4°K and at P_c of -14 db ($H_1=0.033$ G) is also shown in the figure.

Recently Kim, Kaplan, and Bray[1] reported observations of the resonance lines similar to those described here, but their suggestion that the resolved h.f.s. is not due to the F center is inconsistent with our interpretation. On the other hand, our interpretation supports the conclusion of Holton, Blum, and Slichter[2],[3] that the resolved h.f.s. is due to the F center.

The full accounts of this report will be published in a near future. The author would like to thank Professor J. Itoh for helpful discussions and Mr. H. Betsuyaku of Japan Atomic Energy Research Institute for suppling the crystals receiving neutron irradiations.

Linewidth of Cyclotron Resonance of Pure Germanium

By Hazimu KAWAMURA, Masakazu FUKAI,
Yoshikazu HAYASHI and Tamotsu HASHIMURA

Institute for Solid State Physics,
University of Tokyo

(Received June 23, 1961)

The width of the cyclotron resonance line increases with the increase of the microwave power absorbed by crystal as the result of the rise of electron temperature and the consequent increase of the collision frequency. The experiment was made on nearly intrinsic germanium with excess donor concentration of $7\times10^{12}/\mathrm{cm}^3$ at 1.6°K by making use of 6 mm microwave. The free carriers were generated by means of infrared light chopped at 75 cycle/sec. The microwave power was changed by a calibrated attenuator. The maximum power (0 db) falling on the sample cavity is in the order of 1 mW.

Fig. 1 is an example of the resonance pattern displayed on X-Y recorder. The four peaks correspond to the four valleys which have different cyclotron masses for given direction of magnetic field. If the linewidth is resulted only from the finite free time of the carriers, the line shape is Lorentzian and its half width $\Delta H/H$ is equal to $1/\omega\tau$, where ω is the microwave frequency and τ is mean free time of the carriers. From the resonance curves for different powers, we can see that the linewidth becomes broader with the increase of applied power. It may also be noted that $\omega\tau$ is larger for heavier mass valley. It is natural that the rate of power absorption is reciprocally proportional to the mass m^* in the direction of oscillating electric field. In Fig. 2 $1/\omega\tau$ is plotted as a function of P/m^* in log-log scale, where P is the relative power falling on the specimen. It is shown that $1/\omega\tau\propto(P/m^*)^{1/n}$ where n is 2.9 ± 0.3, except in the region of less than one microwatt, where $1/\omega\tau$ tends to a finite value corresponding to the state that electron and lattice are in equilibrium.

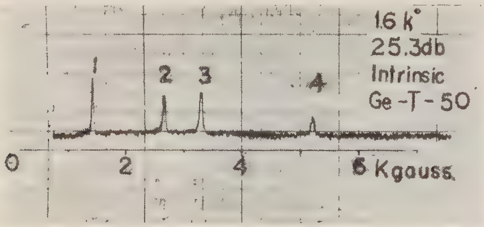

Fig. 1. The cyclotron resonance absorption of pure Ge at 1.6°K. $N_D=7\times10^{12}\,\mathrm{cm}^{-3}$. Microwave power is -25.3 db (~1 micro-watt).

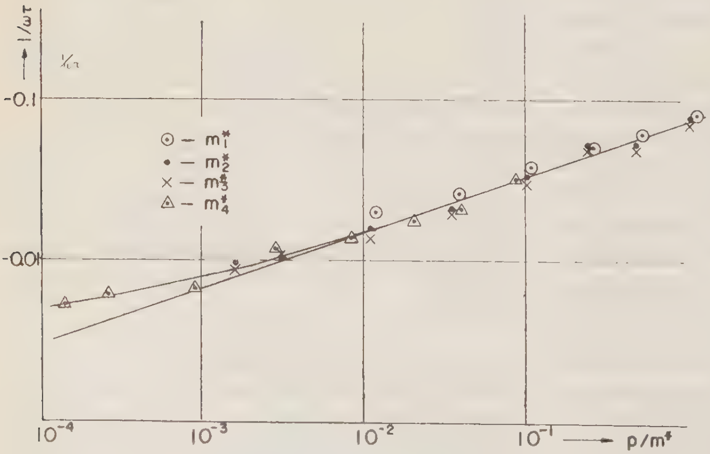

Fig. 2. Linewidth as the function of P/m^*, where P is the applied power and m^* is the effective mass along the direction of oscillating electric field.

If E is the microwave field in the specimen, the rate of power absorption is given by $(eE)^2\tau/m^*$. The rate of energy loss is given by $\langle\Delta\varepsilon\rangle/\tau$, where $\langle\Delta\varepsilon\rangle$ is the mean energy loss per collision. When the lattice temperature is much less than the electron temperature, electron can lose energy only by the spontaneous emission of phonon. The momentum of emitted phonon is roughly equal to the momentum of electron on the average. Hence we find that $\langle\Delta\varepsilon\rangle=\hbar\omega=\hbar c\sigma\simeq\hbar c\kappa$, where σ and k are the momentum of phonon and electron. In this situation $1/\tau$ is proportional to k^2 instead of k, since the factor $2n+1$ $(=2kT/\hbar\omega)$ in the expression of $1/\tau$ should be replaced by one for the case that only the spontaneous emission is effective, and ω is proportional to k. Thus $\langle\Delta\varepsilon\rangle$ becomes proportional to $1/\sqrt{\tau}$. Putting the rate of energy loss and gain are equal, we get the relation that $1/\tau$ is proportional to $(P/m^*)^{1/2.5}$, since P is proportional to E^2. Michel et al.[1] has recently observed the $P^{1/4}$ relation, but we cannot understand the discrepancy.

We should like to express our thanks to Prof. Toyozawa for his suggestive discussion.

Etch Pits on X-Ray Damaged Rochelle Salt

By Kenkichi Okada

Department of Fine Measurements, Nagoya Institute of Technology, Nagoya, Japan

(Received June 2, 1961)

Recently Takahashi and Nakamura[1] published a theory of domains anchored to screw dislocations in ferroelectric crystals, and they pointed out that the dislocations play important roles in certain behaviors of ferroelectrics. Dislocation etch pits were found by Nakamura[2] and Ohi [3,4] on GASH crystals, and by Toyoda[5] on triglycine sulfate crystals. Furthermore, Nakamura and Ohi[6] made a thorough investigation on etch pits on c-plates of rochelle salt. Longer sides of the quadrangular pyramidal pits are in the a-direction. It was concluded that these etch pits correspond to emergence points of dislocation lines running parallel to the c-axis. In rochelle salt crystal there exist open-cored dislocations parallel to the c-axis which are called *sudarés* among Japanese researchers. Some of the etch pits correspond to the *sudarés*.

In the previous paper[7], a phenomenological theory of the ferroelectric properties of damaged rochelle salt was reported. A model was proposed, in which polar anisotropy centers introduced by irradiation interact with the other regions. In order to obtain more concrete image of the polar anisotropy centers in the model, effects of X-rays on the dislocation etch pit pattern and on the distribution of the *sudaré* were studied. An X-ray tube was running at 40 kV and 15 mA. At the ferroelectric temperature region, plates of rochelle salt were irradiated for about 3 hours and were etched by distilled water.

Damaged crystals revealed etch pits of hip roof shape of which ridges were along the a-direction. Fig. 1 illustrates an etch pattern of a natural c-face. The left two-thirds were exposed to the irradiation, while the right one-third was kept virgin under a lead plate protector. In the damaged region, pits which have been arranged in a linear array are extended in hip roof shape by the irradiation. This observation may lead us to the supposition that some serious changes in dislocations would be introduced by irradiation.

It was reported by a few investigators[8,9] that the *sudarés* are increased by X- and γ-radiations. Fig. 2 is a micro-photograph of *sudarés* induced by irradiation in an a-cut plate. *Sudarés* observed in a c-plate are given in Fig. 3. It must be noted that, before the irradiation they are very few and almost undetectable in these plates. Immediately after the irradiation, they are also very few and can hardly be seen. These photographs were obtained a day after irradiation. *Sudarés* which are seen as fine lines in a-plates and as bright spots in c-plates are arranged in a plane perpendicular to the b-axis.

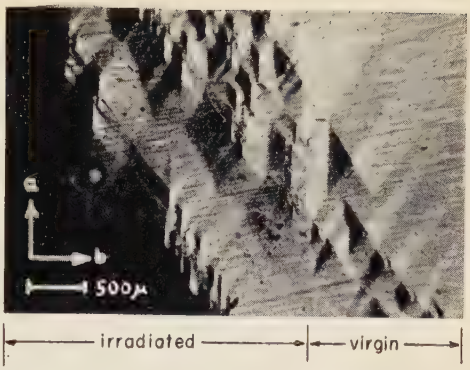

Fig. 1 Changes in etch pits on a natural c-face of rochelle salt crystal by irradiation. The left two-thirds are damaged, but the right one-third is kept virgin.

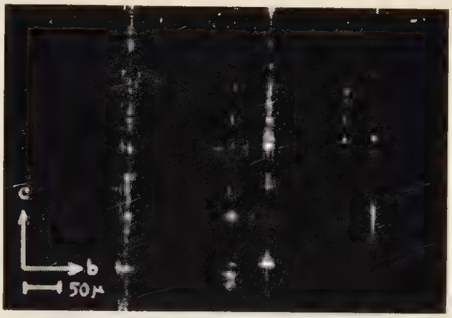

Fig. 2 Open-cored dislocations (sudaré) in a damaged a-cut plate of rochelle salt.

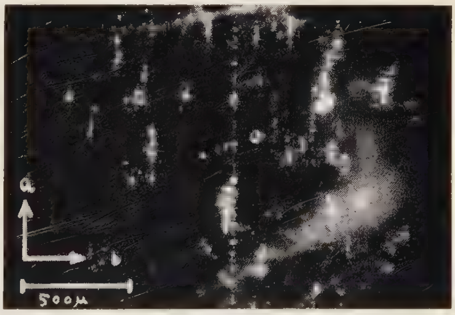

Fig. 3 *Sudarés* in a damaged c-cut plate of rochelle salt.

It was confirmed that these *sudarés* arranged in a plane correspond to the hip roof etch pit. It seems that irradiations induce *sudarés* along the other crystallographic directions than before and give rise to changes in etch patterns on the a- and b-faces also. These observations are now in progress, and will be published in the future.

Spin Echoes of Co^{59} in fcc Cobalt Metal

By Kiyoshi SUGIBUCHI, Motohiro MATSUURA and Tsuneo HASHI

Department of Physics, Kyoto University, Kyoto

(Received June 26, 1961)

The NMR of Co^{59} in ferromagnetic cobalt metal was first observed by Gossard and Portis.[1,2] The subsequent works[3,4,5] were carried out mostly by the steady-state method. The present note reports some of the experimental results obtained by the application of the pulse method. The apparatus was almost the same as that used previously for pulsed PQR experiments in bromine compounds,[6] but some modifications were made in pulsed oscillator so as to measure the shorter relaxation times.

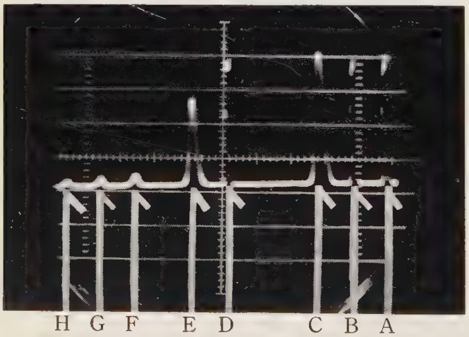

Fig. 1. Spin-echoes of Co^{59} in fcc cobalt metal.
A: first pulse E: second echo (stimulated echo)
B: second pulse F: third echo
C: first echo G: fourth echo
D: third pulse H: fifth echo
Sweep length is about 100 μ sec.

The pulse width used was 2 μ sec or less. The sample consisted of finely divided multidomain particles. The experiments were carried out in the temperature range from 77°K to 300°K.

The strong spin-echo signals were observed, as shown in Fig. 1. The observed values of spin-echo envelope decay time T_2 were almost independent of temperature and about 15 μ sec.

The spin-lattice relaxation time T_1 was measured by the following procedure. The spin system was first saturated by a train of strong rf pulses and then the recovery of longitudinal component of magnetization from saturation was measured from the amplitude of the spin-echo signal produced by application of a pair of pulse at a later time. The observed values of T_1 were 300 ± 30 μsec at 77°K and $85\pm10\mu$ sec at 300°K, and were nearly inversely proportional to the temperature. Both the value and the temperature dependence are different from those reported by Gossard and Portis.[2] The origin of the disagreement is not clear but partly may be due to the difference in the measuring techniques.

It was found that the time constant T_m of the stimulated echo decay curve was generally shorter than T_1 obtained by the above method and could be represented by the following formula:

$$1/T_m = 1/T_1 + k\tau^2$$

where τ is the time interval between the first and the second pulse. The above formula has the same form as that derived by Hahn.[7] This implies the existence of spin diffusion between spins at the different positions of the frequency spectrum, though Hahn's analysis is not directly applicable to the present case. The obtained values of k are about 4×10^{14} sec^{-3} and almost independent of the temperature. The order of magnitude of $k^{-1/3}$ is equal to that of T_2.

The authors would like to express their sincere thanks to Professor I. Takahashi for his continued interest and discussion. Thanks are also due to Dr. Y. Nakamura and Dr. T. Takada of the Department of Chemistry, Kyoto University, for their kind assistances in preparing the sample.

Group Velocity of Moving Striations in Hg-A Discharge

By Hiroshi Yoshimoto and
Yoshihiko Yamashita
Department of Physics, Okayama University

(Received June 3, 1961)

Wojaczek[1] first measured the velocity of the wave packet obtained by his perturbation method in argon discharge, and he deduced that the velocity corresponds to the group velocity of moving striations. His measurements, however, were concerned only with the current region in which the natural moving striations cannot appear. We have carried out the similar measurements in Hg-A discharge not only in the Wojaczek's current region but also in the current region in which the natural moving striations can appear (abbreviated as the current region I and II respectively), and could catch the feedback figures of perturbations on the screen of cathode ray oscilloscope. The discharge tube and other apparatus used have been described elsewhere[2]. In this experiment, pentodes were inserted in series with the discharge tube to modulate the current by the pulses applied to their control grids.

The perturbations of plasma are originated by the current pulses at the negative end of the positive column, and propagate towards the anode in the form of wavepacket shown in Fig. 1, while the each wave in a wavepacket propagates towards the cathode and this wave corresponds to the moving striation. The traveling velocity of the wavepacket is nearly equal to that of moving striation. Some examples of these velocities are columned in Table I. These features can be expected from the dispersion relation of moving striation obtained experimentally by one of us[3]. Thus, it is concluded that the moving striation is a backward wave. The occurrence of wavepacket by this pulse method indicates that the plasma of positive column has a resonance frequency for the moving striation.

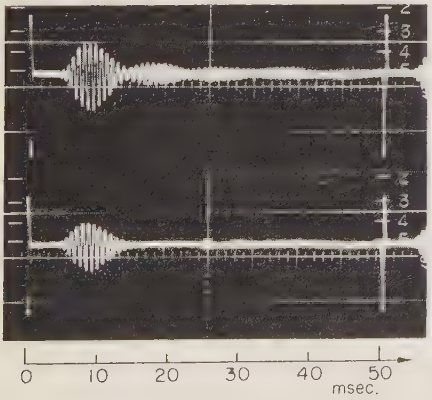

Fig. 1. Photographs of wavepacket at 5 cm from the anode. Current: 160 mA. Mag. Field: 80 gauss. Tube Diameter: 25 mm.

Table I.

Current (mA)	Velocity of wave-packet (m/s)	Velocity of moving striation (m/s)
140	48	49
150	47	50
160	47	51
170	49	54

Tube Diameter: 25 mm. Room Temp: 16°C.

Moving towards the anode, the wavepacket increases and decreases its amplitude in the current region II and I respectively. At the critical current the wavepacket travels without changing its amplitude. These circumstances are shown in Fig. 2.

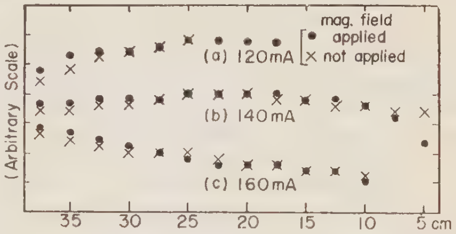

Fig. 2. The amplitude of wavepacket *versus* the distance from the anode. The curves (a) and (b) correspond to the current region II, and the curve (c) to the current region I.

In the curren region II, several sub-wavepackets are observed to follow the primary wavepacket as seen from Fig. 1 (a). The time intervals between the successive wavepacket are all the same in magnitude corresponding just to the transit-time in which the wavepacket travels from the negative end of the positive column to the anode. When a magnetic field is applied in front of the anode perpendicularly to the tube axis, these sub-wavepackets disappear as seen from Fig. 1 (b). While the propagation characteristics of wavepacket remains unchanged in the positive column excepting the domain of the magnetic field. For instance, this circumstance concerning the amplitude of wavepacket is given in Fig. 2. These results ascertain that the sub-wavepackets are the feedback figures of the primary wavepacket. This feedback occurs in such a way that the wavepacket, arriving at the anode, gives a disturbance to the current which induces a new perturbation of plasma at the negative end of positive column. The magnetic field makes the wavepacket damp away preventing its feedback.

The Colloidal Band in KCl Containing NaCl

By Shinichi NAKASHIMA

Matsushita Electronics Corporation
Takatsuki, Osaka

(Received June 5, 1961)

When additively colored alkali halides are exposed to a heat and light treatment a transformation of the *F*-band to a narrow band at a longer wavelength is observed. This Phenomenon is attributed to the transformation of *F*-centers into colloidal particles of the reduced metal. Using the Mie theory, Doyle[1)] and Scott[2)] calculated the wavelength for maximum absorption in the colloidal band. According to Doyle's calculation in the limit of very small particles, the position of the colloidal band in pure KCl is 8200 Å which is in agreement with the results of the observation[1)].

The present report describes the effect of sodium ions on the colloidal band in KCl. KCl crystals were grown from melts to which NaCl was added. The crystals were colored additively in potassium metal vapor. The density of *F*-centers in each crystal was about 10^{17} per cm³. When the additively colored crystals were heated and exposed to the light of a tungsten lamp, the *F*-baed vanished and a narrow band of increasing height appeared at a wavelength well below 8200 Å. Fig. 1 shows the absorption curves of the bands which grow by heating the additively colored KCl-NaCl mixed crystals at 200°C. For a larger doping amount of NaCl in KCl the absorption band grows at shorter wavelengths. In Fig. 2 the position of the absorption bands is plotted as a function of the NaCl concentration in KCl. The concentration of NaCl was analyzed spectrographically. The concentration of NaCl in the most pure KCl was less than 10^{15} per cm³.

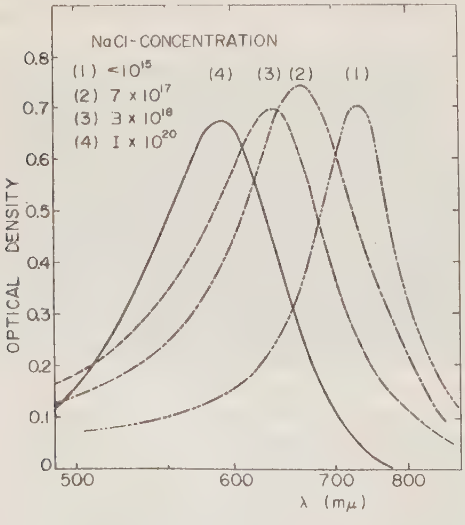

Fig. 1. The colloidal bands in KCl crystals containing various amount of NaCl.

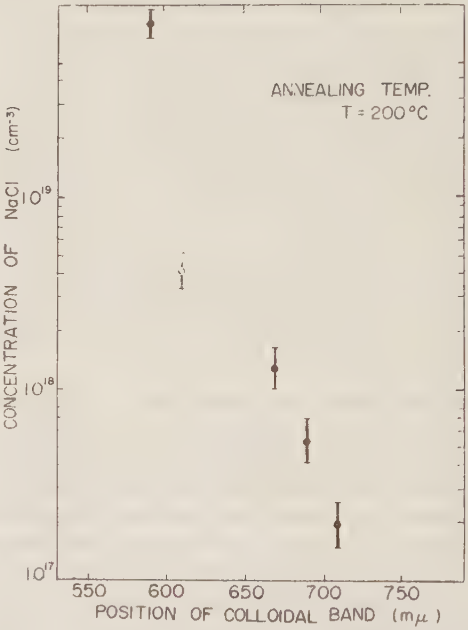

Fig. 2. The position of the colloidal bands in KCl-NaCl mixed crystals as a function of the NaCl concentration.

The position of the absorption band was hardly changed at the temperatures between 15°C and −196°C, but shifted to longer wavelengths with increasing temperature of annealing. Savostinova has pointed out that the position of the colloidal band shifts to longer wavelengths as the particle size increases. The absorption bands in KCl-NaCl mixed crystals appear, however, at shorter wavelength side of the colloidal band in pure KCl, so that the absorption bands can not be identified with the potassium colloidal bands. These absorption bands can not be attributed to a *R'*-band but to K-Na alloy colloids. Applying Doyle's calculations to K-Na alloy colloids, we can estimate the ratio of Na to K in the K-Na alloy colloids. It follows that for the colloidal particle having an absorption maximum at 5900 Å, atomic ratio of Na to K is 60 per cent and at 7100 Å, it is 10 per cent. Comparing the above results with the NaCl concentration of Fig. 2, it is clear that the ratio of Na to K in K-Na alloy colloids is much larger than the ratio of NaCl to KCl of the mixed crystals. This difference might be due to a nonuniform distribution of NaCl in the KCl crystal. In order to confirm the assignment, the colloidal band in KCl containing LiCl is being investigated.

The author wishes to thank Assistant Professor K. Fukuda for his helpful discussions and Professor Y. Uchida for his encouragement.

Nuclear Elastic Scattering of Photons near the Particle Threshold Energy (I)

By Tsutomu TŌHEI, Masumi SUGAWARA, Shigeki MORI
and Motoharu KIMURA

Department of Physics, Faculty of Science, Tohoku University, Sendai

(Received March 3, 1961)

The elastic scattering of photons near the particle threshold energy was studied for Al, Si, S, K, Ca, Ni, Cu, Cd, Sn, Pb and Bi. The bremsstrahlung x-rays from a 25 Mev betatron were used. The pulse of the primary x-rays was expanded up to about 30 μ sec to decrease the pile-up effect. The scattered photons were detected at the scattering angle of 120 degrees with the scintillation spectrometer using an $8''\phi\times8''$NaI(Tl) crystal and a 30 channel pulse height analyser gated by the expansion signal of the betatron orbit. The energy at which the cross section has a peak was compared with the particle threshold energy and the value of cross section was compared with that of particle emission.

§ 1. Introduction

The elastic scattering of photons in the energy region of the giant resonance was studied by Fuller and Hayward[1]. They reported two maxima in the elastic scattering cross section, i. e. one around the particle threshold and the other around the energy where the giant resonance of the photon absorption has maximum value. According to Bethe and Ashkin[2] it is illustrated qualitatively that the peaks around the particle thresholds appear, since the particle emissions which do not take place below the threshold suppress the photon emissions. The available information[3] on the radiation widths of excited levels at nearly several Mev above the ground state was also obtained from the neutron scattering and capture experiments. The studies[4] using the monochromatic 7 Mev γ-rays of the reaction $F^{19}(p, \alpha, \gamma)O^{16}$ revealed that the observed widths and spacings are approximately in agreement with the modified single particle calculation by Weisskopf and Blatt[5].

Recently Fujii[6] has shown theoretically that the nucleus of the core plus one nucleon can be excited owing to the absorption of γ-ray by the last nucleon. According to his theory this excited state should be observed in several Mev above the ground state.

The bremsstrahlung x-rays from the 25 Mev Tohoku betatron have been used to study the elastic scattering cross sections near the particle threshold energies. According to the present experimental result, the energies of the peak of the cross sections near the particle threshold are in agreement with the threshold energies of (γ, p) or (γ, n) in most elements, as were predicted qualitiatively by Bethe and Ashkin[2].

§ 2. Experimental Procedure

The procedure of the present experiment is essentially the same as Fuller and Hayward's[1]. The experimental arrangement is shown in Fig. 1.

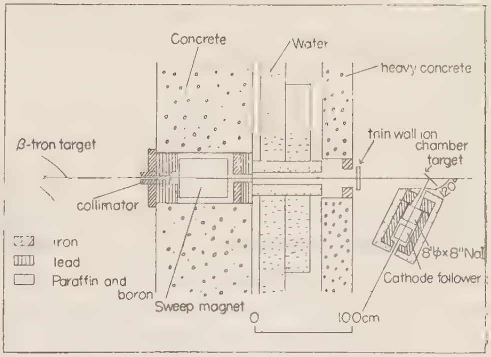

Fig. 1. Experimental arrangement.

The primary x-rays were collimated to 1¾ inches in diameter at the target by lead and iron collimators. The photon detector was an $8''\phi\times8''$ NaI(Tl) crystal with three Du Mont 6363 photomultiplier tubes and was located in a lead container which has 6 inches thick walls at both the betatron room and the collimator sides and has 4 inches thick walls in other sides. The container was surrounded with borax and paraffin.

The measurements were performed setting the detector at the two positions. In the first case the detector was placed at the scattering angle of 120 degrees and the spectra of photons scattered from the target in each betatron energy were measured. In the second case the spectra of bremsstrahlung itself at 0 degree without the target were measured. The tapered lead slit, 4 inches in diameter, was placed in front of the crystal and was filled with 1½ inches thick paraffin in order to remove electrons and low energy photons emitted from the target. On the other hand, a 2 inches diameter, 10 inches long lead slit was used as a collimator in the direct beam. In front of this collimator 12 inches long aluminum and 4 inches long lead absorbers were placed to reduce the intensity of x-rays from the betatron so that pile-up might be negligible. The x-rays were monitored by a thin wall ionization chamber connected to a vibrating reed electrometer. The block diagram of electronic devices is shown in Fig. 2.

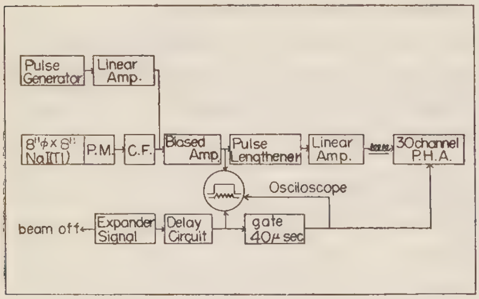

Fig. 2. Block diagram of electronic devices.

The pulses from the detector were amplified by a fast biased amplifier followed by a pulse lengthener and the lengthened pulses were analysed by a 30 channel pulse height analyser. The analyser was operated for the time interval of 40 μ sec in each operation cycle by a gating circuit so that only those pulses occurring in that interval around the primary x-ray pulses were counted. With this gating action the cosmic γ-ray background was reduced to the order of 0.3 counts per hour per one channel at the 7 Mev region. In order to estimate the contribution to the counts of the background γ-rays induced by neutrons in the primary x-ray beam, the test experiment was performed with a Ra-Be neutron source. Judging from the results of this experiment, this background was negligible. The pile-up effect was carefully decreased to the negligible magnitude by expanding the width of the primary x-rays to about 30 μ sec.

In Table I the target thickness is listed. The potassium sample was in the form of K_2CO_3 and the other samples were in metallic form.

Table I. The target thickness.

target	thickness (g/cm²)
Al	8.16
Si	2.20
S	10.16
K*	3.48
Ca	2.33
Ni	11.05
Cu	11.0
Cd	9.28
Sn	9.10
Pb	14.4
Bi	14.8

* K: the sample of K_2CO_3

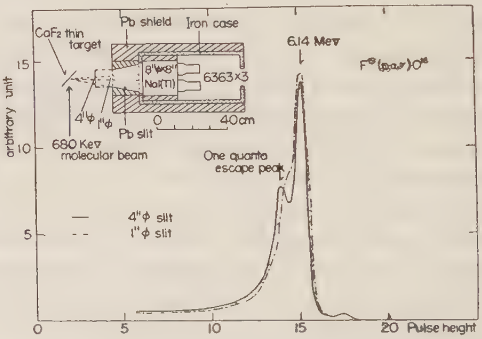

Fig. 3. The response curve of the 8″$\phi\times$8″ NaI(Tl) for the 6.14 Mev γ-rays from the reaction of $F^{19}(p, \alpha, \gamma)O^{16}$. The solid line is the result obtained with the same geometry as the case of scattering experiment, when the γ-rays were collimated to 4 inches in diameter in front of crystal. The dashed line is the results obtained with the tapered lead slit of 1″ diameter.

The measurements were made at the betatron energies from 5 Mev to 12 or 16 Mev with the interval of 1 Mev. In each betatron energy the bias of the fast biased amplifier was adjusted so that the pulses corresponding to the highest energy portion of bremsstrahlung were recorded in the given part of channels of the 30 channel pulse height analyser. The counts in the top ten channels of the spectra which correspond to photons in energy interval of 1 Mev from the top of the bremsstrahlung were summed up. C_s

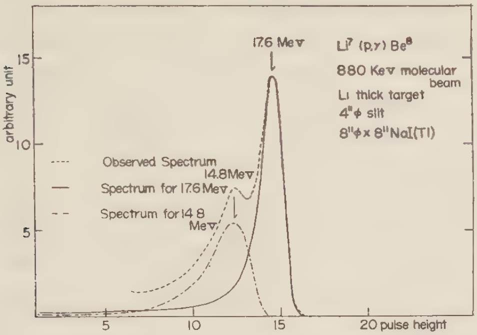

Fig. 4. The response curve of the $8''\phi\times 8''$ NaI(Tl) for 17.6 Mev γ-rays from the reaction of Li^7 (p, γ)Be^8. The dotted line is the measured spectrum. The solid line for the 17.6 Mev γ-rays was evaluated from the dotted line by extracting the contribution of the 14.8 Mev γ-rays. The intensity ratios $I_{17.6}/I_{14.8}$ was assumed to be 1.7[8]. These were measured with the same geometry as in the case of the scattering experiment.

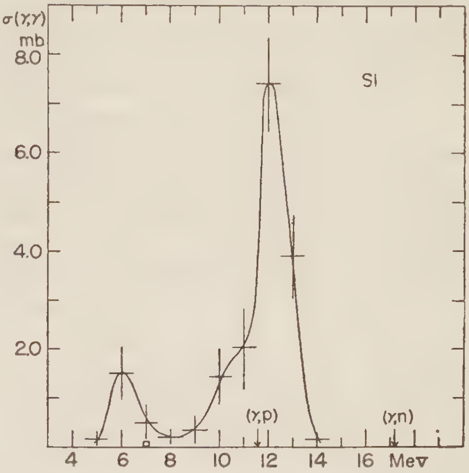

Fig. 5. The elastic scattering cross section of photons by Si. The arrows of (γ, p) or (γ, n) indicate the positions of the particle threshold energies of Si^{28}. □: data from the experiment of the monochromatic γ-rays[4].

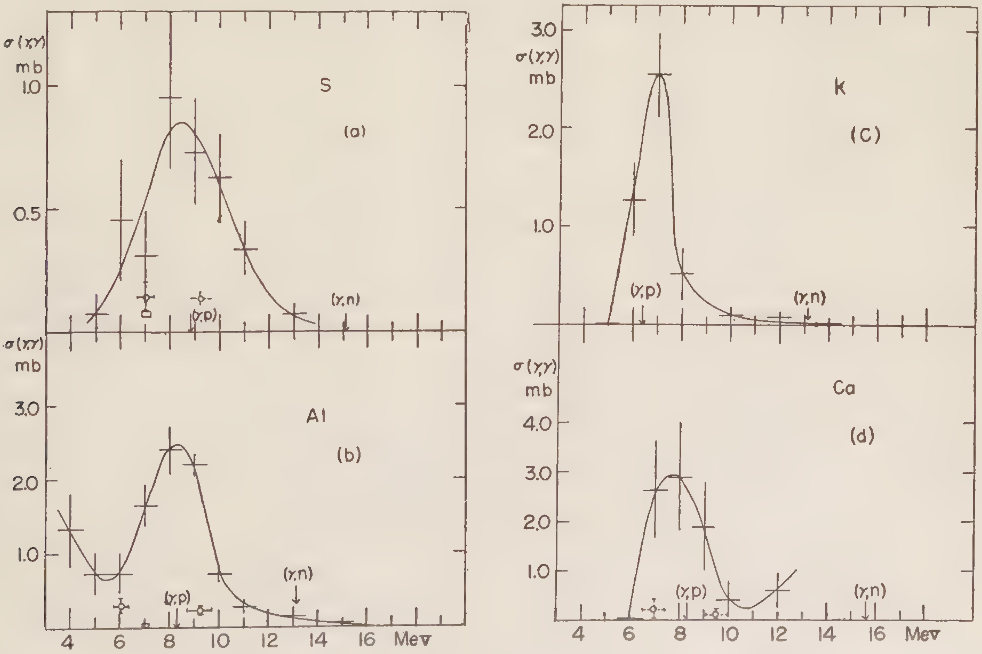

Fig. 6. The elastic scattering cross section of photons. ⊢○⊣: data from Fuller and Hayward[1].
□: data from the experiment used monochromatic γ-rays[4].

(d): $\sigma(\gamma, \gamma)$ by Ca. The arrows indicate the positions of the particle threshold energies of Ca^{40}.

and C_d are the counts at the given scattering angle and the ones in the direct beam position, respectively. They were corrected for the electronic absorption using White's table[7].

The elastic cross sections are calculated from the ratios of C_s to C_d for each betatron energy. This method is appropriate, since the monitor response was not needed for the calculation of the cross sections. We do not give the detailed explanation of it, because Fuller and Hayward discussed it thoroughly in Ref. 1.

The response function of the NaI(Tl) crystal with the present geometry was measured with the 6.14 Mev and 17.6 Mev γ-rays obtained from the reactions $F^{19}(p, \alpha, \gamma)O^{16}$ and $Li^7(p, \gamma)Be^8$. In Figs. 3 and 4 the response curves for γ-rays of these reactions are shown.

In the calculation of the cross sections we assumed that the angular distributions of the scattered γ-rays are isotropic and that the angle subtended by the collimator at the target can be calculated numerically from the geometry.

(b): $\sigma(\gamma, \gamma)$ by Sn. The arrows indicate the positions of (γ, p) and (γ, n) threshold energies of Sn^{116}, Sn^{118} and Sn^{120}. Numbers 1, 2 and 3 correspond to Sn^{116}, Sn^{118} and Sn^{120}.

§ 3. Results

Experimental results are plotted in Figs. 5–9. Here the vertical lines are the statistical errors and the energy spread indicated is the width due to the channels which are summed up as was stated before.

The shapes of the energy dependence of the cross sections are not inconsistent with those of Fuller and Hayward[1], but our absolute values of the cross sections are different in most elements. This discrepancy is not so serious, considering the difficulty of the experiments of this kind.

In comparison with the particle threshold energies, the peak positions of $\sigma(\gamma,\gamma)$ are in good agreement with the (γ,p) threshold energies for light nuclei such as Al, S, K, Ca and Ni, and with the (γ,n) threshold energies for heavy nuclei such as Pb. In the case of Cd and Sn, the peaks are slightly below the particle threshold.

In the case of Bi, however, the peak position is above the threshold. This fact is interesting, because the peak above the threshold can not appear by the process such as mentioned by Bethe and Ashkin. Therefore the peak of the cross section in Bi seems to occur by the process of the single particle excitation predicted by Fujii[6], since Bi^{209} is composed of a double magic core and one outer nucleon.

The case of Si is different from the others. Three somewhat sharp resonances were observed at 12.0 Mev, 10.4 Mev and 6.0 Mev, while the sharp resonance peaks were found at 11.4 Mev and 10.4 Mev by the other experiments[9],[10].

This fact suggests that the peaks below the particle thresholds in photon elastic scattering consist of the assembly of the sharp resonances, especially, in light elements. But it is not clear whether the resonance in other elements decomposes into many levels or not, if we restrict ourselves only to these results.

The energy dependence of the cross sections

Bi	8.0	3.7	7.4	1.00		1.00

near the particle threshold is generally in agreement with the idea of the competition with the particle emission, if we disregard the elements such as Si, the exceptional element in the present experiment.

In Table II, the summary of these cross sections is shown. The first column shows the energies at which the cross sections have maxima. The second and the third columns show (γ, p) and (γ, n) threshold energies quoted from the nuclear data[11], respectively. The fourth column contains ratios of the peak values of the cross sections to that of Pb. In fifth and sixth columns of Table II, (γ, n) and (γ, p) cross sections normalized to (γ, n) cross section of Pb are listed.

For the determination of $\sigma(\gamma, p)/\sigma_{Pb}(\gamma, n)$ we assumed the following approximate equations;

$$\frac{\sigma(\gamma, p)}{\sigma_{Pb}(\gamma, n)} = \frac{\int \sigma(\gamma, p) dE}{\int \sigma_{Pb}(\gamma, n) dE}$$

and

$$\frac{\sigma(\gamma, n)}{\sigma_{Pb}(\gamma, n)} = \frac{\int \sigma(\gamma, n) dE}{\int \sigma_{Pb}(\gamma, n) dE} .$$

The values of $\int \sigma(\gamma, p) dE$ were calculated from the data summarized by Weinstock and Halpern[12]. As these data were given in the unit of protons per mole per roentgen, the integrated cross sections in the unit of Mev-mb were approximately calculated by assuming that the value of Cu in unit of Mev-mb is given by

$$\int \sigma(\gamma, p) dE = \int \sigma_{\text{total}} dE - \int \sigma(\gamma, n) dE .$$

We assumed $\int \sigma_{\text{total}} dE = 0.06 \frac{ZN}{A} (1+0.8x)$ and $x=0.4$, which was determined semi-empirically by

$$\int \sigma_{\text{total}} dE \simeq \int \sigma(\gamma, n) dE$$

for Pb. The values of $\int \sigma(\gamma, n) dE$ were quoted from Ref. 13.

As mentioned above, the peak positions of the cross sections in most elements are in agreement with the threshold energies of (γ, p) or (γ, n). This fact will support, as mentioned by Bethe and Ashkin, that the peaks around the particle thresholds in most of elements appear by the competition with the particle emission. From this point of view the cross section should be approximately proportional to that of (γ, p) or (γ, n), since the (γ, γ) cross section is only the lower part of the giant resonance. This proportionality seems to be roughly satisfied when we compare the fifth column with the last two columns excepting the case of Si.

Acknowledgment

The authors indepted to the Van de Graaff group in Tokyo University for their help in measuring the response curves of the 6.14 Mev and 17.6 Mev γ-rays from $F^{19}(p, \alpha, \gamma)O^{16}$ and $Li^7(p, \gamma)Be^8$ reactions. The authors also ex-

press sincere thanks to Dr. K. Okamoto, who is now at Tohoku University, for his helpful discussions.

Some New Activities Produced by Fast Neutron Bombardments

By Kasuke TAKAHASHI*, Tokihiro KUROYANAGI,† Haruo YUTA††,
Kyûya KOTAJIMA*, Kunio NAGATANI**
and Haruhiko MORINAGA*

Department of Physics, Tôhoku University, Sendai, Japan

(Received April 18, 1961)

Several new nuclides were produced in the internal target of the INS cyclotron from the fast neutron bombardments of Ge, Mo, Gd, Er, Yb and Hf. Their radiation characteristics were determined with the aid of beta and gamma ray scintillation spectrometers. The new activities observed are as follows:

Nuclides	Half-lives	Beta rays	Gamma rays
Ga^{76}	32±3 sec	~6.0 MeV	0.57, 0.96, 1.12 MeV
Nb^{98}	51±5 min	3.5±0.1 MeV others	0.78 MeV many others
Nb^{100}	11.5±1.0 min	4.2±0.1 MeV others	0.53 MeV many others
Eu^{160}	~2.5 min	3.6±0.5 MeV	none
Ho^{168}	~3.5 min	~2.2 MeV	0.85 MeV
Ho^{170}	45±5 sec	~3.1 MeV	0.43 MeV
Tm^{174}	~5.0 min	2.5±0.1 MeV	none
Tm^{176}	1.5±0.3 min	4.2±0.1 MeV	none
Lu^{180}	2.5±0.5 min	3.3±0.1 MeV	none

The radiation characteristics were analysed in the light of the unified model and the conventional nuclear level systematics.

§ 1. Introduction

The study of short half-lived activities with rather high decay energy often yields useful information on nuclear properties. It is because of following reasons: 1) Because of its high decay energy, many excited states in the daughter nuclides are looked at. 2) It can add more to the nuclear systematics. We have been following this line of study by using the (γ, p) reaction and scintillation spectroscopy. We have found many new activities and thus many new nuclear states[1]. The paper which describes results of a part of such investigation carried on the rare earth region[2] will be published later.[2]

In this paper, we describe results of the study of neutron excess short-lived activities produced by the (n, p) reactions. The fast neutron bombardments and the activity measurements were carried out at the Institute for Nuclear Study of University of Tôkyo as one of the co-operation project of the Institute. The technique of measuring the activities and the method of analysis are very much similar to those of previous works.

§ 2. Experimental Procedures

The fast neutron beam was obtained by bombarding an internal graphite target with 20-MeV deuterons of the 160 cm variable energy cyclotron at the Institute for Nuclear Study of University of Tokyo. Samples to be activated by the fast neutrons were placed just behind the graphite target in the internal neutron target assembly in order to make the activation as effective as possible. A very schematic drawing is shown in Fig. 1. The intensity of the fast neutron beam was approximately $10^8\ n/\text{cm}^2\cdot\text{sec}$ at the bombarding position as estimated from the yield of the 9.5-min Mg^{27} produced by the $Al^{27}(n, p)$ reaction. Considerable amount of thermal neutron flux was also present which made the measurements complicated in some cases. After the bombardments the samples were pulled out from the bombarding position by a string. Usually it took only about half a minute before starting the counting after the bombardment in most of the cases. Because of rather short half-lives of the activities produced, no chemical treatment was performed except for the case of molybdenum.

The energy and half-life measurements of beta and gamma rays were performed with scintillation spectrometers with a 60 channel pulse height analyser of a differential discriminator type. For the measurement of half-lives, single channel analysers were also employed.

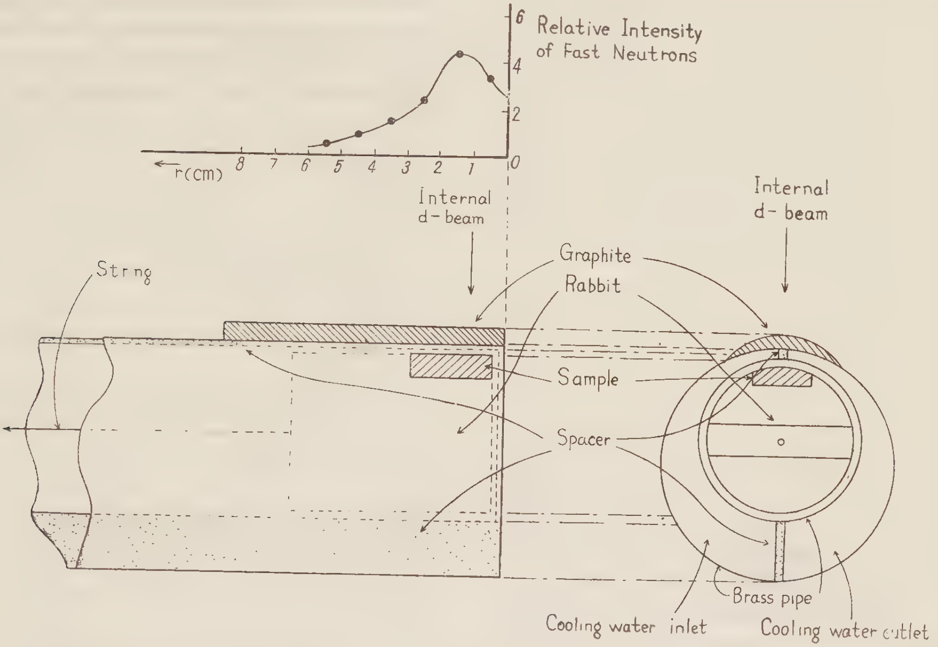

Fig. 1. Schematic picture of internal target system and distribution of fast neutron flux along the radial direction as measured by the $Al^{27}(n, p)Mg^{27}$ reaction.

The gamma rays were detected by NaI(Tl) crystals either 7.6 cmφ × 7.6 cm or 3.8 cmφ × 3.8 cm. Energy calibrations were made by the well known peaks of the gamma rays from In^{114}, Au^{198}, Cs^{137}, Zn^{65} and Na^{22} and the sum peak at 1.788 MeV of Na^{22}. Analysis of spectra was made with the comparison of the spectral shapes of gamma rays from these sources, obtained with the same geometry.

In the present work, since most of activities produced by the (n, p) reactions have rather high beta-decay energy, a large plastic scintillator of 5.1 cmφ × 5.1 cm was employed for the beta ray measurement in spite of its poorer resolution and its high sensitivities of gamma rays. Consequently many of the Kurie plots showed considerable non-linearity at the lower energy side of the curve (cf. Fig. 2). We

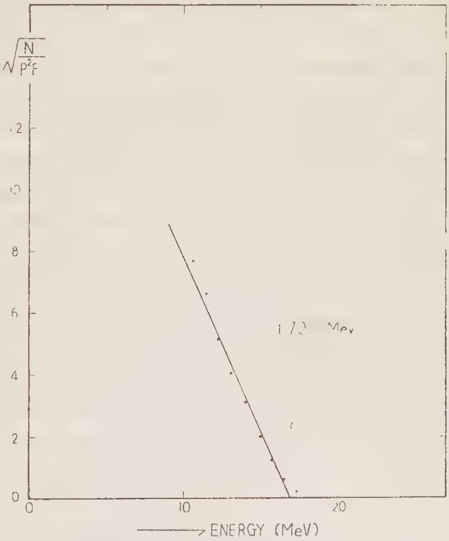

Fig. 2. Kurie plot of the beta ray spectrum of P^{32} obtained with the beta ray scintillation spectrometer.

could, thus, determine end-point energies for only one or two main branchings of the beta rays. For energy calibration, the beta rays from P^{32}, In^{114}, Cu^{66} and Ag^{112} were used. Fig. 3 shows a standard calibration curve for the beta ray scintillation spectrometer.

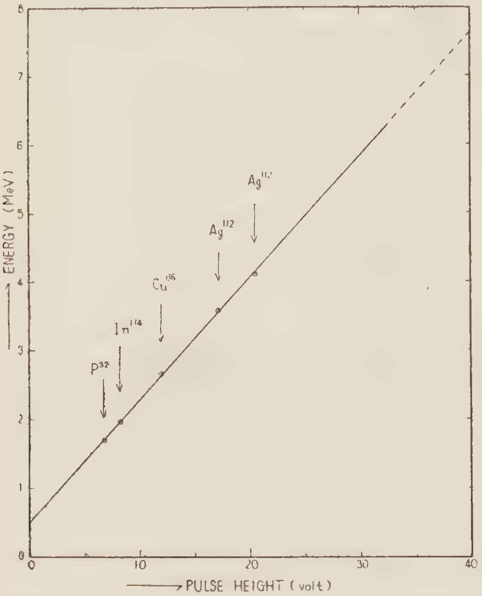

Fig. 3. Typical calibration curve for the beta ray scintillation spectrometer.

§ 3. Results and Discussions

Nine nuclides, Ga^{76}, Nb^{98}, Nb^{100}, Eu^{160}, Ho^{168}, Ho^{170}, Tm^{174}, Tm^{176} and Lu^{180} were studied from the (n, p) reactions of natural germanium, molybdenum, gadolynium, erbium ytterbium and hafnium. Some additional information about the decay characteristics were also obtained for, Tm^{173}, Lu^{178} and Lu^{179}. But in the present paper, no description was made for Tm^{173}, Lu^{178} and Lu^{179} because these are reported in the following paper rather in detail together with other newly found activities from the (γ, p) reactions[2]. Since Dy^{164} has very large thermal neutron capture cross section, bombardment of dysprosium was seriously disturbed by slow neutrons. Accordingly, no conclusive new information was obtained in the case of dysprosium.

1) Ga^{76}

Fig. 4 shows a decay curve of higher energy beta-ray components from Ga activities obtained from the neutron bombardment of germanium. An extremely pure metallic germanium sample was bombarded for about two minutes. Besides the well known high energy component from Ga^{74}($T_{1/2}$=8 min), a very short-lived activity of high energy is seen. The half-life was about 32 sec.

The end-point energy of the activity was determined to be about 6.0 MeV from the analysis of the Kurie plot (Fig. 5). The value is quite comparable to the decay energy of Ga^{76} to be produced by the (n, p) reaction on Ge^{76} (abundance=7.67%). Since no other product

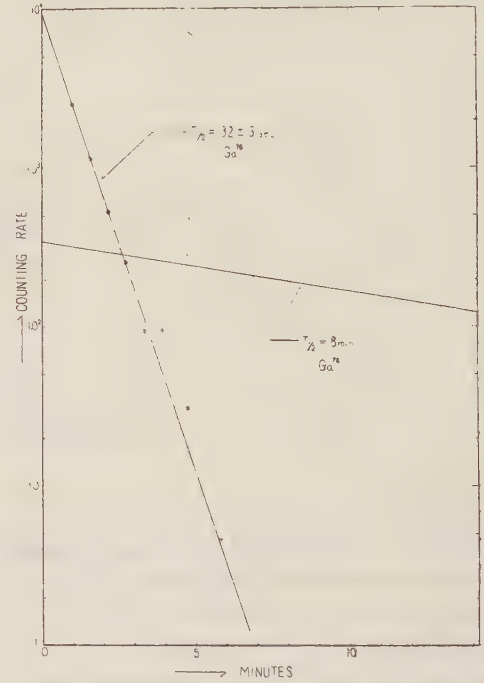

Fig. 4. Decay curve of the beta rays higher than 3.2 MeV from the metallic germanium sample bombarded with neutrons.

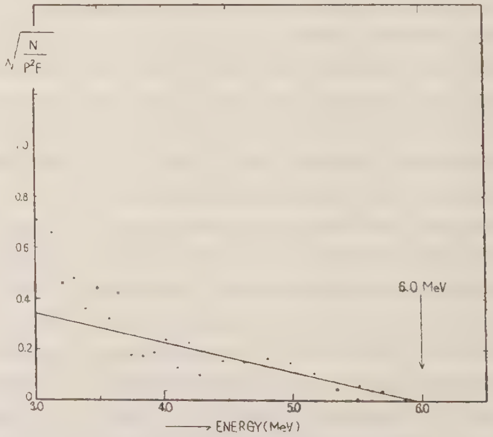

Fig. 5. Kurie plot of the beta rays from a neutron bombarded germanium sample.

of fast neutron reaction on Ge can give such a high energy electron radiation and the cross section to produce the activity is equal in order of magnitude to that of $Ge^{74}(n, p)Ga^{74}$ reaction, the activity is safely assigned to Ga^{76}. The spin-parity value of ${}_{31}Ga^{76}_{45}$ being most likely 2−, or any way not very high, the occurrance of the 6.0-MeV beta ray end-point is reasonable by a comparison with the expected value of the decay energy from the beta decay energy systematics ($E_\beta \sim 7.5$ MeV).

A short half-life of about 1 min or less was also observed in the decay superposed on the 0.58-MeV gamma ray from the 8-min Ga^{74}. Since Ge^{76} has the first excited state observed by the Coulomb excitation at 0.57 MeV³⁾, the short-lived component is assumed to belong to the Ga^{76} activity. This further supports the assignment of this short-lived activity to Ga^{76}.

In addition to the 0.57-MeV gamma ray, a few gamma rays of, 1.12 MeV and 0.96 MeV and some others were observed having a similar short half-life of one minute or less. Although the assignment to Ga^{76} was not completely certain because of the presence of strong disturbing gamma rays of nearly same energies in Ga^{74}. The gamma ray of 1.12 MeV, however, is considered to correspond to the gamma ray decaying from the second 2+ level of Ga^{76} to the ground state which has recently been observed by the Coulomb excitation⁴⁾.

2) Nb^{98} and Nb^{100}

About 10 minutes' bombardment was performed on molybdenum sample. In this case, the half-lives of the activities Nb^{98} and Nb^{100} had been found to be about 10 min or larger in the preliminary experiments. This made it possible to make chemical treatments separating the niobium activities produced by the (n, p) reactions from such disturbing molybdenum activities as Mo^{91}, Mo^{91m} and Mo^{101} which were produced by the reactions of $Mo(n, 2n)$ and $Mo(n, \gamma)$.

The procedures for chemical separation were as follows: after the bombardment of a powder sample of ammonium molybdate, the sample was dissolved into a hot water. In order to make solution acidic, small amount of dilute HCl solution was added. Here, the several millilitre of $FeCl_3$ solution was added. Fe^{+++} ion was used as a carrier of Nb ions. Then, the whole solution was gradually made basic with the addition of ammonia water just enough for making the precipitates of $Fe(OH)_3$.

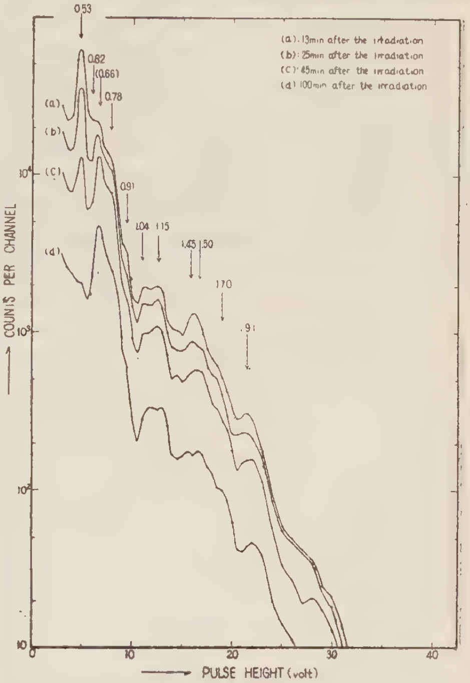

Fig. 6. Typical gamma ray spectra and the variations with time from the chemically separated niobium activities. Here the long-lived and background activities are already subtracted.

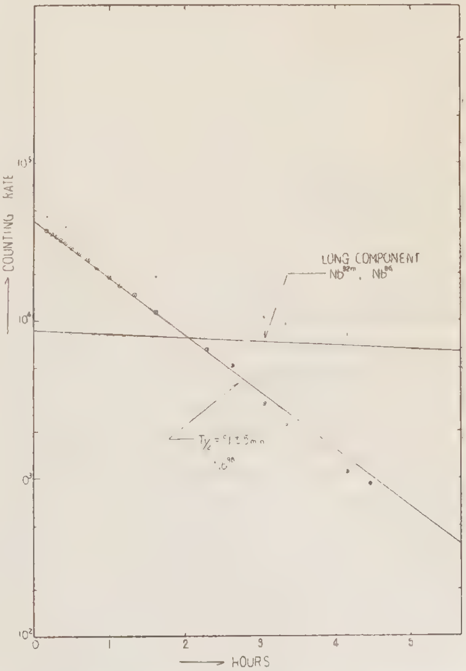

Fig. 7. Decay curve of the 0.78 MeV gamma ray from the niobium activities.

The precipitates with the co-precipitates of Nb activities were centrifuged and washed with dilute ammonium molybdate solution. After the filtration, the precipitates on the filter paper were dried up. It took about 8 or 9 min to carry out the whole chemical procedures.

Fig. 6 shows the gamma ray spectra and their decays obtained for the chemically separated Nb activities. We followed the decays of the gamma ray peaks and observed the two new activities having the half-lives of about 51 min and 11 min. Fig. 7 and Fig. 8 show decay curves obtained for the peaks at 0.78 MeV and 0.53 MeV. The former decays with the half-life of 51 minute and the latter decays with the half-life of 11 minutes. Quite the same results were obtained from the measurements with a single channel analyser. A summary of the results of the gamma ray measurements is given in Table I.

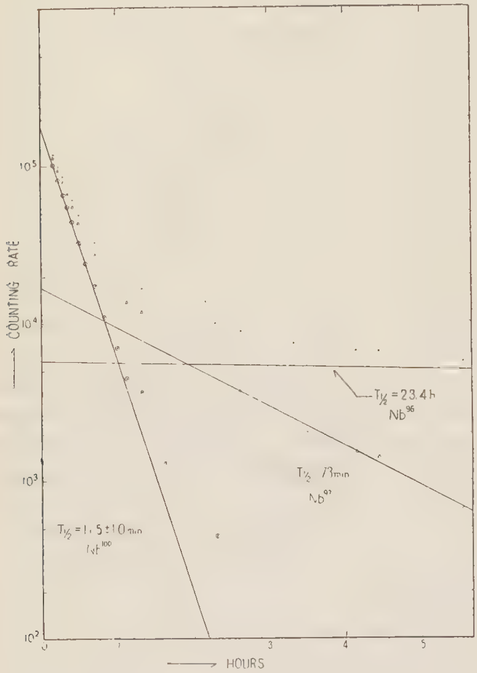

Fig. 8. Decay curve of the 0.53 MeV gamma ray from the niobium activities.

From the results of the Coulomb excitation experiments, the first excited states of Mo^{98} and Mo^{100} are found at 0.78 MeV and 0.53 MeV, respectively[3]. Therefore the 50-min and the 11-min lives are tentatively assigned to the isotopes Nb^{98} and Nb^{100}, respectively.

Table I. Gamma rays from Nb^{98} and Nb^{100}.

Nb^{98}		Nb^{100}	
Energy (MeV)	Relative Intensity	Energy (MeV)	Relative Intensity
0.78	100	0.53	100
0.90	30	0.62	60
1.04	25	1.04	10
1.17	30	1.15	10
1.40	15	1.47	5
1.50	20		
1.70	5		
1.91	5		

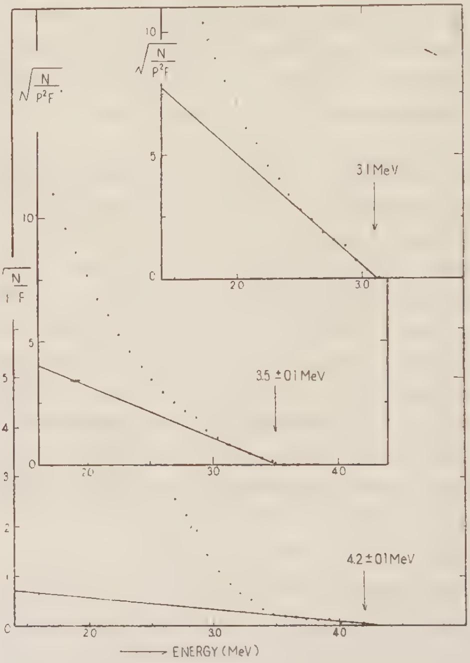

Fig. 9. Kurie plots of the beta rays from the chemically separated niobium activities about 10 min after the irradiation.

Similar decay characters were observed in the decays of the beta ray spectra. The Kurie plot analysis of the beta rays was performed for each spectrum obtained at various times after the termination of bombardment. Fig. 9 shows the Kurie plot for the beta spectrum measured at about 10 minutes after the bombardment, and Fig. 10 shows the spectrum obtained at about 120 minutes after the bombardment when the short component had almost completely decayed. From the analysis of these curves, end-point energies of the beta rays from two activities were determined and several branchings were also suspected to be present with the reference to the results of of a gamma ray measurement. The results are given in Table II. Values of the maximum energies of the beta rays from Nb^{98} and Nb^{100} are in good agreement with the expected values, about 4.2 MeV for Nb^{98} and approximately 4.9 MeV for Nb^{100}, estimated by the conventional beta decay energy systematics. This further supports the above assignments of the activities to Nb^{98} and Nb^{100}.

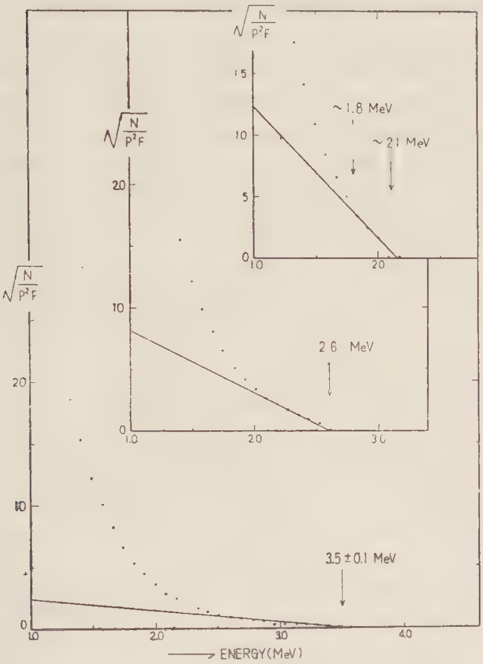

Fig. 10. Kurie plots of the beta rays from the chemically separated niobium activities about 120 min after the bombardment.

Table II. Summary of the beta rays from Nb^{98} and Nb^{100}.

Nb^{98}		Nb^{100}	
Energy (MeV)	Relative Intensity	Energy (MeV)	Relative Intensity
3.5 ± 0.1	intense	4.2 ± 0.1	$\lesssim 10$ (%)
2.6	most intense	3.5 ± 0.1	~45
~2.1		3.1	~45
~1.8		~2.1	~

Recently, Stelson and McGowan have reported the de-excitation gamma ray of 1.050 MeV from the second 2+ state of Mo^{100} as observed in their Coulomb excitation experiment of Mo^{100}.⁵⁾ The above-observed gamma ray of 1.04 MeV from Nb^{100} as shown in Table I, seems to correspond to this de-excitation gamma ray.

3) Eu^{160}

Among the activities produced from gadolynium bombarded with neutrons, only Eu^{160} is expected to have rather high energy beta ray. A decay of the beta rays higher than 2.0 MeV was followed with a single channel analyser. The bias energy of 2.0 MeV was so chosen that most of the activities produced from the (n, γ), the $(n, 2n)$ and the (n, α) reactions of gadolynium were excluded. A result of the measurement is shown in Fig. 11. After the subtraction of the 60-min component from Eu^{158}, an activity of about 2.5 min was observed.

The end-point energy of this short-lived beta ray was determined to be about 3.6 MeV from the Kurie plot analysis. (Fig. 12) The value of the end-point is quite similar to that expected from the beta decay energy systemactics for Eu^{160} (3.5 MeV). The yield of the 3.6-MeV component of about 2.5 min was of same order of magnitude expected for Eu^{160}.

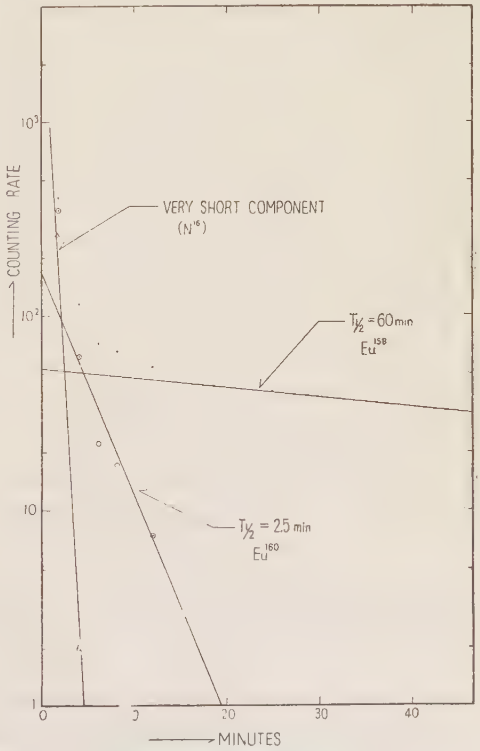

Fig. 11. Typical decay curve of electron radiations higher than 2.0 MeV from a neutron bombarded gadolynium oxide sample.

in comparison with that of the 2.7–MeV beta ray from the 60–min. Eu^{158}. Therefore, one may consider the 2.5–min activity can be assigned to Eu^{160}.

Gamma ray measurements showed no appreciable gamma ray with the 2.5–min life at an energy region higher than 100 keV. Because of the presence of strong gamma rays of about 4 min from Gd^{161} which was produced from the neutron capture, a weak gamma ray may have been missed. We can, however, conclude that most of the beta rays from Eu^{160} decay to the ground state of Gd^{160} or the neighbouring state. The net log *ft* value for the beta transition to lower states in Gd^{160} is, then, approximately 6.2. From the analysis of the Nilsson diagram[6),7)] and the coupling scheme[8)] of the deformed intrinsic states for odd-odd nuclei, the ground state of Eu^{160} is expected to have 1−. Accordingly a beta transition of the first forbidden type is expected. The log *ft* value obtained above, therefore, is plausible from this point of view. The value can be considered to give a further support for the assignment of the newly found activity of 2.5 min to Eu^{160}.

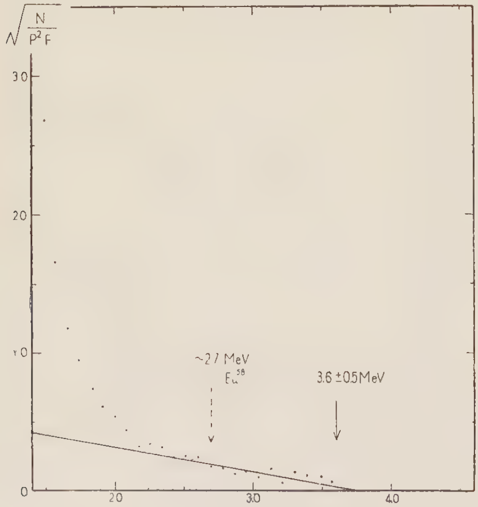

Fig. 12. Kurie plot of the beta rays from a neutron bombarded gadolynium oxide.

4) Ho^{168} and Ho^{170}

About 2-min bombardment was performed for a natural sample of erbium oxide. Activities of Ho^{168} and Ho^{170} were produced from the (n, p) reactions on Er^{168} and Er^{170}. Half-lives of the beta rays from a bombarded sample were measured with a single channel beta ray spectrometer. Fig. 13 shows a typical decay curve of the beta rays higher than 1.8 MeV. Since very small amount of chlorine was present in the sample of erbium, weak high energy beta rays from Cl^{34} and S^{37} which were produced from the $Cl^{35}(n, 2n)$ and the $Cl^{37}(n, p)$ reactions were observed. After the subtraction of the 32–min activity of Cl^{34}, two new activities of 3.5 min and of 45 sec were found. The half-life of the 3.5–min activity, however, has some ambiguities because of the presence of a weak beta ray from the 5.0–min S^{37}. From the Kurie plot analysis of the beta rays from the bombarded sample of erbium oxide, these two short-lived beta rays were proved to have end-points of 2.2 MeV and of 3.1 MeV, respectively. These results are given in Fig. 14.

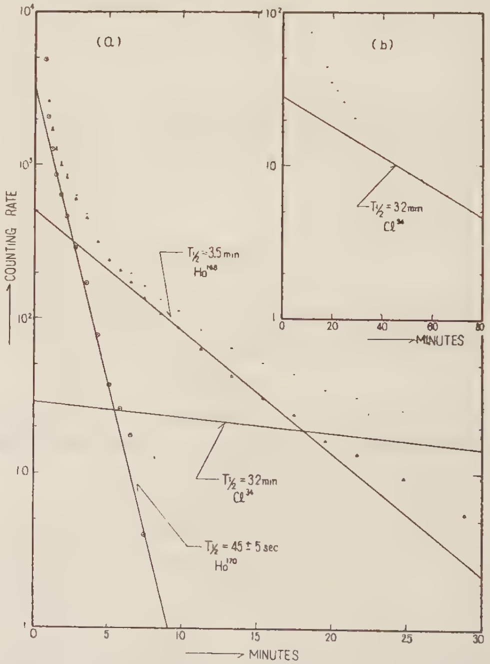

Fig. 13. Decay curves of the electron radiations higher in energy than 1.8 MeV from a neutron irradiated erbium oxide. Fig. (a) shows the early part of the curve and Fig. (b) gives the later part.

Among many activities produced from natural erbium by the neutron-induced reactions, conceivable nuclides which would have such short lives and high beta decay energies are only Ho^{168} and Ho^{170}, or Dy^{165} and Dy^{167} produced by the (n, α) reactions on Er^{168} and Er^{170}.

However, in the gamma ray measurement well known gamma rays from Dy^{165} which would be produced from the $Er^{168}(n, \alpha)$ reaction, were not observed clearly. Thus one may probably assign these two activities, the 2.2–MeV beta activity of 3.5 min to Ho^{168} and the 3.1–MeV of 45 sec to Ho^{170}, from the analyses of the conventional energy systematics (2.8 MeV for Ho^{168} and 3.7 MeV for Ho^{170}) and of the experimental yield ratios. The above assignments concerning Ho^{168} and Ho^{170} agree well with the results of the recent work reported by Willie and Fink[9].

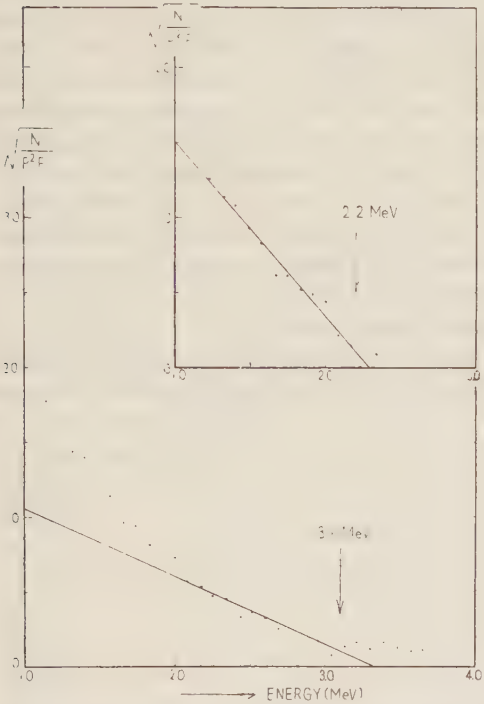

Fig. 14. Kurie plots of the short-lived beta rays from a neutron bombarded erbium oxide sample.

Some weak gamma rays were observed in the gamma ray measurement having half-lives of about 4 min and of 1 min or less. A peak near 0.85 MeV had the 4-min half-life and one at about 0.43 MeV was found to be of the 1-min life. This suggests us that some weak lower energy branchings of the beta rays may be included in the decay of both Ho^{168} and Ho^{170}. Because of a very low intensity of the 0.43–MeV gamma ray, however, most of the beta rays from Ho^{170} are considered to go to the ground state and its vicinity of Er^{170}. A rough estimation gives the log *ft* value of approximately 6. Since the ground state of Ho^{170} is expected to have 1+ from the coupling rule for deformed intrinsic states, an allowed transition is expected. Therefore, this log *ft* value is considered to be a reasonable value.

5) Tm^{174} and Tm^{176}

An oxide powder of natural ytterbium was bombarded for two minutes. Tm^{176} which may be produced from the $Yb^{176}(n, p)$ reaction, was expected to have a beta ray of approximately 4.0 MeV. So, a half-life measurement was performed for beta ray component higher than 3.3 MeV, at which energy any other product activities produced by neutron-induced reactions were excluded. A previously unknown activity of 1.5 min was observed. Similar value of half-life was found in a beta spectrum measurement. Accordingly one may tentatively assign this new isotope to Tm^{176}.

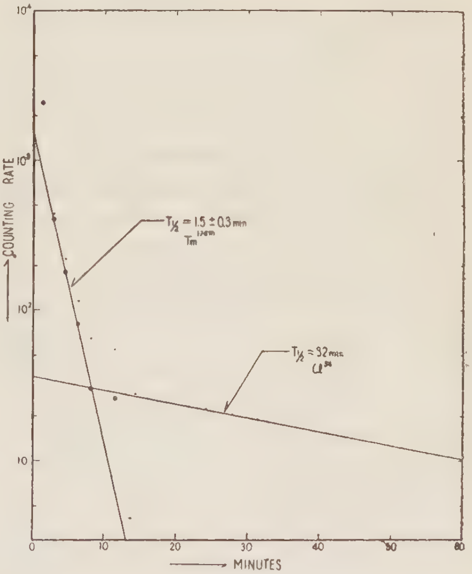

Fig. 15. Decay curve of the high energy electron radiations ($E_\beta \gtrsim 3.3$ MeV) from a neutron irradiated ytterbium oxide.

Fig. 15 shows one of the decay curves obtained. In Fig. 15, the 32–min component was considered to come from Cl^{34} as observed in the case of Ho activities.

A result of the Kurie plot analysis is given in Fig. 16. The value of the end-point was somewhat larger than that estimated from the beta decay energy systematics. Therefore, this new activity may be rather ascribed to an isomer of Tm^{176}. (The level systematics using Nilsson diagram and the coupling rule for the levels of odd-odd nuclei seems to support this assignment).

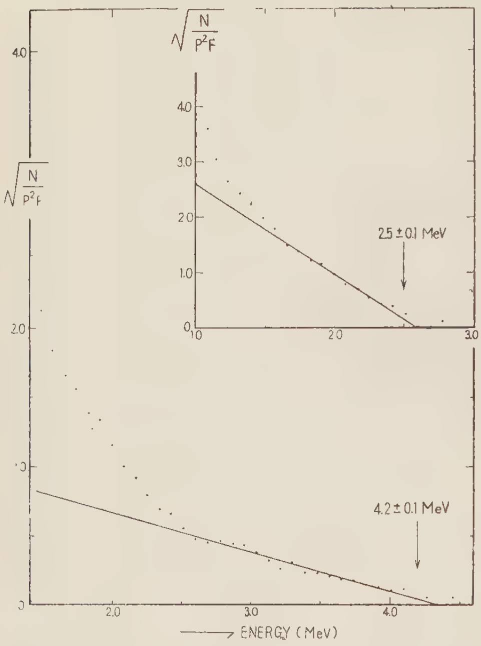

Fig. 16. Kurie plots of the short-lived beta rays from a neutron irradiated ytterbium oxide.

A lower energy beta ray component shown in Fig. 16 was found to decay with the half-life of about 5.0 min. Fig. 17 shows a decay curve of the lower energy component whose energies are ranging from 1.7 MeV to 2.4 MeV. The 1.5-min activity is due to the beta ray from Tm^{176m}. Therefore, one may expect the 5.0-min activity to be attributed to the previously unknown nuclide Tm^{174}. The same assignment has been proposed by Willie and Fink in their recent paper[9]. The end-point energy of 2.5 MeV is very close to the value estimated from the systematics for Tm^{174}.

No appreciable gamma ray decaying with a half-life of 1.5 min was observed in a gamma ray measurement, although some lower energy gamma rays than 0.15 MeV may be missed. From this fact, main component of the beta rays from the 1.5-min activity is considered to the ground state. If this activity is actually due to Tm^{176m}, it probably has zero spin and negative parity from the level systematics in this region, a first forbidden transition can be expected. Because of scarcity of the data, however, the assignment must be considered to be very tentative.

Though some weak gamma rays were found to decay with a half-life of about 5.0 min, no

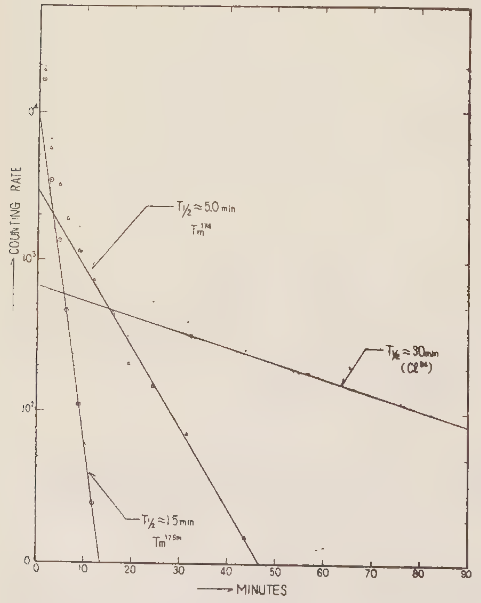

Fig. 17. Decay curve of the electron radiations whose energies are ranging from 1.7 MeV to 2.4 MeV, from a neutron bombarded ytterbium oxide.

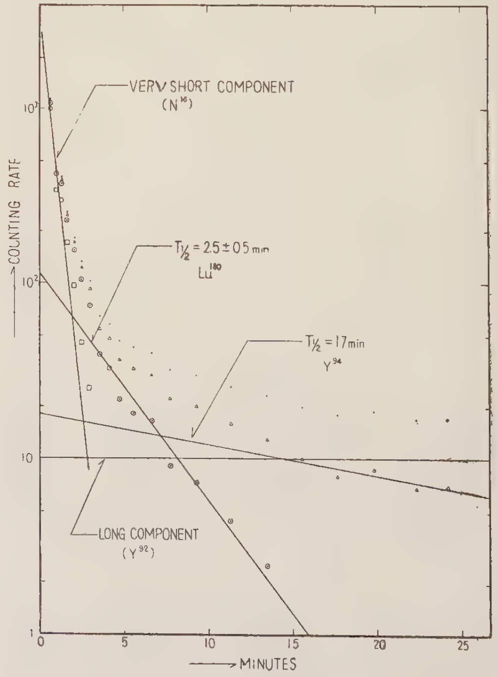

Fig. 18. Decay curve of the beta rays higher in energy than 3.0 MeV from a neutron irradiated metallic hafnium.

decisive information was obtained.

In addition, information about Tm^{172} and Tm^{173} obtained in the present work are in the good agreement with those observed in the experiment performed with activities produced from the (γ, p) reactions[2)].

6) Lu^{180}

A pure metallic hafnium was bombarded for two minutes. Since the beta dacay energy of Lu^{180} was estimated to be about 3.4 MeV from the beta ray energy systematics and the value of end-point for Lu^{178} has been known to be 2.2 MeV from the result of our previous experiment by the photoreactions of Hf, a decay of the beta rays higher than 3.0 MeV, in this case, was followed with a single channel beta ray spectrometer. A result of the measurement is shown in Fig. 18. Usually there are considerable amount of order of a percent of zirconium impurity even in a fairly pure sample of hafnium. In the present case the amount of zirconium impurity has been analysed to be 0.90 percent. So, the contributions from yttrium activities produced from the (n, p) reactions of zirconium impurity can be roughly estimated. In Fig. 18, the contributions of the high energy beta rays from Y^{92} and Y^{94} were subtracted in this way, after the long time measurement. As a result, an unknown activity of the 2.5–min life was found.

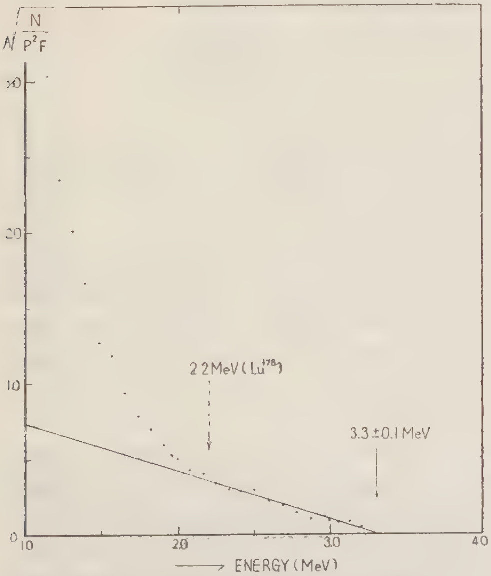

Fig. 19. Kurie plot of the 2.5-min beta ray from a neutron bombarded hafnium sample.

The end-point energy of this short-lived activity was determined to be 3.3±0.1 MeV from the Kurie plot analysis of the beta rays. Fig. 19 shows the result of the Kurie plot analysis after the subtraction of the 5.0–MeV beta ray from $Y^{94}(T_{1/2}=17$ min). The value of the energy indicated by a dashed arrow is considered to correspond to the end-point of Lu^{178} and agrees well with the value obtained for Lu^{178} produced from the $Hf^{179}(\gamma, p)$ reaction. Among the activities produced from the (n, p), (n, α) and other neutron-induced reactions of Zr and Hf, there is not any possible nuclide except Lu^{180} which has such a high energy beta ray and such a short life. Therefore, this unknown activity may be reasonably assigned to Lu^{180}.

In addition, informations concerning the decay characteristics of Lu^{178} and Lu^{179} obtained in the present work are found to be in good agreement with those from the (γ, p) reaction experiment[2)].

In gamma ray measurements, however, no conclusive information was obtained, because of the strong disturbing gamma rays from Hf^{179m} and Hf^{180m}. There is, however, an evidence that several peaks in the gamma ray spectrum included short components, which probably correspond to the four minutes activity obtained by Aten, Jr. and Funke-Klopper after the chemical separation of luthesium isotope[10)]. It seems that the activity we obtained and that found by Aten et al belongs to different isomers in analogy with the cases of Lu^{176} and Lu^{178}. Then, the 2.5–min activity with a high energy beta component represents the low spin state and the 4.5–min component with several gamma rays, which are probably in the cascade, is very much likely to correspond to the decay of the higher spin state.

Acknowledgement

The authors wish to express their sincere appreciation to the operation crew of the Institute for Nuclear Study for the operation of the cyclotron and for helpful assistances throughout the work. They are also indebted to the members of radio-chemistry, especially to Professor K. Saito for his invaluable suggestion to the chemical procedure separating niobium activity from molybdenum. The authors are grateful to the electronic technical staff and the members of the nuclear spectroscopy group of the Institute for their help and maintenance of the electronic equipments during the course of our experiment.

Weak Gamma Rays in the Decay of La^{140}

By Hidekuni TAKEKOSHI, Naomoto SHIKAZONO and Poh-Kun TSENG

Japan Atomic Energy Research Institute, Tokai-mura, Japan

(Received May 31, 1961)

Weak gamma rays of energy 0.63 MeV was found in the decay of La^{140} by means of a scintillation summing Compton spectrometer. This gamma rays are ascribed to the transition between the 2.53-MeV and 1.90-MeV states of Ce^{140}. The transition between this 1.90-MeV state and the 1.60-MeV state was not detected. The results of the present investigations on the conversion electrons and Gamma rays support the suggestion of Dželepow *et al* that the 1.90-MeV state is a O^{+} one.

§1. Introduction

Gamma rays in the decay of 40-hour La^{140} have been studied by a number of investigators[1], and the level scheme of Ce^{140} is fairly well established. In Fig. 1, a level scheme is duplicated from the *Nuclear Data Sheets*[1]. Cork *et al*[2] and Bashilov *et al*[3] observed that the spectrum of electrons had strong lines corresponding to a transition energy of 1.90 MeV. Dželepow *et al*[4] searched for gamma rays corresponding to the transition by means of a Compton-recoil spectrometer, and showed that, if such existed, the yield was less than 0.4×10^{-3} quantum per disintegration. They also reconfirmed the electron lines, and thus concluded the existence of a 0^{+} level of 1.902 MeV which decayed to the ground state of Ce^{140} by a $0^{+}\rightarrow0^{+}$ transition.

In the present paper, a search for gamma rays leading to or leaving this 1.902 MeV level was performed, data of which would form another support for the existence of this level.

§2. Experimental

A sample of spectroscopically-pure lanthanum oxide obtained from Johnson, Mathey & Co., Ltd. was irradiated in a Water-Boiler type reactor at JAERI. The gamma rays from this sample were analyzed by means of a NaI(Tl) summing Compton spectrometer[5]. The gamma rays from the source fall on a

1 inch×1 inch cylindrical crystal after being throughly collimated by a lead block with a hole 1.2 cm in diameter and 20 cm in length. Another crystal, 3 inches in diameter and 3 inches in length, is placed just beside the first crystal with it center axis lying on the plane of the front surface of the first one. The secondary photons, which are produced by Compton scattering in the first crystal, are caught by the second crystal, and the pulses from the two crystals in coincidence are summed to yield pulses corresponding to the full energy of the primary photons.

The spectra of the summed pulses are shown in Fig. 2, in which a, b, c, d and e indicate the spectrum taken with the second crystal pulse-height selector set at 0.14∼0.18, 0.18∼0.24, 0.24∼0.28, 0.28∼0.32 and 0.37∼0.47 MeV respectively. The gamma rays of energies of 0.33, 0.43, 0.485, 0.75, 0.815 and 0.92 MeV which are already reported[1)] are seen in the figure. Besides the peaks of these gamma ray, a small peak is seen at 0.63 MeV, which possibly be ascribed to the transition between the 2.53 and 1.90 MeV states. The order of the yield of this gamma rays is estimated to be 1×10^{-3} quantum per disintegration. Since the spin and parity of the ground state of La^{140} are 3^-, the beta transition to the 1.90 MeV state of Ce^{140} is forbidden. The 1.90 MeV state must be fed by the transitions from the upper levels which have spins 1 or 2. The 2.53 MeV gamma rays are relatively strong and the 2.53 MeV state is considered to be $2^{+1)}$. The 1.90 MeV state will, therefore, be fed by the transition from this state. The peak corresponding to the transition between the 1.90 MeV and 1.60 MeV state was not found. Since this peak might be obscured

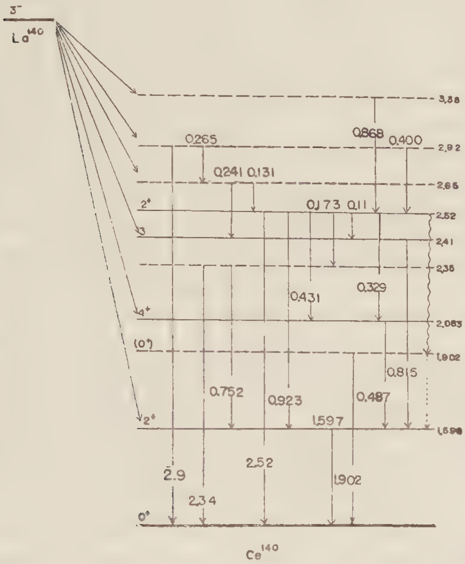

Fig. 1. Level scheme of Ce^{140} duplicated from the *Nuclear Data Sheets.*

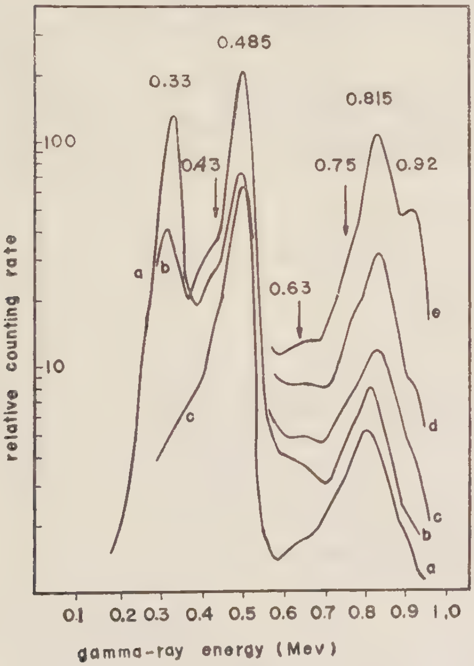

Fig. 2. Spectra of Ce^{140} gamma rays obtained with a scintillation summing Compton Spectrometer. a, b, c, d and e indicate the spectra taked with the second crystal pulse-height selector set at 0.14∼0.18, 0.18∼0.24, 0.24∼0.28, 0.28∼0.32 and 0.37∼0.47 MeV respectively.

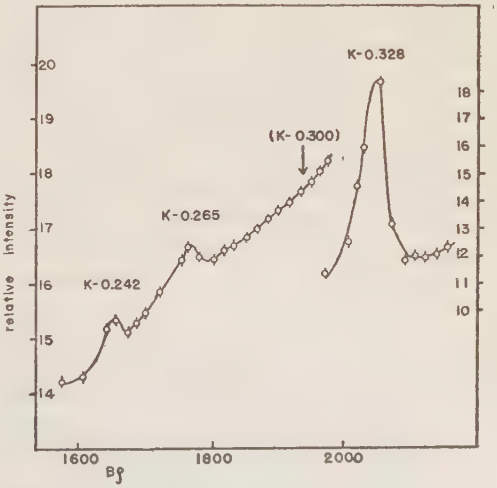

Fig. 3. Spectrum of conversion electrons of Ce^{140} (Bρ=1550∼2150).

by the intense 0.33 MeV gamma rays, the spectrum of conversion electrons was measured carefully by a magnetic spectrometer of 15 cm radius, the source being prepared from an equiliblium Ba^{140}-La^{140} mixture by the ion exchange method. The results are shown in Fig. 3. No bump is seen in the spectrum at the $B\rho$-value corresponding to 0.30 MeV gamma rays. The upper limit of the yield of this conversion electrons is estimated to be less than 8.7×10^{-5} per disintegration. If we assume that this 0.30 MeV transition is a pure E2 one, then the upper limit of the yield of this gamma rays will be 2×10^{-3} per disintegration (conversion coefficient $\alpha_k=4.6\times10^{-2}$)$^{6)}$.

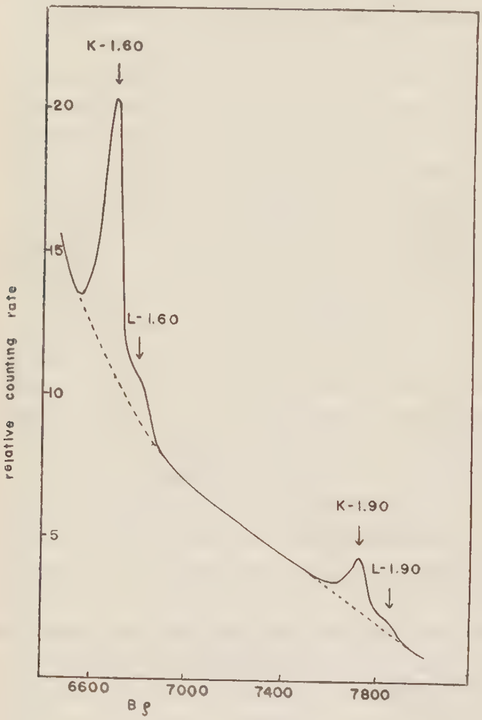

Fig. 4. Spectrum of conversion electrons of Ce^{140} ($B\rho=6400\sim8000$).

In Fig. 4, another part of the conversion-electron spectrum is shown. The existence of K- and L-lines of 1.90 MeV transition is obvious. The yield is about 20% of that of the 1.60 MeV conversion electrons. The K-conversion coefficient of 1.60 MeV gamma rays, which are emitted in almost every disintegration of La^{140}, is determined to be 6.3×10^{-4} from the ratio of the area of the conversion-electron peak to that of the beta ray spectrum. Then the yield of the K-conversion electrons of the 1.90 MeV transition turns out to be 1.0×10^{-4} per disintegration.

An estimation of the upper limit of the yield of 1.90 MeV gamma rays was made by use of a scintillation pair spectrometer. The results are shown in Fig. 5. The yield of 1.90 MeV gamma rays, if such exist, will be less than 1.2×10^{-3} quantum per disintegration. These results are in good agreement

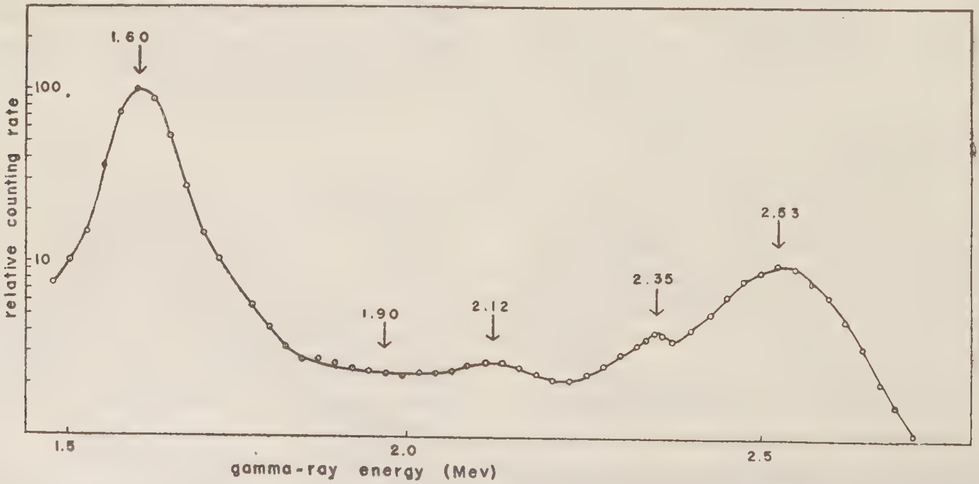

Fig. 5. Spectrum of Ce^{140} gamma rays obtained with a scintillation pair spectrometer. The peak at 2.12 MeV will be the satellite 1.60-MeV gamma rays which were counted by the following process; one of the annihilation quanta escaped the centre crystal and was captured by one of the side crystals and at the same moment a gamma quantum in cascade with this 1.60-MeV gamma quantum, passing through the lead shield, fell on the other side crystal.

with those of Dželepow *et al.*

High energy gamma rays of 2.35 and 2.53 MeV are seen in Fig. 5. By comparing their peak heights with that of 1.60 MeV gamma rays, the yield of 2.35 and 2.53 MeV gamma rays are estimated to be 4×10^{-3} and 2.5×10^{-2} quanta per disintegration respectively. Then the ratio of the yield of the 2.53 MeV gamma rays to that of 0.63 MeV gamma rays (1×10^{-3} quantum per disintegration) turns out to be about 20, a figure which is acceptable if the spin and parity of the 2.53 MeV state are assumed to be 1^{+}4), but out of theoretical expectation7) if otherwise (2^{+})1).

Acknowledgements

The authors wish to thank Teruo Momota for his interest and encouragement. They also wish to thank Haruo Natume for preparing the La^{140} source and Kazumi Ideno for his assistance.

The Magnetic Investigation of Cu-Butyrate Monohydrate and Cu-Stearate.

By Takashi WATANABE

Department of Physics, Faculty of Science,
Tokyo Metropolitan University, Tokyo, Japan

(Received August 17, 1959)

The magnetic susceptibilities of Cu-n butyrate monohydrate, Cu-stearate and Cu-acetate monohydrate were measured in the temperature range from 90°K to the room temperature. The energy of exchange interaction J between the cupric ions Cu^{++} in the nearest neighbour sites were evaluated from the observed values and the relation $\chi_m=(0.125\,g^2/T)\cdot[1+(1/3)\exp(+J/kT)]^{-1}$. The magnitude of J-values thus obtained were $J_{\text{Cu-butyrate}}=430\pm150°\text{K}$, $J_{\text{Cu-stearate}}=485\pm15°\text{K}$ and $J_{\text{Cu-acetate}}=430\pm15°\text{K}$. And it seems that the g-value of Cu-stearate is somewhat larger than the value of Cu-acetate monohydrate.

§1. Introduction

The two cupric ions of Cu-acetate monohydrate are expected to be located at a very short distance in the crystalline state from the results of the measurements of magnetic susceptibility (Guha1); Perakis, Serres and Karantassis2) and Martin and Waterman3)) and paramagnetic resonance (Bleaney and Bowers4)).

Van Nickerk and Schoening (1953)5) have stated that the copper acetate monohydrate consists of a dimeric molecule such as $Cu_2\cdot(CH_3COO)_4\cdot2H_2O$ in which the distance between the two cupric ions is 2.64A. monohydrate was carried out by Abe et al[6], and the spectroscopic measurement of these salt was carried out by Tsuchida and Yamada[7]. These salts show the behavior similar to that of Cu-acetate monohydrate found in the above mentioned studies. The results in the present study for Cu-butyrate monohydrate and Cu-stearate also show the same character as that of Cu-acetate monohydrate.

The method of measurement and the apparatus used are those which have been constantly used in our laboratory and the detail was given in the other report of present author[8]. The merit of figure is $(1.000 \pm 0.015) \cdot 10^{-6}$ e.m.u./gram and the strength of magnetic field used is about 6000 Oe in the air gap of 3 cm. The cooling method is the indirect heat leak method[8] and the measuring temperature is controlled by liquid nitrogen or dry ice in alcohol.

Cu-*n* butyrate monohydrate, and Cu-acetate monohydrate were prepared by Kanto Chemical Co. These samples are carefully purified and recrystallized in water free alcohol by the present author. Cu-stearate was kindly supplied from Dr. S. Yamada.

§ 2. The Results of the Measurement

The results of the magnetic measurement are given in the following tables (Tables I, II and III) and in Fig. 1. In these tables, p^2_{exp} are the empirical value of the square magnetic moment of electron spin in the Bohr magneton unit evaluated by the relation

$$\chi_m = \frac{N\beta^2 p^2}{3kT} + N\alpha = \frac{0.125p^2}{T} + N\alpha \qquad (1)$$

where χ_m, β, N and k are values of the molar susceptibility, the Bohr magneton, the Avogadro number, and the Boltzmann factor.

The following values of molar susceptibility are used as the diamagnetic correction[9]

$(C_3H_7COO)_2^{--} = -108.0\cdot10^{-5}$,

$(C_{17}H_{35}COO)_2^{--} = -437.0\cdot10^{-6}$,

$(CH_3COO)_2^{--} = -62.8\cdot10^{-6}$,

$H_2O = -12.9\cdot10^{-6}$,

and the correction of temperature independent term of paramagnetic ion Cu^{++} ($N\alpha$) is $60\cdot10^{-6}$[4].

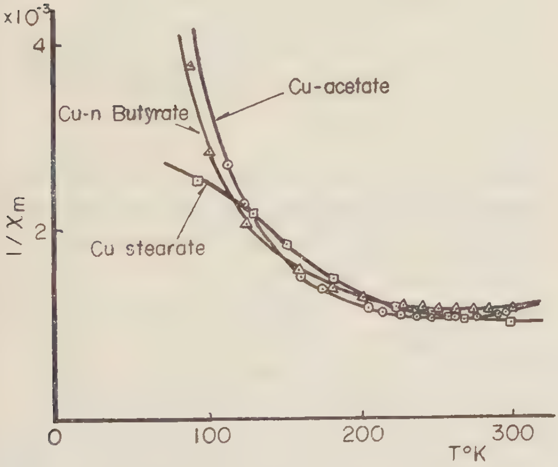

Fig. 1. Relation between the reciprocal magnetic susceptibilities per mole χ_m and T.

§ 3. Discussion

a) Calculation of the exchange interaction energy from the experimental results

The present result for Cu-acetate monohydrate at low temperature agrees well with the result given by Perakis et al[2], while the values of χ_m and p^2 in the Tables I, II and III are different from those given by Guha[1] at low temperature. The temperature at which the value of susceptibility shows a maximum value seems to shift to a higher temperature as the ligand proceeds from acetate to stearate. But the values of susceptibility of Cu-*n* butyrate monohydrate and Cu-stearate at about 100°K are larger than that of Cu-acetate monohydrate. It seems that these unexpected results arise from a paramagnetic impurity (it may be free cupric ion Cu^{++}). In the experiment of paramagnetic resonance of Cu-acetate monohydrate[4], the observed parallel and perpendicular g-values with respect to the principal axis agreed very closely with the values in other copper compounds such as the Tutton salts. It seems reasonable to assume that the individual copper ion is in the ^2D state as shown in Fig. 5. In the present case, it is assumed that Cu-*n* butyrate monohydrate and Cu-stearate are also in the same state as Cu-acetate monohydrate. Accordingly, it is considered that the magnetic character of these salts depends on the electronic splitting of singlet and triplet due to exchange interaction between two cupric ions in the nearest neighbour sites. A rough quantitative conclusion can be drawn from this assumption in the case of powdered samples.

The exchange interaction energy between two nearest copper ions is expressed as $-JS_1S_2$, where J is negative. The orbital ground level in ^2D state of Cu^{++} is singlet and the effect of anisotropic field may accordingly be neglected. Thus we get the Hamiltonian[10] as follows,

$$\begin{aligned}\mathscr{H} &= JS_1S_2 + g\beta SH \\ &= \left(\frac{1}{2}\right)\cdot JS(S+1) + g\beta MH + \text{constant.}\end{aligned}$$

where, $S = S_1 + S_2$. The partition function which corresponds to the above Hamiltonian is

$$Z = \sum \exp(-\mathscr{H}/kT) = 1 + \exp(-J/kT) \cdot \{3 + (g\beta H/kT)^2\} \qquad (2)$$

provided that $S = 1$ or 0, $M = \pm1$ or 0. The molar susceptibility χ_m are given as,

$$\chi_m = \frac{Ng^2\beta^2}{kT} \cdot \frac{\exp(-J/kT)}{1 + 3\exp(-J/kT)}$$

and adding the term of temperature independent paramagnetism of Cu^{++} ion ($N\alpha = 60\cdot10^{-6}$ e.m.u./mol) to the above relation

$$\chi_m = \frac{0.125\,g^2}{T} \cdot \frac{1}{1 + (1/3)\cdot\exp(J/kT)} + 60\cdot10^{-6}. \qquad (3)$$

The constant J of these salts can be estimated from the observed p^2 and the relation (3). The values of g^2, g and J determined in this

Table IV.

	g^2	g	J
Cu-acetate monohydrate	4.74 ± 0.2	2.18 ± 0.05	430±15°K
Cu-n butyrate monohydrate	4.45 ± 0.2	2.11 ± 0.05	430±15
Cu-stearate	5.40 ± 0.2	2.32 ± 0.05	485±15

way are shown in Table IV.

The calculated square magnetic moment p^2_{cal}, evaluated from the relations (1) and (3) by the use of the values in Table IV, are represented by solid curves in Figs. 2, 3 and 4 together with the observed values p^2_{exp} which are represented by broken curves. The curves show that the estimated values of J and g for acetate and butyrate are resonable but the values for stearate are not so reliable because p^2_{exp} deviates considerably from the curves of p^2_{cal} as shown in Fig. 4.

b) g-value

The g-value of Cu-butyrate monohydrate agrees roughly with the value of Cu-acetate monohydrate in the present magnetic measurement, as seen in Table IV. This result shows the fact that the copper ion of these salts is placed in a similar crystalline field. Such a consideration as above mentioned may be reasonable because these salts have the same coordinated ligand except in the number of carbon chain of normal alkyl group—C_3H_6-radicals and CH_3-radicals for Cu-n butyrate and Cu-acetate respectively. However the g-value of Cu-stearate differs considerably from the value of Cu-acetate monohydrate.

The g-values of Cu-n butyrate monohydrate and Cu-acetate monohydrate agree with the value in the other copper compounds such as the Tutton salt. Therefore it may reasonably be assumed that the individual copper ion in these two salts is subject to the similar type of crystalline field with the cubic and tetragonal symmetry. While Cu-stearate has not coordinating water molecule $-H_2O$ and the effect of low symmetry crystalline field may be different from the above two salts.

The orbital levels of the cupric ion Cu^{++} split into higher triplet and lower doublet in the cubic field and this doublet splits into two singlets (A and B) and the other triplet splits into a doublet (C and D) and a singlet (E) in the tetragonal field, as shown in Fig. 5. Each orbital level has an additional double degeneracy associated with the electron spin of 1/2.

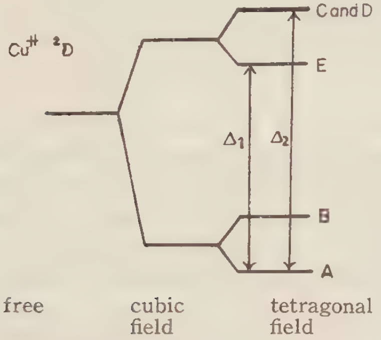

Fig. 5. Energy splitting ^2D level of Cu^{++} ion by crystalline field (not to scale).

If the energy of states (E) and (C, D) relative to the state (A) are denoted by Δ_1 and Δ_2 respectively, the g-values of the parallel and perpendicular components to z-axis of Cu-acetate monohydrate are given by Bleaney and Bowers[3] are following,

$$g_{\parallel}=2(1-4\lambda/\Delta_1)\,, \qquad (4)$$
$$g_{\perp}=2(1-\lambda/\Delta_2)\,.$$

If the spin-orbit coupling constant for free ion $\lambda=828\ \mathrm{cm}^{-1}$ [11] is used, the orbital splitting of Cu-acetate monohydrate can be obtained by them as $\Delta_1=20700\ \mathrm{cm}^{-1}$ and $\Delta_2=15000\ \mathrm{cm}^{-1}$, by use of the above results of paramagnetic resonance. Assuming the same crystalline field as in the Cu-acetate monohydrate and using $g=2.38$ given by the present authors, the numerical values of Δ_1 and Δ_2 evaluated from the relation (4) are about 15% smaller than the value of Cu-acetate monohydrate in the case of Cu-stearate.

c) Exchange interaction

If we consider that the distance between Cu^{++} ions is 2.64A, it seems that the exchange interaction energy of about 400°K can be hardly expected only from the direct coupling between Cu^{++} ions. The super-exchange interaction between two Cu^{++} ions through the nearest carboxyl radial should be also consideration for the interpretation of the exchange interaction energy of these salts.

In addition it should be noted that there is a marked difference in the exchange interaction energy between Cu-stearate and Cu-acetate monohydrate, that is

$$J_{\text{Cu-stearate}}-J_{\text{Cu-acetate}}\approx 55^\circ\mathrm{K}=38\ \mathrm{cm}^{-1}\,.$$

§ 4. Conclusion

1) Since the g-value of Cu-*n* butyrate monohydrate gives the same value as that of the Cu-acetate monohydrate, the symmetry properties and the magnitude of the crystalline field in these salts are similar to each other.

2) Since the Cu-stearate has no coordinated water molecule, the crystalline field and exchange energy in this salt seem to be different from those in the other two salts.

In conclusion, the present author wishes to express his sincere gratitude to Prof. K. Kido who encouraged him for the proceeding of the present study, also to Dr. S. Yamada of Faculty of Science, Osaka University who kindly supplied the sample of copper stearate and to Dr. P. H. Kim for his helpful discussion.

Velocity of Slowly Moving Dislocation

By Tomoyuki TAKEUCHI

National Research Institute for Metals, Nakameguro Meguro Tokyo

(Received December 10, 1960)

It is assumed that the observed dislocation velocity is the average velocity during the successive jumps, and that the jumping distances are large compared with the atomic spacing. The excitation probabilities for large jumps are calculated by the forces on dislocation, in which the thermal effects are introduced as the fluctuation of the local shear stress. The dislocation velocity in otherwise perfect crystals of relatively large Peierls stress are obtained as the functions of applied stress and temperature.

§1. Introduction

When a dislocation line moves, it is required to surmount the Peierls potential hills. Whether the dislocation goes over each hill with the thermal assistances, or it moves a large distance when the dislocation is once excited to go over a hill, is an essential problem in the considerations of the dislocation motion.

There are two experiments which reveal the motion of a dislocation line. The one is the direct observations of dislocation motion under the electron microscope, and the other is the observation of the dislocation motion under the applied stress by means of the etch pits. The former shows qualitatively the discontinuous motions having jumps and stays, and the latter[1] shows that a dislocation line moves by the successive jumps of about one micron of distance. If these facts are the normal properties of the dislocation in motion, it is suggested that the thermally excited dislocation line can move a large distance compared with the atomic spacing.

According to this standpoint, the average velocity v of a dislocation under the successive jumps can be expressed by the product of the jumping distance D and the jumping frequency ν:

$$v = D\nu\,. \tag{1}$$

When the stress and temperature dependence of the jumping distance is very small compared with that of the jumping frequency, the functional relations of dislocation velocity with the applied stress and the deformation temperature can be expressed approximately by those of jumping frequency.

For simplicity, the following considerations on the excitation probability are restricted to the case of a straight dislocation line in otherwise perfect crystals. Then the force which restrain the excitation of the dislocation motion is the Peierls stress. The jumping processes are treated as independent to each other, which is the meaning of the slowly moving dislocation. A distinct feature of the following considerations is the calculation of the excitation probability of dislocation by the use of the thermal forces, i.e. fluctuating local shear stress.

§2. Fluctuation of Local Shear Stress

The probability that a small region of the crystal has a component of the shear stress fluctuation $\Delta\sigma$ is

$$w = C\exp\left(-\frac{V(\Delta\sigma)^2}{2GkT}\right),$$

where G is the shear modulous and V is volume of the small region. In order to treat the fluctuation of the local shear stress around the dislocation line, V is expressed by the product of the effective cross-sectional area f (atoms) and the length l (atomic planes) of the dislocation:

$$V = v_0 f l\,,$$

where v_0 is the volume of atom or molecule. The probability that the dislocation segment is under the stress fluctuation $\Delta\sigma$ is

$$w(l,\Delta\sigma) = C\exp\left\{-\frac{\alpha}{T}l(\Delta\sigma)^2\right\}, \tag{2}$$

where

$$\alpha = v_0 f/2Gk\,. \tag{3}$$

In the consideration of the fluctuation, any fixed volume is usually considered. However, in the case of the dislocation in otherwise perfect crystals, there is no need to consider a fixed length of the dislocation line. Then it is assumed that some region of a dislocation line can be excited when a fluctuation satisfying specified conditions on l and $\Delta\sigma$ (see the following section) appears somewhere of the dislocation line. Under these conditions, factor C in (2) would be of the form

$$C=\phi(l)\left(\frac{\alpha l}{T}\right)^{1/2}, \tag{4}$$

where $\phi(l)$ arises from the freedom of the position of the fluctuation, and is considered to be $\phi(l)\propto l^0\sim l^{-2}$, which gives only a minor effect to the final results.

§ 3. The Conditions for the Excitation of Dislocation Line

At first, the apparent stress required to elongate the total length of the dislocation line is introduced. Suppose a length l of the dislocation has moved for m units distance of the Peierls potential, then the work done by the stress σ_l is

$$W=\sigma_l b(a_l)(cm)\ ,$$

where b is the magnitude of Burgers vector, a and c are the units of the atomic planes. By this motion, the total length of the dislocation line increases by $2m$ atomic planes, then the increase of the dislocation energy is $2mE$, where E is the energy per atomic plane. The necessary stress σ_l satisfying the condition $2mE=W$ is given by

$$\sigma_l=\beta/l\ , \tag{5}$$

where

$$\beta=2E/bac=2E/v_0\ . \tag{6}$$

In order to displace a length of the dislocation line from the initial position of the of the Peierls potential valley, the sum of the applied stress σ and the fluctuation stress $\Delta\sigma$ should be larger than the sum of the Peierls stress σ_0 and the stress required to increase the total length of the dislocation line β/l:

$$\Delta\sigma>\sigma_0-\sigma+\frac{\beta}{l}\ . \tag{7}$$

In order to displace a segment l of a dislocation line for large distance, the energy required to increase the line length should be provided by the applied stress alone, thus

$$l>\beta/\sigma\ . \tag{8}$$

When the both conditions (7) and (8) are satisfied, the excited segment of the dislocation line can be accelerated.

§ 4. Excitation Probability

When a fluctuation stress satisfying (7) appears on the dislocation line of the length satisfying (8), the motion of the dislocation line for large distance is started. Then the excitation probability of dislocation is

$$P(T,\sigma)=\int_{\beta/\sigma}^{\infty}dl\int_{\sigma_0-\sigma+\beta/l}^{\infty}C\exp\left\{-\frac{\alpha}{T}l(\Delta\sigma)^2\right\}d(\Delta\sigma)\ . \tag{9}$$

Integration with respect to $(\Delta\sigma)$ gives, when $f(l)\gg 1$,

$$P(T,\sigma)=\int_{\beta/\sigma}^{\infty}\frac{\phi(l)}{2}\ \frac{\exp\{-f(l)\}}{\{f(l)\}^{1/2}}dl\ , \tag{10}$$

where

$$f(l)=\frac{\alpha}{T}l\left(\sigma_0-\sigma+\frac{\beta}{l}\right)^2. \tag{11}$$

Integration with respect to l is rather complicated, and the following consideration gives the approximate integration. $f(l)$ can be rewritten as

$$f(l)=\frac{\alpha\beta}{T}(\sigma_0-\sigma)\left\{\left(\frac{\sigma_0-\sigma}{\beta}\cdot l\right)^{1/2}+\left(\frac{\sigma_0-\sigma}{\beta}\cdot l\right)^{1/2}\right\}^2,$$

then it is found that $f(l)$ is minimum at $l(\sigma_0-\sigma)/\beta=1$ and $\exp\{-f(l)\}$ is maximum at this point. When $\alpha\beta(\sigma_0-\sigma)/T\gg 1$, $\exp\{-f(l)\}$ has a sharp maximum. In this case, the probability density is predominant at the largest of $\exp\{-f(l)\}$ over the range of the integration. Inserting $l=\beta/\sigma$ when $\beta/\sigma>\beta/(\sigma_0-\sigma)$, and $l=\beta/(\sigma_0-\sigma)$ when $\beta/\sigma<\beta/(\sigma_0-\sigma)$ into the integrand of (10), the approximate functional relations of the excitation probabilities can be expressed by

$$P(T,\sigma)=B_1\exp\left(-\frac{\alpha\beta\sigma_0^2}{T\sigma}\right) \qquad \text{for} \quad \frac{\hat{\beta}}{\sigma}>\frac{\hat{\beta}}{\sigma_0-\sigma} \tag{12a}$$

$$=B_2\exp\left(-\frac{4\alpha\beta(\sigma_0-\sigma)}{T}\right) \qquad \text{for} \quad \frac{\hat{\beta}}{\sigma}<\frac{\hat{\beta}}{\sigma_0-\sigma}\,, \tag{12b}$$

where B_1 and B_2 are the functions of T and σ, which can be calculated, if necessary, by more accurate calculations.

§ 5. Dislocation Velocity

The excitation frequency ν of the dislocation line for large jumps is

$$\nu=\nu_0 P(T,\sigma)\,, \tag{13}$$

where ν_0 would be of the order of Debye frequency. From (1), (12), (3), (6) and (13), the dislocation velocity is obtained as

$$v=A_1\exp\left(-\frac{fE\,\sigma_0^2}{GkT\sigma}\right) \qquad \text{for} \quad \sigma<\sigma_0/2 \tag{14a}$$

$$=A_2\exp\left(-\frac{4fE(\sigma_0-\sigma)}{GkT}\right) \qquad \text{for} \quad \sigma_0/2<\sigma<\sigma_0\,, \tag{14b}$$

where

$$A_1=D\nu_0B_1 \qquad \text{and} \qquad A_2=D\nu_0B_2\,.$$

In order to compare (14) with the observed dislocation velocities, it is convenient to use the velocity-stress relations at constant temperature. When the relation (14a) is rewritten in the form

$$v\propto\sigma^n \tag{15}$$

in the small range of applied stress, the corresponding value to n is given by

$$n=\left(\frac{\partial\ln v}{\partial\ln\sigma}\right)_T=a_1+\frac{fE\sigma_0^2}{GkT\sigma}\,, \tag{16a}$$

in which the term a_1 arises from $\phi(l)$ in (4) and the integration processes, and is about 0.5~2.5. The similar calculation for (14b) gives

$$n=a_2+\frac{4fE\sigma}{GkT}\,, \tag{16b}$$

in which the term a_2 is of the order of one except at very low temperature. When n is very large compared with a_1 and a_2, the terms A_1 and A_2 can be set to be constant as an approximate functional form of the dislocation velocity. In this case, the stress and temperature relations at constant velocity are of the form

$$\sigma\propto\frac{1}{T} \qquad \text{for} \quad \sigma<\sigma_0/2 \tag{17a}$$

and

$$\sigma_0-\sigma\propto T \qquad \text{for} \quad \sigma_0/2<\sigma<\sigma_0\,. \tag{17b}$$

§ 6. Discussion

In the preceding calculations, three parameters are used: effective cross-sectional area of dislocation f, dislocation energy E, and Peierls stress σ_0. These parameters can be estimated from the observed values of n by the relation (16a).

From the observed dislocation velocities (10^{-2}~10^{-7} cm/sec) at 300°K, it had been shown that $n\approx 18$ ($\sigma\approx 0.25\,\text{kg/mm}^2$) for the softened crystals of lithium fluoride[1], and $n\approx 38$ ($\sigma\approx 12\,\text{kg/mm}^2$) for silicon-iron crystals[2]. Neglecting the term a_1 in (16a), and using the above observed values and $G=11.6\times 10^3\,\text{kg/mm}^2$ (Si–Fe) and $3.5\times10^3\,\text{kg/mm}^2$(LiF), one gets $fE\sigma_0^2=400\,\text{eV}\,(\text{kg/mm}^2)^2$ for LiF and $fE\sigma_0^2=1.35\times10^5\,\text{eV}\,(\text{kg/mm}^2)^2$ for Si–Fe. When the values $f=16$ atoms and $E=2$ eV per atomic plane are tentatively assumed, the Peierls stress becomes $\sim 3.5\,\text{kg/mm}^2$ for the lithium fluoride crystal and $\sim 60\,\text{kg/mm}^2$ for the silicon-iron crystal.

The condition ($n\gg 1$) used for the final results (14) and (17) is satisfied for the slowly moving dislocation in the crystals of relatively large Peierls stress under the moderate temperature range.

The important points of the present treatment are the excitation conditions (7) and

(8). Especially, (8) is the expression of the jumping motion of the dislocation line for many atomic spacings. The excitations of the dislocation line merely through (7) without satisfying (8) are considered to be not essential for the plastic deformation of the crystals, and are neglected in the calculation of the dislocation velocity. Such excitations would cause the motions of dislocation line similar to Brownian motion[3,4]. The theory of Lothe and Hirth[5] on the dislocation dynamics is essentially based on this motion.

It is the excitation condition (8) that distinguishes the present model from the current theories. In order to test the validity of the model, the assumption of the jumping distances large compared with the atomic spacing, which seems to be supported by the experimental evidences[1], should be explained by another theory.

A Note on the Theory of Barium Titanate

By Hidetosi TAKAHASI

Department of Physics, University of Tokyo

(Received April 3, 1961)

A careful consideration on lattice vibrations in the ionic ferroelectric crystals such as $BaTiO_3$ reveals that a correct physical picture of the ferroelectric transition in these crystals may rather be regarded as an order-disorder transition of orientation of dipoles. A strong local order in the disordered phase is a characteristic feature. The model gives natural interpretation of the occurrance of three successive transitions in $BaTiO_3$, and predicts dielectric dispersion of relaxation type in the paraelectric phase.

§1. Introduction

Quite a number of papers have appeared dealing with the theory of the ferroelectricity of barium titanate since the discovery of the substance being ferroelectric. The first paper by Mason and Matthias[1] assumed each titanium ion to be situated in a multiple-well potential field, and tried to interpret the ferroelectric transition as an order-disorder transition of the distribution of the Ti atoms among these potential wells. A subsequent paper by Devonshire,[2] as well as one by Slater,[3] denied the possibility of a multiple-well potential in the paraelectric phase, and gave a theory based on a single-well potential. The transition to ferroelectric phase occurs, just as in Mason-Matthias's theory, as a result of Lorentz interaction among Ti ions, but the transition is not of the order-disorder type but a simple simultaneous spontaneous shift of the Ti ions parallel to one crystallographic axis. Since then, the latter theory got wide acceptance and Mason-Matthias's theory seems to have been completely discarded.

It is doubtless that Mason and Matthias's assumption of the existence *a priori* of a multiple-well potential for the Ti atom is entirely inadequate for the paraelectric barium titanate. Nevertheless, it is the purpose of the present note to point out that a closer investigation of the model of Devonshire and Slater leads to a physical picture which is strikingly akin to Mason-Matthias's model, and that the ferroelectric transition of barium titanate is also properly an order-disorder transition.

§ 2. Nature of the Thermal Motion

In the theory of Devonshire and Slater, the ferroelectric transition of barium titanate is explained as follows. Each Ti atom in the paraelectric (cubic) phase of $BaTiO_3$ is situated in a field of the surrounding atoms which is practically harmonic, that is, a linear restoring force acts on the Ti atom when it is displaced from the centre of the cell. In addition, there is a Lorentz (electrostatic) interaction among these Ti atoms, which is negative and is proportional to the square of the displacement when all the Ti atoms are displaced in the same direction and by the same amount. If the coefficient of restoring force is small enough so that interaction energy dominates, the simultaneous displacement of all Ti atoms lowers the total energy and a spontaneous displacement takes place, and the crystal becomes ferroelectric.

In order to explain the transition, that is, the appearance of spontaneous displacement within a specified temperature region, one has to assume some form of temperature dependence in either or both of these coefficients. There are at least two possible origins for such a temperature dependence: thermal expansion and the anharmonicity of the potential.

The effect of the thermal expansion on the one hand tends to favour the spontaneous displacement at higher temperature by decreasing the restoring force, but on the other hands tends to disfavour it by decreasing the Lorentz energy. The anharmonic term in the potential in general tends to increase the effective restoring force with temperature, since, with increasing amplitude of the thermal motion, the atom tends to spend more time in the vicinity of surrounding atoms, where the potential is 'harder', that is, has a greater second derivative. The usually negative temperature coefficient of the dielectric constant in the paraelectric region and the fact that ferroelectric phase lies *below* the transition point seems to show that the effect of anharmonicity is the most important.

In the above argument, the thermal motion of an atom was considered independently of the other atoms in the crystal, that is, we used the Einstein model.

In order to take a more detailed account of the effect of thermal motion, let us now try to use the Debye model. The motion of each atom is now considered as a superposition of a great many normal oscillation modes, which are regarded as being approximately independent of each other. The modes are grouped to several branches, which are either acoustical or optical, and only the acoustical branch contains modes of a wide range of frequency, including those of very low frequency. We are, however, interested in the motion of an atom relative to its neighbours, and since the low-frequency acoustical modes are those for which the relative positions of neighbouring atoms are little changed, we can neglect these low-frequency modes. Then we have only to consider the modes lying in a relatively narrow frequency region. This means that we may approximate all the modes by a single frequency, and the former consideration based on the Einstein model is justified.

However, in *potentially ferroelectric* crystals, that is, the paraelectric state of ferroelectric substances, the situation is somewhat different. In such crystals, the frequency of the long-wave optical modes also becomes very low, and the lowest frequency tends to zero as the temperature tends to the Curie point (assumed to be a second order transition). Since the amplitude of thermal oscillation is inversely proportional to the frequency, these slow oscillations will have very large amplitude, and it is probable that most part of the relative thermal motion of the atoms are the contribution of these slow oscillations.

§ 3. Role of Anharmonicity

So far we have neglected the anharmonicity of the interatomic forces. One of the effect of anharmonicity will be to cause the coupling between different normal modes.

However, an attempt to develop a consistent theory taking account of the anharmonicity faces an unexpected difficulty.

From what was said in the preceding section it follows that the temperature dependence of the frequency spectrum of the optical modes is actually an indirect effect of the coupling of modes due to the anharmonicity. Accordingly, a more rigorous approach would be to start by taking the normal mode spectrum at the absolute zero temperature, and to consider thereupon the effect of coupling between these modes. In ordinary substances, such a treatment may give a satisfactory theory, although it may lead to a rather elaborate formulation. In ferroelectric substances such as barium titanate, however, it would lead to a fundamental difficulty, since the frequency of certain long-wave modes become *imaginary*, corresponding to the fact that unpolarized state of $BaTiO_3$ is unstable at low temperature.

The origin of this difficulty will be traced to the fact that the amplitude of thermal motion in such substance is so large, and the Lorentz interaction of the atoms is so strong, that a conventional quasi-harmonic picture of the thermal motion becomes entirely invalid. It seems more probable that the displacement of most Ti atoms in $BaTiO_3$ is saturated, even in paraelectric state, and the effect of thermal motion would be to bring a Ti atom from one saturated position to the other, just as in KH_2PO_4 and other dipole-type ferroelectrics. In such a situation, the Debye approach as considered above seems quite inadequate. However, in the following sections we will try to make a qualitative picture of such potentially ferroelectric crystals, so as to become the basis of a more quantitative theory.

§ 4. Proposed Picture of the Barium Titanate above the Curie Point.

In accordance with the above considerations, the following picture will be proposed for the paraelectric phase of the barium titanate (Fig. 1).

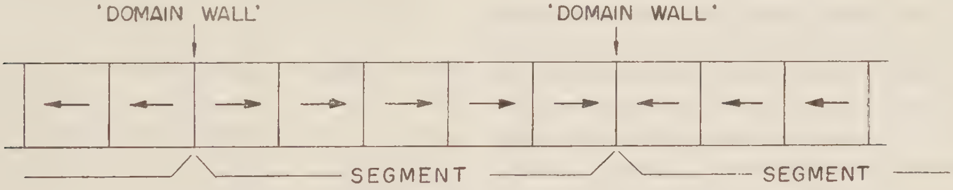

Fig. 1. One-dimensional picture of the paraelectric state. Arrows indicate displacement of Ti atoms.

Consider a row of unit cells extending in the direction of one of the crystal axes. Every Ti atom on this row is displaced from the centre of the cell to either direction along the row, producing dipole moments of either direction but of constant magnitude. The directions of these dipoles are not independent of each other, but the adjacent dipoles strongly tend to be parallel so that the whole row is split up into a number of *segments*, so that within each segment the dipoles are all parallel but the dipoles in the adjacent segments are directed oppositely. These segments are not fixed, but their boundaries or the 'domais walls' are always moving randomly back and forth, with eventual creation and annihilation of segments, or 'pairs' of the boundaries. If we fix our eyes on a single Ti atom, it is normally at rest in one of the extreme positions in the cell (making, of course, a small thermal vibration about this position), but eventually it jumps from one extreme position to the other and vice versa, as the 'domain wall' passes the cell in question.

The reader will at once notice the striking resemblance of this picture with Mason-Matthias model. In fact, the ferroelectric transition deduced from our model will be essentially an order-disorder transition of the orientation of dipoles of fixed magnitude. However, in spite of the apparent similarity, a fundamental difference must be noticed. Mason and Matthias assumed, *a priori*, that there exist several equilibrium positions for each individual Ti atom, and considered the order-disorder transition by interactions. That is, the permanent dipole they assumed existed entirely independently of the surrounding atoms and the interactions affected only the alignment of dipoles. In our picture, on the contrary, we assume that the dipoles or the displacement of Ti atoms are created just by the cooperative effect, namely, the Lorentz interaction of a great many atoms within the row, even in the paraelectric phase. In the transition to ferroelectric state, the length of the segment becomes infinite (that is, of macroscopic size), while a transverse ordering also appear. Thus we are dealing with an order-disorder transition with a high degree of local order in the disordered phase. It is to be noted that this high local ordering is the characteristic feature of our picture.

§ 5. Three-Dimensional Picture.

In the foregoing we have restricted ourselves in a somewhat unnatural way to discussion of the interaction of dipoles within a single row of cells, and also the possibility of displacement of atoms in other crystallographic axes has been neglected. Now the former restriction seems to be justified on the ground of the special feature of barium titanate that the Lorentz interaction energy between adjacent rows of dipoles is probably very weak compared to that between the cells within the same row.[4] In the following we will extend the model to include the dipole orientation in three dimensions.

Since the symmetry of barium titanate is cubic, there is no reason to exclude the possibility for the Ti atom to be displaced parallel to the other two crystallographic axes. It may be possible that the displacement of an atom in one direction (say z direction) prevents the displacement of the same atom in a direction orthogonal to it. Here, however, it will be assumed that the displacement of the same atom can occur along the three crystallographic axes simultaneously, and independently of each other. Thus we can imagine three orthogonally intersecting bundles of rows of cells, each being of the kind just described, running parallel to the three crystallographic axes respectively. Accordingly, each Ti atom is displaced in one of the eight crystallographic directions equivalent to (111) hence having the displacement vector ($\pm\delta$, $\pm\delta$, $\pm\delta$). Each one Ti atom defines three orthogonal segments of the rows of cells, and the displacement of that Ti atom is the vectorial sum of the displacements associated with each of these three segments. An example of the configuration of the displacements is given in Fig. 2 in a two-dimensional form for illustration.

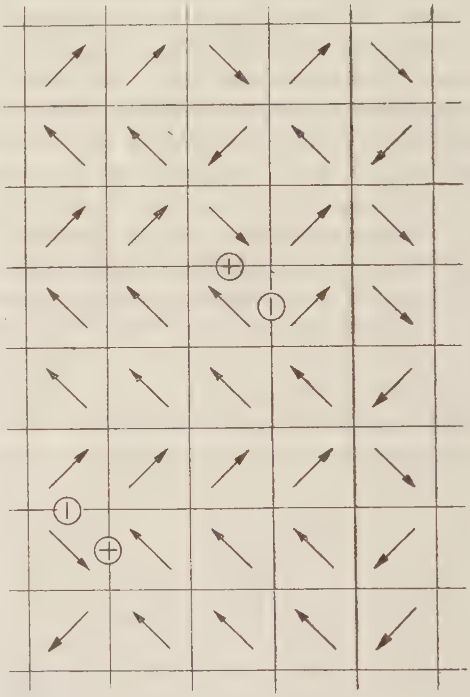

Fig. 2. Two-dimension illustration of dipole configuration. Note the flux closure.

In the simple one-dimensional picture, it was necessary to care for the free electric pole that is produced at every 'domain wall'. The present three-dimensional picture has the advantage that a free pole produced in one row of cells can be neutralized by a free pole of opposite polarity produced in another intersecting row, resulting in approximate flux closure. In Fig. 2 is an example of such a closure configuration. In this way, a rather complex pattern of flux-closed dipole configuration may be obtained. Since a great energy is required to create a free pole, it is probable that actual configurations mostly take the form with closed electric flux

§ 6. Consequences.

Our picture can give a natural explanation of the occurrance of three successive phase transitions: cubic→tetragonal→orthorhombic→trigonal, in $BaTiO_3$ upon cooling. At high temperatures, the configuration of dipoles is completely disordered although a strong local order exists. As the temperature is lowered, a point is reached where a complete order is set up in the z-component of the dipole moment, the x- and y-components being still disordered. The crystal becomes tetragonal. Setting up of the order in the z-component and the accompanying lattice distortion somewhat affects the parameters relating to the x- and y-components, but on still lowering the temperature, another transition takes place and the y-component of the dipole moment becomes also ordered. The x-component still remains disordered owing to the accompanying change of parameters. Now the crystal is orthorhombic.

At a still lower temperature, the last transition takes place and the x-component of the dipole moment becomes also ordered, and now the dipoles are completely ordered. This is the trigonal phase.

The above discussion may of course be too simple to be of general validity, but the fact that the form stable in lower temperature has always less randomness and hence less entropy than the form stable at higher temperature is very convincing.

One consequence of our picture that may be verified by experiment is the dielectric dispersion in the paraelectric region. The current model which assumes a temperature-dependent restoring force for the Ti atoms, gives a resonance type dispersion with a rather low resonance frequency, the resonance frequency varying proportionally to $T-T_c$ where T_c is the extrapolated Curie point. Our model would give, on the contrary, a relaxation type dispersion of some form. Existing data on the dispersion is not sufficient to decide which of the two models is correct. It may also be possible to test the correctness of our model by X-ray structure analysis. Since the existing result of the analysis did not take the disordered structure into account, it seems worthwhile to reexamine the existing data in the light of the new assumption.

§ 7. Conclusion

Starting from an accepted model of barium titanate and following purely logical steps, we have arrived at a physical picture which is unexpectedly similar to the long abandoned model due to Mason and Matthias. The argument has been throughout qualitative and the result has been formulated in a rather idealized form, and the author does not claim that the current model should be completely replaced by the present one. The real picture would be something midway between the two extremes. Anyway the aim of the present note is to suggest the possibility of a new viewpoint in the theory of barium titanate and to emphasize the importance of statistical approach to the ferroelectrics of $BaTiO_3$ type. A quantitative analysis of the model along this line remains still to be done.

Internal Magnetic Field in Rare Earth Metals

By Jun KONDO

The Institute for Solid State Physics, University of Tokyo, Tokyo

(Received May 4, 1961)

The effective magnetic field at nuclei in rare earth metals has been calculated. The contribution from the orbital angular momentum of 4f-electrons was found to amount to several thousand kilo-oersteds.

We have calculated the effective magnetic field at nuclei in rare earth metals. This arises from four sources.

1. It comes from the magnetic moments of all rare each ions except the one whose nucleus we are considering. The intensity of this field amounts to 10∼20 koe.

2. The s-f interaction may polarize the spins of conduction electrons and this may result in an effective field at nuclei through the hyperfine interaction between conduction electrons and nuclei. Inferring from the magnitude of this interaction in 3d metals, this field may be several hundred kilo-oersteds.

3. The spins of inner shell electrons may be polarized by the spin moments of 4f electrons to some extent. This may also results in an effective field at nuclei. We can get a rough idea about the magnitude of this field from the observed values of hyperfine interactions in ESR experiments of the Gd^{+++} and Eu^{++} ions which have no orbital angular momenta. These are around 300 koe.

4. The orbital angular momenta of 4f electrons of the ion whose nucleus we are considering produce a large amount of magnetic field at the nucleus which amounts to several thousand kilo-oersteds. Thus in the following we shall confine ourselves to this source of magnetic field and calculate its magnitude, neglecting the first three sources. We shall note that the spin angular momenta also produce a magnetic field and we shall take account of this contribution in the following calculation. But we shall find that the magnitude of the field from spin angular momenta is about one tenth of that from orbital angular momenta.

The Hamiltonian for the nuclear hyperfine interaction has been given by A. Abragam and M. H. L. Pryce[1] as follows:

$$H=2g_n\mu_N\mu_B\sum_i\{(\boldsymbol{l}_i-\boldsymbol{s}_i)\cdot\boldsymbol{I}/r_i^3+3(\boldsymbol{r}_i\cdot\boldsymbol{s}_i)(\boldsymbol{r}_i\cdot\boldsymbol{I})/r_i^5\}+\{e^2Q/2I(2I-1)\}\sum_i\{I(I+1)/r_i^3-3(\boldsymbol{r}_i\cdot\boldsymbol{I})^2/r_i^5\}\,, \tag{1}$$

where μ_N and μ_B are the nuclear and Bohr magnetons, respectively, and g_nI is the magnetic moment (in units of nuclear magneton) of the nucleus. Q is the electric quadrupole moment of the nucleus. Except samarium and europium, we may consider only the lowest multiplet of the ion, which will be specified by L, S and J. Then the above Hamiltonian can be represented by

$$H=2g_n\mu_N\mu_B\zeta\langle r^{-3}\rangle(\boldsymbol{J}\cdot\boldsymbol{I})+\{3e^2Q/4I(2I-1)\}\beta\langle r^{-3}\rangle\sum_{i=1}^5 J_iI_i\,, \tag{2}$$

where

$$\zeta=2-g_J+\xi[L(L+1)(g_J-1)-3(2-g_J)\{J(J+1)-L(L+1)-S(S+1)\}/2]\,, \tag{3}$$

$$g_J=1+\{S(S+1)-L(L+1)+J(J+1)\}/J(J+1)\,, \tag{4}$$

$$\xi=(2l+1-4S)/S(2l-1)(2l+3)(2L-1)\qquad(l=3)\,, \tag{5}$$

$$\beta=\pm2S\xi\gamma\,, \tag{6}$$

$$\begin{aligned}\gamma=(2-g_J)^2&-(J+L+S+2)(J-L+S+1)(J+L-S+1)(-J+L+S)/4(J+1)^2(2J+1)(2J+3)\\&-(J+L+S+1)(J-L+S)(J+L-S)(-J+L+S+1)/4J^2(2J-1)(2J+1)\,.\end{aligned} \tag{7}$$

The sign of β depends on whether the shell is less than or more than half-filled. J_i are defined as follows;

$$J_1=\{3J_z^2-J(J+1)\}/\sqrt{3}\ .\qquad J_2=J_x^2-J_y^2\ ,\qquad J_3=J_yJ_z+J_zJ_y\ ,$$
$$J_4=J_zJ_x+J_xJ_z\ ,\qquad J_5=J_xJ_y+J_yJ_x\ , \tag{8}$$

I_i being defined by similar equations.

Equation (2) can be written as

$$H=A(\boldsymbol{J}\cdot\boldsymbol{I})+B\sum_{i=1}^{5}J_iI_i\ . \tag{9}$$

a: from ref. (2), *b*: from ref. (3), *c*: from ref. (4), *d*: from ref. (5), *e*: from ref. (6), *f*: from ref. (8) and (9), *g*: from ref. (7).

In order to obtain the magnitudes of A and B, we must know the values of $g_nI\langle r^{-3}\rangle$ and $Q\langle r^{-3}\rangle$. We may assume that the 4f wave functions in rare earth metals is not very different from those in paramagnetic salts, so that we may put the values of $g_nI\langle r^{-3}\rangle$ and $Q\langle r^{-3}\rangle$ found in ESR experiments of rare earth ions in these salts into the expressions of A and B. The values of $g_nI\langle r^{-3}\rangle$ and $Q\langle r^{-3}\rangle$ (in units of nuclear magneton × Å^{-3} and barn × Å^{-3}, respectively) from ESR experiments[2)-7)] are listed in the second and third columns of the Table I. In the case of thulium, there is no resonance data, but g_nI and $\langle r^{-3}\rangle$ have separately been obtained from optical data[8),9)]. Then, A and B are given in units of 10^{-4}cm^{-1} in the fourth and fifth columns of the table. The resonance frequency of NMR experiments at low temperatures is given by $\langle J_z\rangle A/h$, when B vanishes. The values of JA/h are listed in the sixth column of the table in units of Mc/sec. Using the published data for nuclear magnetic moments[8),10)] and assuming $\langle J_z\rangle=J$, we can obtain the magnitude of the internal magnetic field at the nucleus, which is listed in the last column of the table in units of koe. The direction of the field is parallel to that of the magnetic moment of the ion, because $\langle \boldsymbol{L}\rangle$ is parallel to $\langle \boldsymbol{J}\rangle$ and so the magnetic moment associated with $\boldsymbol{L}$ is parallel to the total magnetic moment of the ion.

The author thanks to Professor K. Yosida and Mr. H. Miwa for many suggestions and discussions.

Quenched-in Vacancy in Solid Solution Alloys

By Yoshikazu HAMAGUCHI

Japan Atomic Energy Research Institute
Tokai-mura, Ibaraki-ken, Japan

(Received May 11, 1961)

From the difference in the electrical resistivity change induced by quenching between pure Au and Au-Pd solid solutions, the binding energy for a vacancy and a solute atom was determined. The rate of decrease of quenched-in additional resistivity with decreasing temperature in the alloy was more rapid than in the pure metal and the resistivity after quenching was smaller than that before quenching in high concentration alloys below a certain quenching temperature. It was concluded that the interaction of a Pd atom and a vacancy in Au-Pd alloys was attractive, which formed a contrast with the expectation of Lazarus theory, and an additional resistivity by the solute atom was conceled partly by the binding of the vacancy. In Ag-Pd alloys the same results would be expected.

§ 1. Introduction

Excess charge introduced by solute atoms interacts with free electrons in the solvent metal. This resultant effect is expressed by the screening potential around the solute atom.

According to the theory of Mott[1], the interaction energy between an impurity and a neighbouring monovalent ion at a distance r_0 is

$$\Delta E_e(r_0)=\frac{Ze^2}{r_0}\exp[-qr_0] \qquad (1)$$

Z being the valence difference and q the screening constant.

This interaction energy might be an important cause for the electrical resistivity due to a solute atom, the formation energy of imperfections and the activation energy or impurity diffusion.

Using the simplified model which has been adopted by Lazarus[2], in which the change in formation energy of a vacancy adjacent to the impurity is assumed to be given by $-\Delta E_e$, and the change in energy of motion is given by the change in the microscopic (110) shear modulus resulting from the perturbation ΔE_e, it is concluded that the activation energy Q for diffusion of the impurity is changed relative to the values for self-diffusion of the solvent in the same face-centered cubic lattice in the way

$$Q\,(\text{impurity})-Q\,(\text{solvent})=$$
$$-\Delta E_e(r_0)\left\{1-\frac{1}{4}(q^2r_0^2-5qr_0-5)\right\} \qquad (2)$$

Even by a more improved theory, no change in introduced in the essential relation between Q(impurity) − Q(solvent) and valence difference.

These theories are in fairly good agreement with the experiment for impurity diffusion in silver, but in poor agreement with those for that in copper, especially for negative valence impurity diffusions. One of the causes for this discrepancy is in the use of an oversimplified model to calculate the changes in formation energy and jump probability for a vacancy. Now it is desired to obtain the formation energy of a vacancy adjacent to the impurity by the other method and to compare it with the theoretical value.

For pure metals, such as Au[3),4)] Ag[5),6)] and Cu, the formation energies of a vacancy have been obtained by the measurements of the quenched-in resistivity increase, thermal expansion at high temperatures and so on. These results are consistent with the self-diffusion data. Applying these techniques to the alloys of noble metals and comparing the results with those for pure noble metals, it is expected that the formation energy of a vacancy influenced by the alloying element is obtained. First of all, the quenching method has been tried for its simplicity.

As the testing materials, silver alloys containing a element of positive excess valence for the solute should be best for comparing the results with the diffusion data, but to our regret, in these alloys the decrease in the electrical resistivity by the evaporation of solute atoms during the heating was much larger than the increase by the formation of excess vacancies, so that the accuracy of the measurements was very poor. For this reason Au-Pd alloys were selected as a specimens, regardless of the lack of impurity diffusion study for these combinations. Both alloys form the continuous series of solid solution, and there are no phases such as a long range ordered phase. Pd atom has the valence difference of -1 to both solvents.

§ 2. Experimental Procedure

The raw materials for the specimens were 99.95 % pure Au, 99.95 % pure Ag and 99.5% pure Pd. The concentration of Pd in both alloys were 1, 2, 3 and 4 weight per cent, and the form of the specimens were wires of 0.25 and 0.4 mm diameters, which were obtained from Tanaka Kikinzoku K. K. The concentrations of Pd were checked by the X-ray measurement of lattice parameters of those wires.

Two kinds of heating method were used, one of which was a current-heating method and the other was a furnace-heating method. The former was used for pure Au, Au 1 % and 2 % Pd alloys of two kinds, of wire, and the latter for Au-3 %, 4 % Pd alloys, pure Ag and Ag-Pd alloys of 0.4 mm diameter wire.

The instrument for the current-heating method was almost like that used by Bauerle and Koehler for pure Au[3)], but some improvements were made in heating and quenching in the atmospheres of A or He. The gauge length was about central 5 cm of about 18 cm length and the temperature was determined by measuring its resistance. The quenching rate was measured with an oscilloscope to be about 2.5×10^4 degrees per second for the 0.4 mm diameter pure Au specimen, and was the same as the rate of Bauerle and Koehler.

The furnace-heating method was very simple: a specimen, annealed in vacuum at about 850°C and slowly cooled, was suspeneded in the furnace, and then, after heating about 2~10 minutes at a certain temperature, was dropped into room temperature water. The cooling rate in this technique would be several times slower than that in the former technique. In addition, the specimen migh be streched during the setting on the instrument. Thus the results by this method would have less accuracy than that by the former. In the experiment of silver alloys, a virgin specimen was used in each quenching to avoid the accumulated contamination due to oxidation and others, but in gold alloys the same specimen was used through a series of quenchings.

§ 3. Results

Experimental results for Au and Au alloys are shown in Figs. 1 and 2, in which the specific resistivity increase and its logarithm are plotted respectively *versus* reciprocal of the quenching temperature.

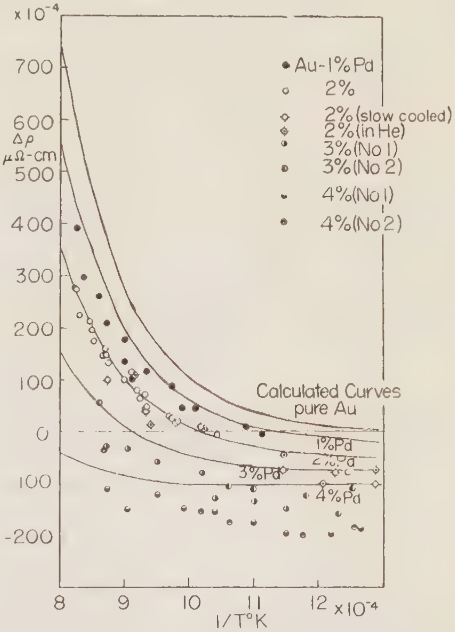

Fig. 1. The specific resistivity increase *versus* reciprocal of the quenching temperature in Au and Au-Pd alloys, and the calculated curves by Eq. (4).

In pure Au it was found that the resistivity increase on quenching could be described by the equation

$$\varDelta\rho = NA\exp(-E/kt) \qquad (3)$$

were $\varDelta\rho$ is the specific resistivity increase, NA is a constant, E is the energy required to form a defect, k is the Boltzmann constant and T is the quenching temperature. The results for the three different specimens fell almost on the same line in the semilogarithmic plot, and the formation energy is obtained as about 0.90 ev, which is a little smaller than that by Bauerle and Koehler[3)] and a little larger than that by Lazarev and Ovcharenko.[4] The value of NA is also obtained as about 1×10^{-4} Ω-cm. In the case of the alloy specimens, as would be expected, the experimental data deviated from the straight line in the semilogarithmic plot, and the deviation increased with increasing Pd content. In addition, it was very surprising that when the Pd content increased more than 1 %, the decrease in the resistivity due to quenching appeared below a certain temperature, the temperature becoming higher with increasing Pd content, as shown in Fig. 1. In 3 and 4 % alloys there were minima at about 500°C.

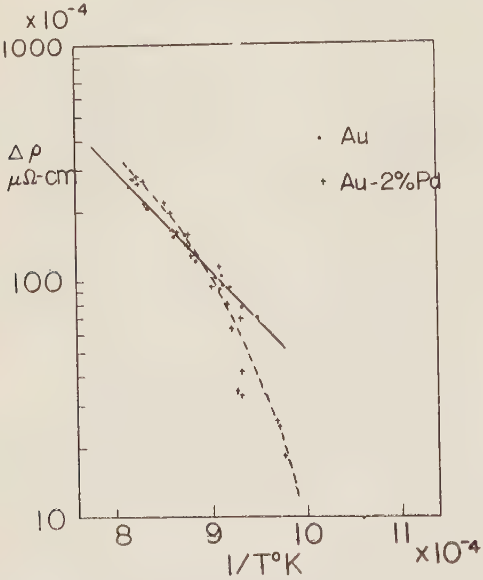

Fig. 2. A semilogarithmic plot of the specific resistivity increase *versus* reciprocal of the quenching temperature in Au and Au-2% Pd alloy.

Attempts were made to check some systematic errors, which might be important, on 2 % alloy. First of all, to rule out the possibility that for the insufficient preannealing the residual stress was annealed out during the quench-heating, specimen were annealed prior to the measurement about 4 hrs. at 850°C in vacuum, furnace cooled to room temperature, and then set carefully to the measuring instrument. In this case the decreases in resistivity were about the same amount (Fig. 1). By this check a possibility of formation of a short range ordered arrangement of solute atoms during the quench-heating may also be rule out. Another possible source of the resistivity decrease on quenching would be a evaporation of solute atoms during the quench-heating. This effect would not be very large as the melting temperature of Pd was high enough, but the results were calibrated by the measurements of the resistance of the slowly cooled state at the initial, middle and final points of one experimental series. Finally it was examined whether a change in the quenching atmosphere had an influence on the amount of resistivity quenched in. The quenching in He gas gave about the same resistivity as that quenched in A gas, so that the influence would be not so large (this is also shown in Fig. 1).

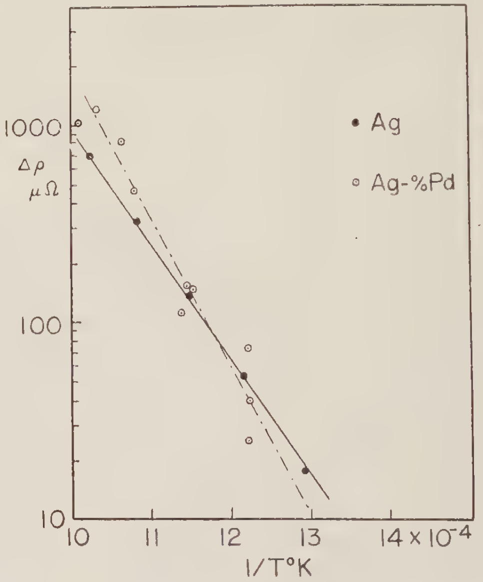

Fig. 3. A semilogarithmic plot of the resistivity increase *versus* reciprocal of the quenching temperature in Ag and Ag-Pd alloy. (the size of specimens are about 0.4 mm$\phi\times$200 mm)

The results for Ag and Ag-2 % Pd alloy are shown in Fig. 3, and the activation energy for Ag is about 1.1 ev, which is almost identical to the results of Doyama and Koehler.[5] The data on the alloy were not so well reproducible mainly due to the contamination. In spite of this the change of quenched-in resistivity with the content of the solute element would be of the same type with that in Au alloys. The change was obtained qualitatively by preliminary experiments of quenching in air.

§ 4. Discussion

As seen in the the experimental results, the formation energy of a vacancy in the pure metal could be obtained directly from the gradient of the straight line in Fig. 2, but in the alloys some further considerations were needed for the analysis of the results, for the data deviated from the straight line. The characteristic nature in the alloys was that the quenched-in resistivity decreased with increasing alloy content and became negative below a certain temperature.

In the pure metal all lattice sites are equivalent and it is sufficient to describe the quenching resistivity with only one activation energy. In the alloys, however, there are two kinds of lattice site, that is, one which is adjacent to the solute atom and is affected by an electrostatic potential of the solute atom, and the other which is not affected by the solute atom and in which the formation energy of a vacancy seems to be equal to that in the pure solvent metal.

The quenched-in resistivity increase may be expressed by the following equation,

$$\Delta\rho_{\text{alloy}} = NA[(1-12x)\exp\{-E/kT\} + (B/A)\cdot 12x\exp\{-(E+\Delta E)/kT\}] \quad (4)$$

where the difference of the formation energy of a vacancy in the free site from that in the adjacent site is described as ΔE, N is the total number of lattice sites in the unit volume, x is the atomic content of solute atoms and A and B are, respectively, the resistivity increase due to one vacancy in the free and the adjacent lattics sites.

In Eq. (4) some assumptions are made: first the region in which the formation energy of a vacancy is influenced by the solute atoms is restricted to the nearest neighbour site, second the solute atoms are dispersed perfectly at random, because the probability of a Pd atom pair may be negligible until the 4 % alloy, and third the quenched-in vacancy is retained in the specimen perfecly during the quenching, or the rate of escape of the vacancies is equal in both sites.

There are some questions in the first assumption. The calculation of screening potential of an solute atom in a dilute solution shows[7] that it is concentrated around the solute atom, so the influence on the next-nearest neighbour lattice site can be neglected, which may justify our assumption. But when the concentration of solute atoms becomes large the mutual interference between solute atoms may not be neglected, and the form of the screening potential should be deformed. When the deformation occurs, we cannot assert that the effect of the solute atom on the next-nearest neighbour site is negligibly small. However, for the simplification of our qualitative discussion the first assumption is adopted.

The values of B/A and ΔE are determined, independent to the values of A and E, in such a way that the calculated values of the temperatures at which $\Delta\rho_{\text{alloy}}$ is equal to zero have a best agreement with the measured values of those for four kinds of alloy. The values B/A and ΔE are -6.5×10^{-5} and -0.85 ev, respectively. Then, using those values the values NA and E in Eq. (4) are determined as 2.3×10^{-4} Ω-cm and 0.87 ev The calculated and the measured values of $\Delta\rho_{\text{alloy}}$ make a qualitatively good fit in the alloy, the calculated curves being shown in Fig. 1 as the full line. The calculated curve can also explain the fact that $\Delta\rho_{\text{alloy}}$ have a minimum in the 4 % alloy at about 500°C.

Because of the less accuracy, especially in high concentration alloys, the reliability about the numerical results are poor. But it should seem to be sure that ΔE had the large negative value and B had the small negative value.

The fact that ΔE has the negative value forms a striking contrast with that expected from the diffusion data. Moreover, the other important result is that the coefficient B has the negative value. This means that the increasing of resistivity with the solute atoms which have a negative valence in the monovalent metal can be canceled by the binding of the vacancy or other imperfections to the solute atom. In the case when the solute atoms have a positive valence difference, i. e. Zn, Ga and Ge in Cu, such cancel out effect due to the binding with a vacancy may be theoretically expected. But when the solute is a transition element, the effect can not be easily understood for the existence of defect 3d electrons. We have known from the calculations by Seeger and Bross[8] and Sugiyama [9] that the formation energy and the contribution to the electrical resistivity for the pair vacancy are smaller than two times of them for the single vacancy. So it may be possible to explain our results by the model that one vacancy in the pair is replaced by the negatively charged solute atom and in this pair the wave functions of electrons may deform to exhibit a scattering to the conduction electrons.

Similer experimental result showing the attractive interaction between a solute atom and a vacancy have been reported in a Al–Cu alloy be Kimura et al,[11] and the decreasing of the resistivity after quenching have also obtained in Cu–Al alloy.[12]

In our results the value of ΔE is unexpectedly large, so it is desired to obtain the density of vacancies by other methods, such as the thermal expansion method, and compare it with the results by the quenched-in resistivity method. Because there are two parameters to be determined, B and ΔE, in the latter.

About the silver alloys the exact experimental results on high concentration alloys could not be obtained, however, from the preliminary tests on 4 and 6% alloys it may be expected that the formation energy and the contribution of vacancies adjacent to solute atoms in the electrical resistivity are similar to those in Au–Pd alloys.

In order to make certainty of our conclusions that the origin of the quenched in resistivity change is the quenched-in vacancies of both kinds, one of which are in the free lattice sites and the other of which are in the adjacent lattice sites to the impurity ions, it is desired to make recovery experiments on these alloys. The recovery experiments on Au–2% Pd alloy at about 90°C has been insufficient to a quantitative discussion, but two qualitative results was obtaind. First, the rate of the recovery of the resistivity in the alloy was slower than in pure Au for the quenching from about 850°C. Second, the negative quenched-in resistivity that appeared in quenching from 650°C had to tendency to recover to the initial zero value.

There will be many causes to hinder the recovery of vacancies, i. e. increasing of the migration energy of the vacancy, decreasing of the number of sink sites, et al. The fact that the value of NA from the pure Au is smaller than that from the alloys can be explained by the assumption that more free vacancies are retained in alloys mainly because the escape of vacancies is obstructed by solute atoms. This fact also explains the first result. But the other explanation can be also possible, that is, decreasing of the resistivity by the disappearence of free vacancies is partly canceled with increasing of it by the disappearance of the trapped vacancies. To decide on a definite conclusion it is desired to determine the migration energies of free and trapped vacancies, but there will be may difficulties to determine those because many complex factors should be analysed. The second result will mean that the origin of negative resistivity may no be something like precipitation but may be imperfections, especially vacancies, and this will support our conclusions.

§5. Conclusions

It was found that the difference of the quenched-in resistivity increase between Au and Au-Pd alloys was remarkable, and it had a certain relation with the concentration of solute atom. The resistivity increase in alloys could be described qualitatively with two activation energies. The difference between two energies, ΔE, would mean the change in formation energy of a vacancy at the lattice site adjacent to the solute atom. The obtained value of ΔE in Au-Pd alloys was negative and unexpectedly large. Moreover, the increase of resistivity with the solute atoms must have canceled by the binding with a vacancy.

Unfortunately the measurement is much more difficult for alloys than for pure metals. For quantitative discussions it would be necessary to obtain more careful and accurate results. And it has been very much desired to obtain the value ΔE by other method for the comparison with the results by the resistivity method.

The author wish to express his hearty thanks to Dr. Y. Takagi for his interest and encouragement in this work, and Drs. N. Kunitomi and H. Suzuki for their encouragement and valuable discussions. His thanks is also to Miss S. Kimura for her continued assistance in this work.

Some Experimental Studies on the Parasitic Ferromagnetism of $\alpha\mathrm{Fe_2O_3}$

By Akira TASAKI and Shūichi IIDA

Department of Physics, Faculty of Science, University of Tokyo

(Received June 3, 1961)

The temperature dependence of magnetization of polycrystalline hematite ($\alpha\mathrm{Fe_2O_3}$) which contains several per cent of foreign atoms (Al, Mn, Ga and Cr) was measured at various field strengths. The results were analyzed into so-called parasitic magnetic moment σ_0 and susceptibility term χ_g. It has been found that the parasitic nature of σ_0 is not influenced severely by the addition of foreign atoms but the transition temperature is lowered in general and the step transition in σ_0 *vs* temperature curve becomes gradual.

The residual magnetization was measured with an astatic magnetometer. It was found that the memory effect (in the ratio of the residual magnetization between before and after cooling treatment) is little affected by the addition of foreign atoms or by change in oxidation. The residual magnetization decreased by about 50% at the first cooling-heating cycle, but is maintained completely in following cycles.

§1. Introduction

Hematite ($\alpha\mathrm{Fe_2O_3}$) is an antiferromagnet, it is accompanied by a weak ferromagnetism, which is called "parasitic ferromagnetism", above the transition temperature (−15°C). It is known from studies by neutron diffraction[1] that the spins lie in the basal plane (111) above the transition temperature and below it the spin direction is parallel to the [111] direction. In order to explain the parasitic ferromagnetism, many studies have been made and several mechanisms have been proposed. These proposed mechanisms can be classified into two: the "homogeneous" theory and the "inhomogeneous" theory. According to the inhomogeneous theory, this parasitic ferromagnetism is thought to have its origin in the magnetic moment of some other phase ($r\mathrm{Fe_2O_2}$ etc.) or imperfectly compensated magnetic moments of the sublattices originating in irregularities of spin alignment around the impurity atoms or lattice imperfection[2,3]. On the other hand, the homogeneous theory ascribes this phenomenon to an intrinsic nature of the crystal structure. Dzyaloshinsky[4] has pointed out that the low symmetry of the atomic arrangement in this rhombohedral antiferromagnet should result in a spin canting when the spins lie in the basal plane and that this atomistic canting is the origin of the parasitic ferromagnetism. An semi-quantitative theory of this spin canting has been presented by Moriya[5]. According to this theory, there exists between spins of the magnetic ions the anisotropic interaction, in additions to the ordinary super-exchange interaction, that causes spin canting, as the crystal symmetry is so low and the orbital moment of the magnetic ions is not completely quenched. Although there are several unknown factors, the main feature of the parasitic ferromagnetism is explained by this homogeneous theory.

In a previous paper[6], we have reported our study of the influence of oxidation and reduction on this parasitic ferromagnetism; it was found that the origin of this weak ferromagnetism was not the same for the isotropic part and for the anisotropic part. The isotropic part (after Néel) remains below the transition temperature of −15°C, but the other part disappears completely at this point on cooling down. Since the isotropic part largely changed with the progress of oxidation or reduction and became almost zero by a proper heat treatment, we are led to believe that the origin of this part is due to the non-stoichiometry of αFe_2O_3. The anisotropic part, however, did not change by these treatments; therefore this part is certainly due to Dzyaloshinsky's mechanism, i.e., it should be explained by the homogeneous theory.

In the present work, we have studied the effect of the substitution of cations and the memory phenomenon. Regarding the substitution effect, Haigh[7] has already studied the influence of the addition of Ti and Al on the residual magnetization of αFe_2O_3.

§ 2. Experimental Procedures

Specimens

The weighed electrolytic iron* and another metal (Al, Mn, Ga or Cr) were dissolved separately in nitric acid. However, as Ga was not dissolved easily, a small amount of sulfuric acid was added in this case. The solutions were mixed with a desired proportion and the mixture was dried by infrared-ray lamp. Then the dried oxide was ground, densely packed into a platinum crucible, heated to 1000°C and kept for 3 hours in air. The specimens that contained manganese were kept at 800°C for 24 hours in air to eliminate the presence of Mn^{2+} ions. By these procedures, polycrystalline specimens containing 1, 2 and 4 at. % concentration of each added element were prepared.

Magnetic measurements

The magnetic measurements were made with a magnetic balance automatically controlled[8]. The magnetization of αFe_2O_3 is expressed by

$$\sigma=\sigma_0+\chi H\ , \qquad (1)$$

where σ_0 is the saturation magnetization of the so-called parasitic ferromagnetism and χ is the susceptibility. These two terms are functions of temperature. In order to separate these two terms at a given temperature, the magnetization was measured at three different field strengths, i.e. 4.80, 8.80 and 13.36 KOe. The temperature measurements were made with a copper-constantan thermocouple which was inserted into the powdered sample.

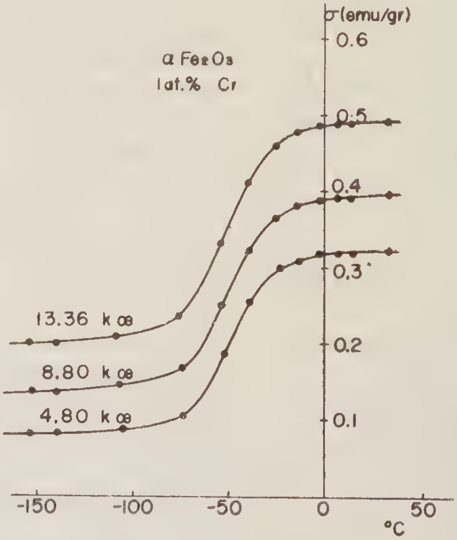

Fig. 1. Magnetization *vs* temperature curves of αFe_2O_3 added with 1% Cr, at three different field strengths.

Since the temperature was not maintained constant during the magnetization measurements at the three different field strengths, the separation of σ_0 and χ was made by using the curves that are shown in Fig. 1. Strictly speaking, the linear relation between field strength and magnetization does not hold exactly, especially above the transition temperature. In the present work, however, we have disregarded this effect.

---

* In the course of the present study we once prepared αFe_2O_3 from carbonyl iron of commercial grad and found that this αFe_2O_3 showed a high isotropic term (~0.4 emu/g). In natural crystals, we also found frequently the same character. But when we prepared αFe_2O_3 from spectroscopically pure iron (Johnson-Mathey Co.) or from electrolytic iron, there was no such term.

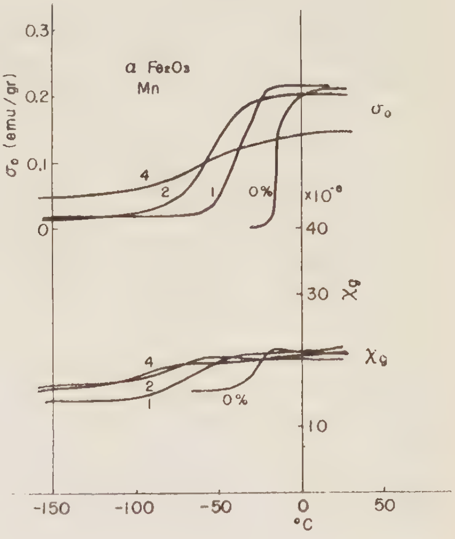
(c)



(d)

Fig. 2. Parasitic ferromagnetism σ_0 and susceptibility χ_g *vs* temperature curves of αFe_2O_3 that contain foreign atoms of 1, 2 and 4% with respect to iron atoms.

An astatic magnetometer, which was used to measure the residual magnetization, consists of two 5 mm length magnets suspended 15 cm apart in opposit directions and a fine phosphor-bronze wire suspending the two magnet system. The terrestrial magnetic field at the magnetometer was compensated by a pair of Helmholtz coils. Our experimental procedure was as follows: at first, a specimen was magnetized in a strong field (~30 KOe) at room temperature, and the residual magnetization of the specimen was measured. Then the specimen was cooled down through the transition temperature, and after the temperature recovered to room temperature, the magnetization was measured again.

§ 3. Experimental Results

Fig. 2 shows the experimental results. We notice that the transition temperature decreases in all cases, especially in the case of Cr.

Above the transition temperature, the values of σ_0 are almost the same, except for the case of 4% Mn, and below it they become almost zero. This means that the isotropic part of σ_0 is zero in almost all cases, except when Mn or Ga is added to 4%, in which case this isotropic part appears slightly. The susceptibility χ_g shows corresponding variation to that of σ_0, and in each case the transition temperature of χ_g is nearly equal to that of σ_0. In the case of Al, each χ_g *vs* T curve shows a maximum at the transition temperature.

The Néel temperature was measured with the same magnetic balance that was used for magnetization measurements. Fig. 3 shows the Néel temperature as a function of the concentration of foreign atoms. In all cases, the Néel temperature decreases by the addition of foreign atoms and, except in the case of Cr, decrement of the Néel temperature appears to be saturated by 1 or 2 at. % addition.

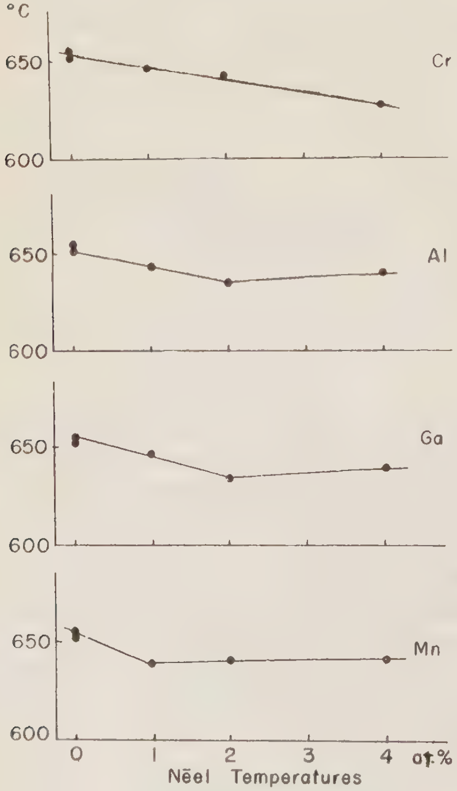


Fig. 3. Variation of Néel temperature of αFe_2O_3 when foreign atoms are added with several per cent with respect to iron atoms.

In Fig. 4, the ratio of the residual magnetization before and after the cooling treatment is shown. According to this result, memory of the residual magnetization does not depend on the addition of foreign atoms nor on oxidation. Fig. 5 shows the effect of repetition of cooling treatments. It is a very interesting fact that, except for the first cooling-heating cycle, the ratio of the residual magnetization of the nth cycle to the $(n+1)$th cycle is nearly 100 %.

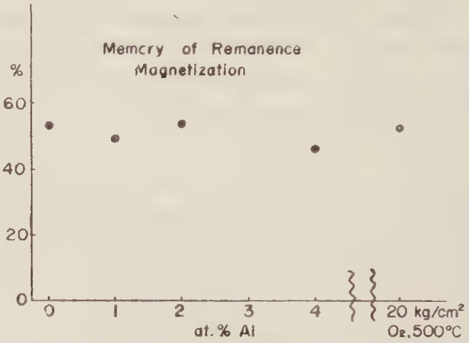

Fig. 4. Residual magnetization of αFe_2O_3 at room temperature after a cooling-heating cycle *vs* concentration of foreign atoms and oxidation.

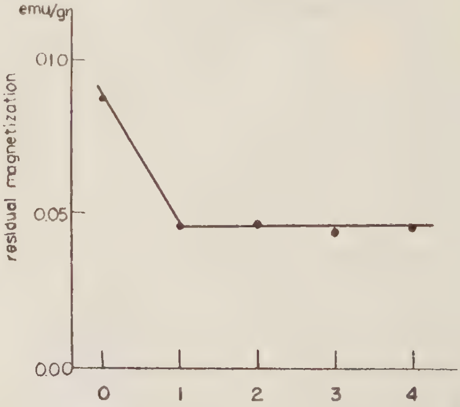

Fig. 5. Residual magnetization of polycrystalline αFe_2O_3 at room temperature after cooling-heating cycles.

§ 4. Discussion of the Results

By the present study it has become clear that, when a small amount of foreign atoms is added, the absolute value of σ_0 does not change appreciably, while the transition temperature of σ_0 decreases considerably. The former fact can be understood easily as a confirmation that the anisotropic parasitic ferromagnetism is not caused by impurity atoms.

However, it is not easy to understand the latter fact, if we assume that this change of easy axis from within the basal plane to along the c-axis is due to the difference in temperature variation of the two distinguished mechanisms for the anisotropy energy of this crystal. The competition between the one-ion type anisotropy energy of Fe^{3+} due to the crystalline field, and the magnetostatic dipole-dipole interaction between Fe^{3+} ions will lead to an increase of the transition temperature when a small amount of Fe^{3+} ions are substituted by foreign non-magnetic ions. It is a simple conclusion that the one-ion type anisotropy energy decreases linearly with the concentration of Fe^{3+} ions, whereas the dipole-dipole interaction energy decreases quadratically. If we denote the corresponding energy differences between the two spin orientations as $E_{\text{cryst}}(T, x)$ and $E_{\text{dip}}(T, x)$, then

$$|E_{\text{cryst}}(T, 0)|<|E_{\text{dip}}(T, 0)| \quad \text{when} \quad T>T_t \, , \qquad (2)$$

$$|E_{\text{cryst}}(T, 0)|=|E_{\text{dip}}(T, 0)| \quad \text{at} \quad T=T_t \, , \qquad (3)$$

and

$$|E_{\text{cryst}}(T, 0)|>|E_{\text{dip}}(T, 0)| \quad \text{when} \quad T<T_t \, . \qquad (4)$$

On the other hand, when $x \langle\langle 1$.

$$E_{\text{cryst}}(T, x)=E_{\text{cryst}}(T, 0)\ (1-x) \, , \qquad (5)$$

$$E_{\text{dip}}(T, x)=E_{\text{dip}}(T, 0)\ (1-x)^2$$
$$=E_{\text{dip}}(T,0)\ (1-2x+x^2) \, , \qquad (6)$$

so that for $T=T_t$, $x \ll 1$,

$$|E_{\text{cryst}}(T_t, x)|>|E_{\text{dip}}(T_t x,)| \, . \qquad (7)$$

In the case of Al, as shown in Fig. 2, each χ_a *vs* T curves shows a maximum at the transition temperature. Although there is some possibility that errors in the temperature measurement introduced a considerable effect on the analyzed curve in the transition temperature region, this maximum seems to be a little more pronounced than being due to such possible experimental errors. It is suggested that in this system presence of the field induced rotation of the spin axis of antiferromagnet might be the possible origin of this maximum. It is also possible for all cases that, in a certain narrow range of temperature at the transition, the easy axis of spin lies in a certain direction which is between the c-axis and c-plane[9].

It might be very probable that, in the case of Cr, the magnetic interactions of Cr would introduce a large effect on the decrease of the transition temperature. But, as shown in Fig. 3, no peculiarities are found in the decreasing behavior of the Néel temperature for Cr. In the case of Mn, the presence of Jahn-Teller effect of Mn^{3+} ion might be expected. But we cannot find any peculiarities in Fig. 2. Further, the isotropic part which appears in the case of 4 % Ga is not understood.

It is noted that, in all the cases, the addition of foreign atoms not only decreases the transition temperature, but also makes the transition gradual. Although, in general, it is thought that the existence of impurities make a sharp phase transition gradual, this is not expected *a priori*. We have made a short statistical calculation for this impurity effect. In the calculation we have assumed a distribution of small regions each of which is affected by the presence of impurity atoms and have a lower transition temperature. It is also assumed that the size of each region is a constant and the variation in population of impurity atoms in each region is statistical. Then, for the case of Cr, the calculation gives a value of 200 atoms (5 atomic distance) by which the three experimental curves with different impurity content are represented adequately. However, in other cases, this calculation can not reach a self-consistent result.

The memory phenomenon is another interesting feature of αFe_2O_3. It has been known for polycrystalline specimens that the residual magnetization, which has temporarily disappeared by cooling, recovers to 50% of the initial value after heating. It has also been ascertained that the direction of the magnetization is unchanged. In the present work, we have found that the memory amount does not depend on the presence of impurity atoms nor on the change of oxidization and that, when the cooling-heating cycles are repeated, the memory amount is always almost 100%[10], except for the first one cycle. The first fact indicate that the memory does not depend on the amount of impurity atoms nor on lattice imperfections. In other words, the origin of this memory phenomenon seems to be purely intrinsic rather than due to inhomogeneities. As this concept is consistent with the second fact, we are led to think that there is a tight correlation between the phases of the states above and below the transition temperature and that, when the spin changes its direction, there must be a reversible route of the transition by which the phase of the spin states is conserved. In a previous paper¹¹⁾, Siratori and the present authors have already offered a possible mechanism of this tight correlation based on the presence of a trigonal symmetry anisotropy energy of the crystal and assuming tentatively the presence of another uniaxial type anisotropy energy.

Quite recently, an interesting character of this memory phenomenon has been discovered by Akimoto et al¹²⁾. When the specimen was cooled odd times, the amount of memorized residual magnetization was larger (more than by 10%) than when it was cooled even times, except after the first one cycle. This effect was found to become eminent when the specimen is magnetized in a weak magnetic field. Such a tendency has been also recognized in our measurement, but we have not studied it in detail nor have we any good explanation for this effect.

It is hoped that more precise and fundamental measurements are performed on single crystals. It should be added that our measurements of torque performed on well-selected natural single crystals (which have almost zero isotropic part) have given the presence of a uniaxial anisotropy of ~40 dyne-cm/gr., as a primary anisotropy in the (111) plane. Although we have tried to make a synthetic single crystal large enough for the torque measurements, we have yet been unsuccessful*. The effect of Fe^{4+} is now being studied by using an oxygen pressure of 1000 Kg/cm². The results will be published shortly.

Acknowledgement

The authors wish to express their hearty thanks to Prof. T. Nagata and Dr. S. Akimoto of the Geophysical Department who kindly permitted us to use their astatic magnetometer and to refer to their unpublished results.

Determination of the Extension of Linear Polymer Molecule in the Solution by the Light Scattering

By Yasuhiro Miyake

Department of Physics, Faculty of Science,
Hokkaido University, Sapporo, Japan

(Received March 6, 1961)

With use of Peterlin and Mizutani's light scattering function $P(\theta)$, a simple method has been developed to determine the mean square end-to-end distance $\langle r^2\rangle$. Following Peterlin and Mizutani, $\langle r^2\rangle$ is assumed to be proportional to N^γ, where N is the degree of polymerization and γ is a parameter. Obtained values of $\langle r^2\rangle$ are $(5.53)^2\times10^{-16}N^{1.15}$, $(42.51)^2\times10^{-16}N^{0.70}$, and $(6.39)^2\times10^{-16}N^{1.11}$ for polystyrene in toluene, in methylethylketone and in cyclohexane solutions, respectively. These results suggest that the excluded volume of chain elements and the interaction between the polymer and the solvent are important factors to determine the extension of polymer molecules in both good and poor solvents. Brief discussions on the polydispersity of the system are also given.

§ 1. Introduction

Recently, several theories have been developed on the high polymer solution taking into account of the excluded volume effect of the chain element and the interaction between the elements and the solvents[1]. These theories give expressions for the molecular extension of high polymer, which are somewhat different from that derived on the basis of the random flight theory. In order to examine the significance of this difference, experiments have been carried out to obtain informations of the molecular extension.

The light scattering measurement seems to be one of the most powerful tools to investigate the molecular extension or the mean square end-to-end distance $\langle r^2\rangle$. Debye and Zimm[2] first gave an expression for the light scattering function, $P(\theta)$, on the basis of the random flight theory and determined $\langle r^2\rangle$ experimentally. Peterlin[3] and Mizutani[4] (abbreviated as P–M below) independently proposed the same expression for $P(\theta)$ considering the recent development of the theories on the high polymer solution. Although expressions which are more accurate than that of P–M have been given by several authors[5],[6], it is very laborious to determine $\langle r^2\rangle$ using them, as seen in the work of Hyde et al[6]. Therefore, P–M expression will be used throughout in the present work. In the next section it will be shown that P–M expression of $P(\theta)$ is especially suitable for the present approximate method of calculation. In sections 3 and 4 experimental procedures and results will be given. In section 5, the condition will be given, under which our method gives as good results as others. The polydispersity will also be discussed.

§ 2. Method of Determining the Parameters

By changing some of the notations, P–M expression for the mean square end-to-end distance $\langle r^2\rangle$ and the scattering function $P(\theta)$ of a linear molecule can be rewritten as

$$\langle r^2\rangle = C_2 N^\gamma , \tag{1}$$

$$P(\theta)=2/N\int_0^N (1-Z/N)\exp(-uC_2Z^\gamma)\,dZ\ . \tag{2}$$

Here N is the degree of polymerization, γ and C_2 parameters, and $u=(8\pi^2/3\lambda^2)\sin^2\theta/2$, λ being the wave length of the light in the solvent, θ the angle between the primary and scattered beams. The relation between the intensity of the scattered light $I(\theta)$ and $P(\theta)$ is first given by Zimm[2]:

$$I(\theta)/C=KMP(\theta)\{1-2A_2MP(\theta)C\}\ , \tag{3}$$

where M is the molecular weight of the solute, A_2 the second virial coefficient, C the concentration and K the proportionality constant. As seen in Eq. (1), we can estimat $\langle r^2\rangle$ from γ and C_2. In the following it will be discussed how to determine γ and C_2 by the experimental observation of $P(\theta)$.

Expanding Eq. (2) and then integrating it, we obtain the following result

$$\begin{aligned} P(\theta)=1 & \\ &-(2uC_2N^{\gamma}/1!)\{1/(\gamma+1)-1/(\gamma+2)\} \\ &+(2u^2C_2{}^2N^{2\gamma}/2!)\{1/(2\gamma+1)-1/(2\gamma+2)\} \\ &-(2u^3C_2{}^3N^{3\gamma}/3!)\{1/(3\gamma+1)-1/(3\gamma+2)\} \\ &+(2u^4C_2{}^4N^{4\gamma}/4!)\{1/(4\gamma+1)-1/(4\gamma+2)\}-\cdots . \end{aligned} \tag{4}$$

As an approximation, those terms with higher power than u^2 are neglected and Eq. (4) is rewritten as

$$\begin{aligned} P(\theta)=1-\{2BC_2N^{\gamma}/(\gamma+1)(\gamma+2)\}U \\ +\{B^2C_2{}^2N^{2\gamma}/(2\gamma+1)(2\gamma+2)\}U^2 , \end{aligned} \tag{5}$$

where $B=8\pi^2/3\lambda^2$, $U=\sin^2\theta/2$. In Eq. (5), the second and third terms show the initial slope and the curvature of $P(\theta)$ plotted against U, respectively. Using these two quantities the the parameters are determined in the following manner. The initial slope K_1 is given by

$$K_1=2BC_2N^{\gamma}/(\gamma+1)(\gamma+2) . \tag{6}$$

Hence

$$C_2=K_1(\gamma+1)(\gamma+2)/2BN^{\gamma} . \tag{7}$$

With the aid of Eq. (7), Eq. (1) can be rewritten as

$$\langle r^2\rangle=C_2N^{\gamma}=K_1(\gamma+1)(\gamma+2)/2B . \tag{8}$$

Let us now consider a region where the curve begins to depart from the initial slope but is negligibly affected by the U^3 term. This curvature is determined by the coefficient of the third term in Eq. (5), which is expressed as

$$K_2=B^2C_2{}^2N^{2\gamma}/(2\gamma+1)(2\gamma+2) . \tag{9}$$

Eqs. (6) and (9) give the following equation for γ

$$\gamma^3+5\gamma^2+(8-16X)\gamma+4-8X=0 , \tag{10}$$

where

$$X=K_2/K_1{}^2 . \tag{11}$$

Eq. (10) has three roots for γ, of which the positive one has a physical significance. It is easy to prove Eq. (10) has a positive root only if

$$X>1/2 . \tag{12}$$

With the aid of obtained value of γ, we can calculate C_2 and $\langle r^2\rangle$ using Eqs. (7) and (8). Then Eq. (10) can be rewritten as

$$X=(\gamma+1)(\gamma+2)^2/8(2\gamma+1) , \tag{13}$$

which means that X does not depend on N. The algebraic equation for γ as given by Eq. (10) is quite simple. This comes from the present use of an approximate equation of P-M expression of $P(\theta)$.

§ 3. Apparatus and Experimental Procedure

The light scattering apparatus similar to Brice's photometer[7] has been constructed. Slit systems for incident and scattered light have been designed considering Hermans' factor[8]. A high pressure mercury lamp and a solution filter gave satisfactorily monochromatic light of wave length of 4358 A[9]. The sample solution in a cylindrical cell was held on a black copper plate which was kept at a constant temperature (±0.2°C) by circulating water. The accuracy in the measurement of the relative intensity of the scattered light in the angular range from 35° to 145° was checked using the θ dependence of the intensities of toluene and cyclohexane. Fig. 1 shows intensities of the scattered light from these liquids. The dissymmetry coefficients Z calculated from these data are 1.01 and 1.00, respectively. These results suggest reliability of our apparatus. Commercial polystyrene was fractionated twice by the precipitation method and divided into thirty fractions. Three fractions were chosen from these thirty and used as the solute. Toluene, methylethylketone (M.E.K.) and cyclohexane were used as the solvents, which were purified by the usual method[10]. Polystyrene solutions of various concentrations were made by diluting the mother solution, which was 0.5 g solute per 100 cc for each solvent and were stirred for about eight hours at 50°C. The diluted solutions were further stirred for about one hour at room temperature and then freed from dust by repeating filtration four and five times with the sintered glass filter of No. 4. For the system of polystyrene in

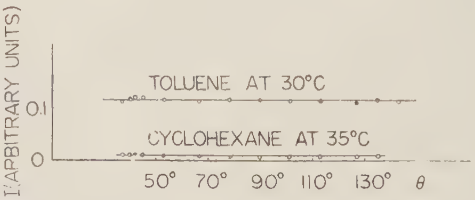

Fig. 1. Intensity of scattered light obtained for toluene and cyclohexane.

cyclohexane, the solution was stirred once again for about one hour at 35°C immediately before the measurement. The measurements of the scattered light were made at 30°C for toluene and M.E.K. solutions and at 35°C for cyclohexane solution. Toluene, M.E.K. and cyclohexane solvents are examples of good, poor and Θ solvents, respectively. Benzene was used as the scattering standard to reduce the measured relative intensity of the scattered light into the absolute intensity.

§ 4. Results

Results of the present light scattering measurements of three fractions are given in Table I and an example of Zimm plot[11] is shown in Fig. 2, in which $P(\theta)$ vs. U and $1/P(\theta)$ vs. U relations were obtained from Zimm plot. The initial slope K_1 was determined by use of these curves. The absolute values of initial slopes of both curves should theoretically coincide. Here K_2 was determined by the plot of $P(\theta)-(1-K_1U)$ vs. U^2, of which the initial slope is K_2 itself. The values of γ and C_2 were obtained from Eqs. (7) and (10). The molecular weight M and thus the degree of polymerization N were determined from Zimm plot of Eq. (3). The values of the refractive index increment, $\partial n/\partial C$, which were necessary to determine K in Eq. (3), were taken from other articles[11]. Thus, the molecular extension in the solution was determined from Eq. (1). Results are given in Table II, in which the values calculated from Zimm's data[11] are also shown. For comparison, $\langle r^2\rangle_z$ and the square of characteristic length, b_2, which were obtained from Zimm's expression for $P(\theta)$[2] are also given. (Eq. (2) can be reduced to Zimm's $P(\theta)$ by putting $\gamma=1$ and $C_2=b_2$.)

*: From Zimm's data[11].

**: The value cited from the Table in Zimm's article[11].

In the last two columns our values calculated from Zimm's $P(\theta)$[2] (see section (1)) are given. b_2, square of a characteristic length of chain, is equal to C_2 when $\gamma=1$.

and curvature of $P(\theta)$ in the vicinity of $\theta\approx0$. In general, the accuracy in measurement of the small angle scattering is poorer than that of the large angle scattering. We could, however, obtain very good linear relations both for $P(\theta)$ vs. U and $P(\theta)-(1-K_1U)$ vs. U^2 curves. The relative errors in both K_1 and K_2 seem to be of the order of $\sim5\%$. Also the present method has been checked by using Zimm's data and the values of $\langle r^2\rangle$ which are very close to those reported by Zimm has been obtained as shown in Table II.

The fundamental assumptions in the derivation of P-M's $P(\theta)$ are that the solution is non-branched, monodispersed system. These are the reason why we chose very well fractionated polystyrene, which was expected to have no branches[12],[13]. There appears, however, to be some effect due to small polydispersity such as will be discussed below. According to Flory's interpretation[14], the parameter γ expresses the long-range effect on $\langle r^2\rangle$ while C_2 is closely related to the short-range effect. The deviation of γ from unity is expected to be positive in good solvents, negative in poor solvents and zero in Θ solvent[4],[6]. On the other hand, C_2 is large if the solvent is poor and high polymer is stiff, while it is small if the solvent is good and high polymer is flexible.

Further discussions will be given on these parameters and $\langle r^2\rangle$ for our examples of good, poor and Θ solvents. Toluene was studied as an example of good solvent. As seen in Table II, the values of γ are larger than unity in both the F. 1-2 and F. 7-1 solutions as expected. The values, however, are not the same in both cases. This seems to come from the fact that γ depends on a molecular weight distribution as seen in Appendix. The values of γ and C_2 of F. 1-2 seem to be reasonable. The value of γ is in good agreement with that obtained from the well fractionated samples of polymethylmethacrylate in acetone solution by Cantow and Schulz[15] and the rather small value of C_2 suggests

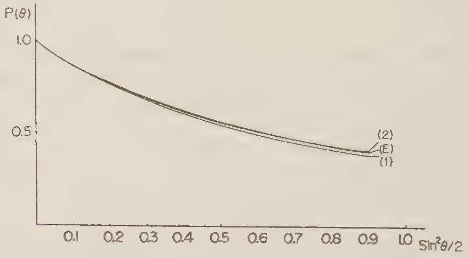

Fig. 3. Experimental values of light scattering intensity in comparison with calculated light scattering functions for polystyrene F. 1-2 in toluene at 30°C. (1): $\gamma=1$, (2): $\gamma=1.15$, (E): Experimental.

that the polymer is flexible. $\langle r^2\rangle^{1/2}$ is about 10% larger than $\langle r^2\rangle_z^{1/2}$ calculated from Zimm's $P(\theta)$. Fig. 3 shows experimentally determined $P(\theta)$ curve in comparison with P–M's $P(\theta)$ and Zimm's $P(\theta)$ calculated from with use of the parameters in Table II. P–M's $P(\theta)$ gives much better agreement with experimental $P(\theta)$ than Zimm's $P(\theta)$. In F. 7–1, γ is rather large and C_2 is too small. Probably these rather unreasonable values are caused by the fact that the solution was actually polydispersed and by the experimental errors in determining the molecular weight. In the calculation of γ of RT.H-toluene at 20°C, it was turned out that X does not satisfy the condition of Eq. (12) and no positive root for γ could be obtained from Eq. (10). Probably this result was caused by too large molecular size of the polymers. In such a case, higher order terms of $P(\theta)$ expansion which were neglected in Eq. (5) become significant even for small angle scattering. In the system of polystyrene in M.E.K. solution, which is an example of a little poor solvent[14], γ obtained by our measurement is slightly smaller than unity as shown in Table II. This fact seems to be in contradiction to Flory's theory[6),14] because our observation was done at the temperature much higher than Θ temperature. The value of C_2 of this system also seems to be too large. Zimm[11] reported $C/I(\theta)$ values for this system (Ep-2-M.E.K.). We have evaluated $P(\theta)$ from his data and Eq. (3) and plotted it against U. It was difficult to interpret the obtained curve by adjusting the parameters in $P(\theta)$ given by Eq. (5). Hence, no values of γ and C_2 are given in Table II. It should be mentioned here that Boyer et al[16] reported somewhat strange behavior of this system. Further investigation seems to be needed. For the system of polystyrene in cyclohexane solution, which is an example of the Θ solvent ($\Theta=$34.5°C), the obtained γ is larger than unity and C_2 seems to be slightly too small. These values suggest that the polymer molecule in this solution is fairly flexible, the fact which can be hardly expected from the usual behavior of the Θ solvent. For definite conclusion, however, effect of polydispersity on the experimental values of γ and C_2 should be studied in detail. In the last row of Table II, values of the parameters are given for RT-H-M.E.K. (89%)-2-propanol (11%), which is a very poor solvent as shown by Zimm[11]. These values have been calculated using Zimm's data[11] of $C/I(\theta)$. His measurements were carried out at a temperature well below the Θ temperature. As seen in Table II, $\gamma<1$ and $C_2\gtrsim b_2$, which are reasonable values for a poor solvent. In Table II, as described above, $\langle r^2\rangle^{1/2}$ was calculated on the basis of P-M expression of $P(\theta)$ where the excluded volume and molecular interactions were taken into account, while $\langle r^2\rangle_z^{1/2}$ was calculated using Zimm's $P(\theta)$ based on the random flight theory. The table shows $\langle r^2\rangle^{1/2}$ is generally different from $\langle r^2\rangle_z^{1/2}$ by about 10%. Other authors[5),6),15),17] also reported such values of this difference and the dependence of $\langle r^2\rangle$ on N similar to the present results. In conclusion it may be stated that the present method provides a simple way to determine $\langle r^2\rangle$ with better accuracy than that of Zimm. For a further improvement of this light scattering method, probably one has to consider the effect of polydispersity in more detail.

Appendix

It has been shown by Zimm[2),12] that for a polydisperse system characterized by its normalized weight distribution $f(N)$, $P(\theta)$ is given by the following expression:

$$P(\theta)=\int Nf(N)P_N(\theta)\,dN\Big/\int Nf(N)dN\,. \quad \text{(A.1)}$$

Substituting Eq. (5) into $P_N(\theta)$ of Eq. (A.1), assuming that C_2 and γ are independent of N and denoting the weight average value of any function $\varphi(N)$ by $\langle\varphi(N)\rangle$, we obtain the following equation.

$$P(\theta)=1-g_1(\langle N^{\gamma+1}\rangle/\langle N\rangle)U + g_2(\langle N^{2\gamma+1}\rangle/\langle N\rangle)U^2\,, \quad \text{(A.2)}$$

where

$$g_1=2BC_2/(\gamma+1)(\gamma+2)\,,$$
$$g_2=B^2C_2^2/(2\gamma+1)(2\gamma+2)\,,$$

which are independent of N. Using Eq. (A.2) and Liapounoff's inequality[12], X is given as

$$X=(g_2/g_1^2)\langle N\rangle\langle N^{2\gamma+1}\rangle/\langle N^{\gamma+1}\rangle^2\geqq(g_2/g_1^2)\,. \quad \text{(A.3)}$$

From Eq. (A.3), it can be seen that X depends on the polydispersity and has a greater value than that in the system of monodispersity. It can be proved from Eq. (10) that the larger X is, the greater the value of γ. In Eq. (A.3) X in appearance depends on N, but actually it depends only upon molecular weight distribution itself. It might be worth noting that in Eq. (10) the effect of the change in X on γ is emphasized by the coefficients 16 and 8, respectively.

Three-Level Maser Action in Gas
II. Experimental Study on Formic Acid

By Tatsuo YAJIMA

Department of Physics, Faculty of Science,
University of Tokyo, Tokyo

(Received March 4, 1961)

The quantum mechanical behavior of the three-level maser was experimentally studied by using the rotational spectrum of HCOOH molecule at microwave frequencies. By using the $2_{11} \leftarrow 1_{10}$ line at the frequency of 46581 Mc as the pumping, the induced emission of the $2_{11} \rightarrow 2_{12}$ line at the frequency of 4916 Mc was obtained. For a strong pumping, the splitting of emission line due to resonant modulation effect was observed. The line-shape of emission signal under off-resonant pumping was studied in detail. The emission spectrum due to simultaneous emission and absorption of two photons corresponding to the signal and the pumping was observed for the condition of far off-resonant pumping. The results were compared with the theory described in the previous paper, and was found to be in good agreement in many respects. Some discrepancies concerning emission intensity are also discussed. An application of the multiple quantum transition to a four-level system of HCOOH is described.

§ 1. Introduction

The principle of the three-level maser has usually been stated in terms of "negative temperature" which yields net induced emission as a result of population inversion between two levels. This is only a semiclassical explanation, and the quantum mechanical theories of three-level maser predicted various behavior which can not be explained by the semi-classical theory as has been described in the previous paper[1] (hereafter referred to as Part I). However, the observations of such effects have not yet been reported in the numerous experimental works of the solid state microwave masers. This is due to the facts that, under the circumstances of usual operation, the action of a solid state maser obeys semiclassical theory to a good approximation because of their relaxation properties, and that an enormous pumping power is required for the appearance of the quantum mechanical effects. On the other hand, the three-level gas maser can conveniently be used to study these effects by the reason as described in Part I. Therefore, an experiment of gas maser to realize and examine this new type of maser action was planned.

The quantum mechanical effects in the three-level maser are the characteristics of a molecular system which is subject to two or more coherent radiations, and the phenomena such as resonant modulation effect and multiple quantum transition are expected to appear in the emission spectrum. The resonant modulation effect has been studied in the microwave absorption spectrum of OCS molecule.[2] The multiple quantum transitions, which do not obey usual Bohr frequency condition, have also been widely observed in the various fields[3] such as atomic and molecular beam spectroscopies, paramagnetic resonance in gases and solids, nuclear magnetic resonance and recently in the rotational spectrum of gas molecule.[4] As to the net induced emission spectra, there have been few experimental results which involve such effects. The spectrum of induced emission as well as absorption by a double quantum transition in a two level system has been observed at radio frequencies in electron spin resonance of DPPH and other materials.[5] Recently, Elschner[6] reported the observation of the quantum mechanical behavior of the three-level maser using a free radical $(SO_3)_2NO^{--}$ in alkaline aqueous solution at signal frequencies of 13∼16 Mc. In the microwave frequencies, however, such a type of emission signal has not been obtained yet.

In the present paper we report the observation of the quantum mechanical behavior of the emission spectrum in the three-level maser using rotational spectrum of gas molecules at microwave frequencies. The results were compared with the calculated ones described in Part I.

§ 2. Molecular Energy levels suitable for Experiment

Many energy level systems which constitute three-level masers can be found in the rotational levels of molecules. However, there are some restrictions for the use in the experiment of the type intended here. Two conditions must be considered in choosing molecular energy levels. The first is that the available microwave power is sufficient to achieve strong enough pumping for the marked appearance of the quantum mechanical effects. This requires the pumping transition to have large transition probability and to be in a conventional frequency range. The condition can be expressed in the form which is equivalent to Eq. (1) of Part I.

$$w_p = \frac{2\pi\,|\,\mu_p\,|^2 P_0}{3ch^2(\Delta\nu)^2 S} \gtrsim 1 \;,$$

where P_0 is the pumping power for plane polarized wave, μ_p the dipole matrix element for the pumping transition, $\Delta\nu$ the half line-width, S the cross-sectional area of the wave-guide, and w_p is called the pumping parameter. The second condition is that the intensity of the signal line must be strong enough for observing the details of the line shape in both the presence and absence of pumping radiation. This requires that the absorption coefficient of the signal line must be of the order of 10^{-7} cm^{-1} or more, and the ratio of the pumping and the signal frequencies must be sufficiently high. Generally speaking, the heavier molecules are more suitable for the former condition because of their closely spaced energy levels, while the lighter molecules are more suitable for the latter condition because of their strong intensity of the spectrum. Further, asymmetric top molecules may be preferable because of their variety of energy levels and allowed transitions.

Considering these circumstances, the molecule of formic acid, HCOOH, was selected. HCOOH is a slightly asymmetric prolate rotor molecule, and has a large number of K-type doubling transitions, one of which can be used as the signal transition. These K-type doubling transitions are connected with each other by relatively strong R^a-type transitions, one of which can be used as the pumping transition. The three-level system used in the present experiment is shown in Fig. 1. The frequencies, the dipole matrix elements and other quantities of two transitions are listed in Table I. The pumping parameter, w_p, which is an important measure of the degree of pumping is shown in Fig. 2 as a function of the pumping power, P_0/S, and the half line-width, $\Delta\nu$. The microwave spectrum and the molecular structure of HCOOH have been studied by many workers[7], and the frequency of the pumping transition, $2_{11} \leftarrow 1_{10}$, has already been measured. The signal transition, $2_{11} \leftarrow 2_{12}$, was measured first in our experiment so far as the author is aware, and its frequency was found to agree within 0.2 Mc with the calculated value using rotational constants obtained by Trambarulo *et al*

absorption coefficient* (cm^{-1})	2.1×10^{-7}	3.1×10^{-5}
maximum emission coefficient (cm^{-1})	5.1×10^{-7}	

* Calculated under the assumption of $\Delta\nu = 15$ Mc /mmHg.

by using a rigid rotor approximation. There are also many b-type transitions in HCOOH which constitute three-level masers, but these were not used in our experiment, since the dipole moment along b-axis is very small in this molecule.

The other molecule which can be used for the present purpose is vinyl cyanide or acrylonitrile, CH_2CHCN, which has a large dipole moment of 3.89 Debye.[8] A preliminary observation of the spectrum showed that the lines were rather weaker and broader than expected probably due to the quadrupole hyperfine effects and low vibrational frequencies. Therefore, the three-level maser experiment has not yet been performed on this molecule.

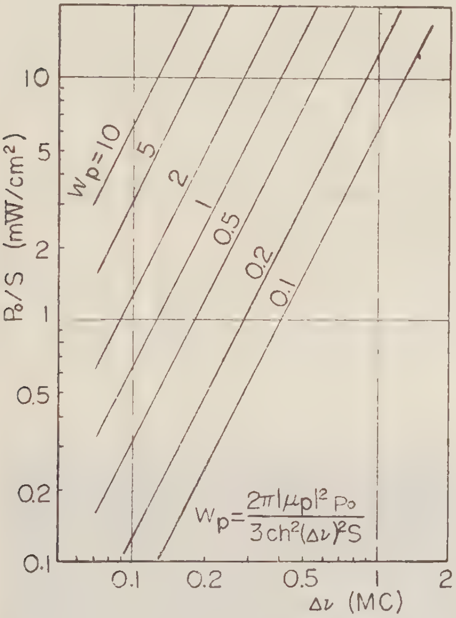

Fig. 2. Calculated pumping parameter, w_p, as a function of half line-width, $\Delta\nu$, and pumping power, P_0/S.

The emission coefficient, α_e, (negative absorption coefficient) is related to the effective Q value of the emission, Q_e, as

$$\frac{1}{Q_e}=\frac{\lambda\alpha_e}{2\pi},$$

where λ is the free space wavelength. If the gaseous materials are filled in a cavity whose loaded Q is Q_L, the self-sustained oscillation will occur, when $Q_L > -Q_e$. The realization of oscillation in the above three-level systems is hard, if not impossible in principle, because the required Q_L is nearly 10^6. Another levels or molecules should be considered for the purpose of oscillation or net amplification.

§ 3. Apparatus

The maser experiment on HCOOH molecule was performed by using a waveguide absorption cell which constitutes a travelling wave type maser. A block diagram of the whole experimental arrangement is shown in Fig. 3.

The absorption cell is made of 7000 Mc band waveguide of 3 meters in length, with the cross-section of 34.85 mm × 15.85 mm I.D. The signal frequency lies near the cut-off frequency of the fundamental TE_{10} mode. This results in an increase of the absorption coefficient of the signal line by a factor of about

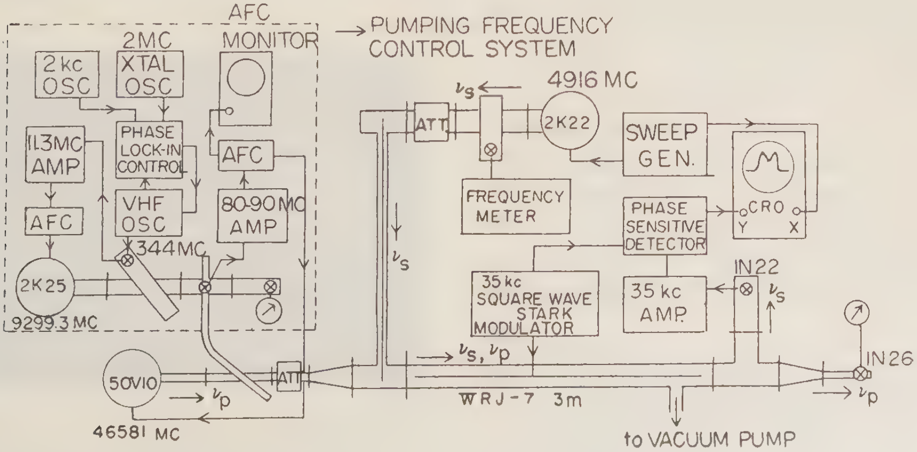

Fig. 3. Apparatus for the study of three-level maser action in HCOOH.

2 compared with the value in the free space, although the waveguide loss also increases to some extent. A usual Stark septum was inserted for Stark modulation with a particular precaution against the attenuation of millimeter-wave pumping field due to supporting insulator. For the more effective pumping, a coaxial absorption cell of much smaller cross-sectional area seemed to be preferable. Preliminary test of such a cell showed, however, excessive attenuation of the pumping field, and hence it was not used.

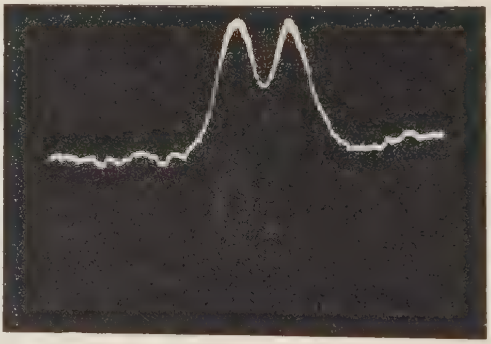
The weak signal power was supplied by a 2K22 klystron, and was introduced to the cell through a coaxial line feeder. The pumping power was supplied by a millimeter wave klystron 50V10 which yields maximum power of about 30 mW at the pumping frequency. In order to prevent the pumping power from entering the detector, the signal wave was separated from the pumping wave after passing through the cell by using a T-junction. The short millimeter-waves in an over-sized waveguide propagate nearly straight without detectable leakage in the side arm of a T-junction, while the long signal wave propagates into the side arm.

A square-wave Stark modulation at a frequency of 35 kc was employed to observe the signal line with good sensitivity. The undisplaced main line was used to observe three-level maser action. All the Stark components of the signal were pushed far away from the main line by a sufficiently strong Stark voltage of about 600 V to avoid a confusion, because after a phase sensitive detector the Stark component appears in the opposite sign to the main line and hence looks like an emission signal. The three-level maser action were observed and recorded on an oscilloscope screen by sweeping the signal frequency around its resonant value with fixed pumping frequency. A slow sweep of about 5 sec. period and corresponding large time constant at the output of the phase sensitive detector were used to attain a good signal-to-noise ratio.

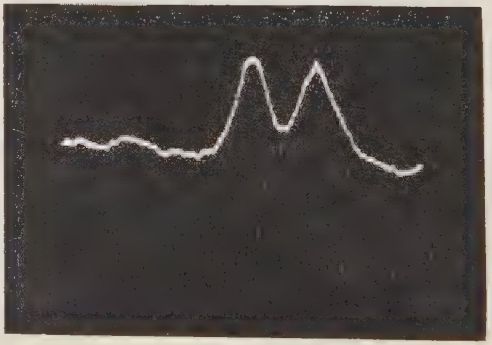
The most difficult work in the present experiment was the high stabilization of the frequency of pumping klystron near the resonant value. An automatic frequency control system using heterodyne method and phase lock-in method was adopted and worked well with the stability of about $10^{-6} \sim 10^{-7}$. This part is indicated in an enclosure of dotted line in Fig. 3. Using a 2 Mc crystal oscillator as a standard, a 2K25 klystron is stabilized at the frequency of 9299 Mc by the same method as used in the frequency control system of the ammonia frequency standard.[9] A beat signal between 50V10 and the stabilized 2K25 is then amplified by a receiver tunable in a range 80∼90 Mc, and the output of a frequency discriminator is fed back to control 50V10 klystron. The fine control and the measurement of the pumping frequency were carried out by controlling the tuning frequency of the above receiver with the AFC on.

§ 4. Experimental Results and Comparison with the Theory

In order that the pumping effect is large, the gas pressure must be low so that the line-width is narrow enough. The line-width is limited, however, by the broadening due to the wall collision and the Doppler effect.



(a)



(b)

Fig. 4. Typical patterns of the emission doublet in the three-level gas maser. The gas pressure in (b) is lower than in (a).

The wall collision width is calculated as 4.4 kc for the cell used, and the Doppler widths for signal and pumping are 4.5 kc and 43 kc, respectively. When the half-width of actual signal line becomes below about 100 kc, the intensity was found to decrease more rapidly than expected probably due to increasing impurity, and therefore most experiments were carried out with the line-width of above 100 kc.

Now, the three-level maser action was observed when the gas pressure is reduced below about 10^{-2} mm Hg with a pumping power of 30 mW. When the pumping frequency is resonant, the intensity of the absorption signal decreases initially, then the emission line appears and finally the line splits into a doublet. Typical patterns of the emission doublets are shown in Fig. 4. This may be interpreted as the resonant modulation effect which is one of the quantum mechanical effects in the three-level maser. For sufficiently strong pumping, the separation of two peaks is theoretically given by

$$2(\varDelta\nu)_m=\frac{|\bar{\mu}_p|\,E_p}{h}$$

where E_p is the peak electric field of the pumping radiation, and $\bar{\mu}_p$ the electric dipole matrix element along the direction of electric field for the pumping transition. In general, the separation is slightly dependent on the absorption line-width due to the effect of the interference between two peaks. The separations were measured for several values of absorption line-width, $\varDelta\nu$, with a nearly constant pumping power, and was compared with the theory. The result is shown in Fig. 5. The theoretical curve was calculated from Eq. (11) of Part I, using the values $P_0=30$ mW, $S=5.53$ cm², $|\mu_p|^2=1.00$ (Debye)², and $R=9.47$. The error of the effective pumping power was estimated to be about 30% considering the

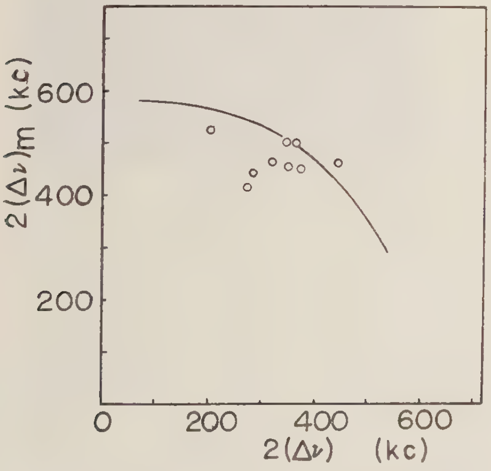


Fig. 5. Separation of two peaks in the emission doublet, $2(\varDelta\nu)_m$, as a function of absorption line width, $2(\varDelta\nu)$. The solid line is the calculated curve, and the open circles are the observed points.

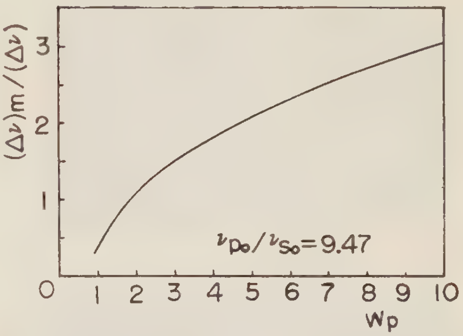

Fig. 6. Theoretical curve of $(\varDelta\nu)_m/(\varDelta\nu)$ versus pumping parameter, w_p.

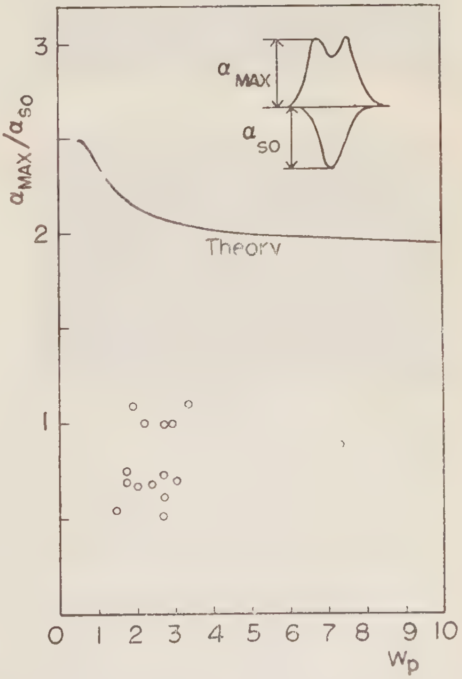

Fig. 7. Ratio of maximum emission and absorption intensities, $\alpha_{\max}/\alpha_{s0}$, as a function of pumping parameter, w_p. The solid line is the theoretical curve, and the open circles are the observed points.

effect of non-uniform field distribution and the accuracy of power measurement. In view of this, the agreement between observed and calculated values seems to be satisfactory. Then, the doublet separation may be used to determine the value of the pumping parameter, w_p, experimentally without detailed knowledge of the pumping power. A theoretical curve which determines the values of w_p from the observed values of $(\Delta\nu)_m/(\Delta\nu)$ is shown in Fig. 6. This curve and all other theoretical curves described below were derived numerically on the basis of Eq. (11) of Part I. The value of w_p was varied in the experiment mainly by the change of gas pressure. Fig. 7 shows observed and calculated values of the ratio of maximum emission and absorption intensities, $\alpha_{\max}/\alpha_{s0}$, as a function of w_p. It was found that the observed intensity of emission is about 1/2~1/3 times as large as the value expected from the theory. Fig. 8 shows observed and calculated values of the ratio of minimum and maximum emission intensities in a doublet structure of the emission line, $\alpha_{\min}/\alpha_{\max}$, as a function of w_p. The general tendency of the experimental results was found to agree with the theory, but it is noted that the observed values are slightly smaller than the calculated ones.

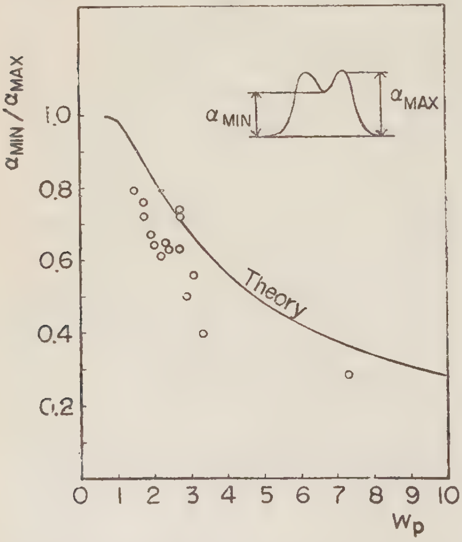

Fig. 8. Ratio of minimum and maximum intensities in a doublet structure of the emission line, $\alpha_{\min}/\alpha_{\max}$, as a function of pumping parameter, w_p. The solid line is the theoretical curve, and the open circles are the observed points.

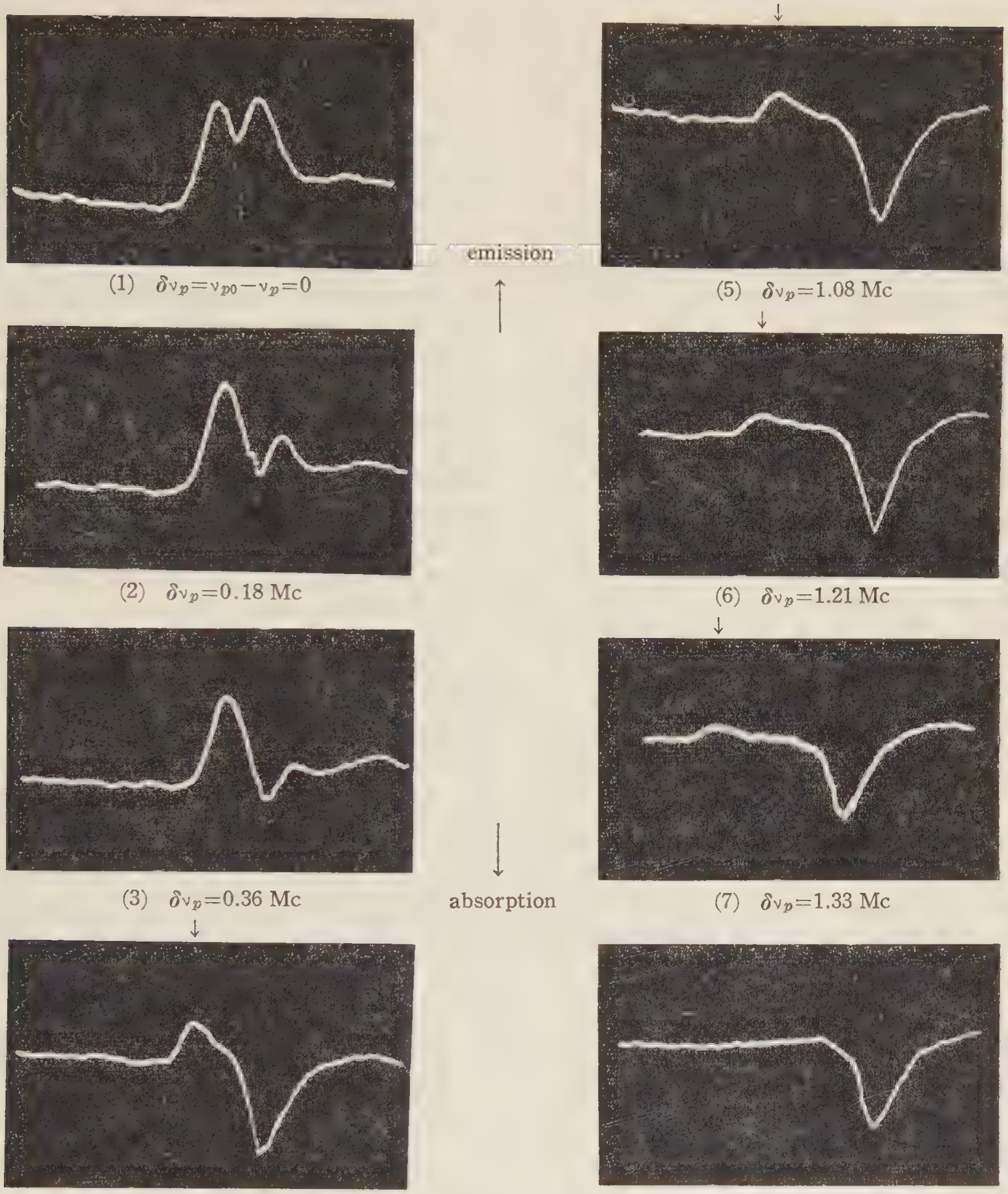
The line-shapes of the signal are studied in detail when the pumping frequency is shifted from the resonant value. Typical oscilloscope traces of a series of results are shown in Fig. 9, where each photograph corresponds to the different pumping frequency with the same pumping power and gas pressure. It is shown in Fig. 9 that, when the pumping frequency is shifted gradually from resonance, the frequency at the peak of emission doublet shifts and the peak intensity decreases. Finally, one of the peaks becomes a weak emission line separated entirely from the original absorption line. This is the induced emission due to double quantum transition associated with the three-level maser. The whole behavior agrees at least qualitatively with the calculated line-shapes as given in Fig. 3 of Part I. A number of series of such experiments were made, and the change of frequency and relative intensity of the emission peak as a function of pumping frequency are then compared with the theory more quantitatively. The results are shown in Fig. 10 and Fig. 11. The theoretical curves were calculated by the help of the curves such as given in Fig. 3 of Part I. Fig. 10 reveals that the frequency shift of the emission peak agrees well with the theory within the experimental accuracy, and that, when the pumping frequency is shifted sufficiently from resonance, it actually approaches to the following relation,

$$\nu_s-\nu_{so}=\nu_p-\nu_{po}\,,$$

where ν_s and ν_p are the signal and pumping frequencies, and ν_{so} and ν_{p0} are their resonant values. The agreement of general tendency between theory and experiment in Fig. 11 may also be recognized, although the accuracy of the measurement of intensity is rather poor because of the circuit charactor. However, one finds a discrepancy that a distinct maximum occurs in the experimental curve while it is much smaller in the theory. The whole off-resonant behavior was also found to occur in the same way whether the pumping frequency is higher or lower than the resonant frequency, as expected from the theory.

§ 5. Discussion

It was shown by the experimental results described above that various quantum mechanical effects predicted from the theory can be realized in the three-level gas maser, and that



(1) $\delta\nu_p=\nu_{p0}-\nu_p=0$

(2) $\delta\nu_p=0.18$ Mc

(3) $\delta\nu_p=0.36$ Mc

(4) $\delta\nu_p=0.78$ Mc

(5) $\delta\nu_p=1.08$ Mc

(6) $\delta\nu_p=1.21$ Mc

(7) $\delta\nu_p=1.33$ Mc

(8) Original absorption line

Fig. 9. Signal lines of the three-level gas maser, when the pumping frequency is shifted from resonance. $\delta\nu_p$ is the deviation of pumping frequency from the resonant value. The vertical arrows in each figure indicate the emission lines due to double quantum transition separated from the original absorption line. The abscissa represents the signal frequency with the sweep range of about 3.5 Mc. The pumping power was kept at 30 mW.

the main characteristics agree with the theory well. There are, however, some discrepancies between theory and experiment which are summarized as follows.

(1) The observed intensity of the emission at resonance is about 1/2∼1/3 times as large as the value expected from the theory. (Fig. 7).

(2) The observed valley in the emission doublet is slightly deeper than that of the theory. (Fig. 8).

(3) A maximum occurs in the experimental curve of peak emission intensity versus pumping frequency. (Fig. 11).

Possible origins of these discrepancies will be discussed briefly in the following.

According to the theory described in Part I, the influence of the Doppler effect on the intensity and shape of the signal line may be neglected in the present case, since the Doppler-width for pumping frequency is 1/3~1/5 times as large as the total line-width.

A transient effect caused by a finite collision relaxation time will decrease the emission intensity, when the frequency of Stark modulation is not low enough. The amount of decrease by this effect is estimated as about 20% for the modulation frequency and gas pressures used.

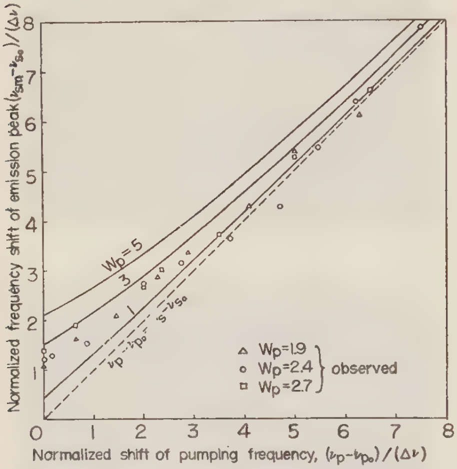


Fig. 10. Frequency shift of the emission peak as a function of pumping frequency. Solid lines are the theoretical results, and observed points are indicated by △, ○, □. The dotted line represents the relation, $\nu_s-\nu_{so}=\nu_p-\nu_{po}$.

$w_p=2\pi|\mu_p|^2P_0/[3ch^2(\Delta\nu)^2S]$

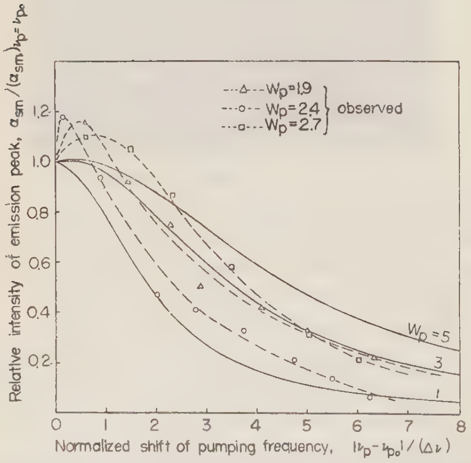

Fig. 11. Intensity of emission peak as a function of pumping frequency. Solid lines are the theoretical results, and dotted lines are the experimental results.

$w_p=2\pi|\mu_p|^2P_0/[3ch^2(\Delta\nu)^2S]$

The main part of the above discrepancies may be attributed to the effect of spatial inhomogeneity of the pumping radiation field. The inhomogeneity arises from the standing wave formation in both transverse and longitudinal directions of the waveguide and from the attenuation of pumping field along the cell. If a considerable region of weak field occurs by this effect, a residual absorption will overlap the emission spectrum. All the discrepancies indicated above may be explained by this mechanism at least qualitatively. However, correct estimation of the effect is difficult because a complicated field distribution is expected due to multimode transmission of the pumping wave in an over-sized waveguide absorption cell.

The degeneracy of each rotational level by a magnetic quantum number M will also contributes to the above discrepancies as has been pointed out in § 3 of Part I. This effect is somewhat analogous to the inhomogeneous field effect in the sense that different transition probabilities associated with different Stark or Zeeman components result in an "inhomogeneous" pumping action.

For complete account of the above effects,

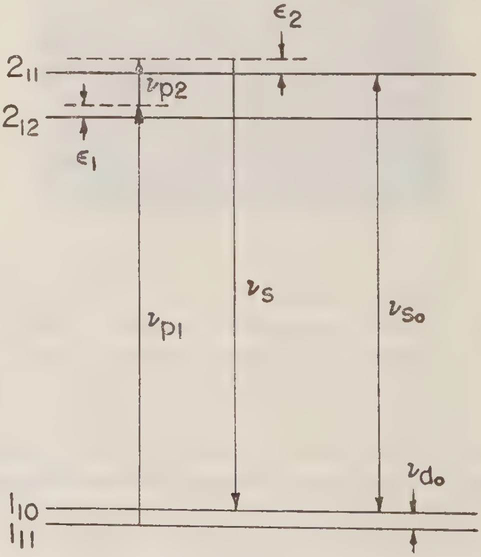

Fig. 12. A four-level system involving triple quantum transition. Induced emission at the frequency ν_s can be obtained by the two pumping radiations of the frequencies ν_{p1} and ν_{p2}.

more refined experiments and theoretical considerations will be necessary.

§ 6. Application to Four-level System

An interesting application of the multiple quantum transition to four-level system is possible as pointed out in Part I. The principle can be illustrated by the same level system of HCOOH as used in the present experiment. Consider a four-level system as shown in Fig. 12, where a new level of 1_{11} participates in the action. Suppose that a weak radiation of the frequency ν_s, and two strong radiations of the frequencies, ν_{p1} and ν_{p2}, are applied to the system. The frequencies, ν_s, ν_{p1}, ν_{p2}, are assumed to be slightly off-resonant from the transition frequencies of $2_{11} \leftrightarrow 1_{10}$, $2_{12} \leftrightarrow 1_{11}$, $2_{11} \leftrightarrow 2_{12}$, respectively, and to satisfy the relation

$$\nu_{p1}+\nu_{p2}-\nu_s=\nu_{do},$$

where ν_{do} is the transition frequency of $1_{11} \leftrightarrow 1_{10}$. The frequency deviations, ε_1 and ε_1, from resonance are assumed to be much smaller than transition frequencies of the molecule.

Then the net induced emission at the frequency ν_s can be obtained for a normal state of populations as a result of triple quantum transition, in which the absorption of two photons, $h\nu_{p1}$ and $h\nu_{p2}$, and the emission of one photon, $h\nu_s$, occur simultaneously. This is a type of maser using the pumping frequency lower than that of signal. The intensity of the emission thus obtained can be calculated by the similar method as used in § 2 of Part I as

$$\alpha_s=-\alpha_{so}\frac{\nu_{do}}{\nu_{so}}\left[\frac{|\bar{\mu}_{p1}|^2\,|\bar{\mu}_{p2}|^2\,E_{p1}{}^2E_{p2}{}^2}{16\,h^4\varepsilon_1{}^2(\varepsilon_1-\varepsilon_2)^2}\right],$$

where α_{so} is the absorption coefficient at the frequency ν_{so} without pumping, $\bar{\mu}_{p1}$ and $\bar{\mu}_{p2}$ the dipole matrix elements of the pumping transitions, E_{p1} and E_{p2} the peak electric field intensities of the pumping radiations. Assuming that the value of the quantity in the square bracket can be increased to the order of unity, and using the values $\alpha_{so}=3.1\times10^{-5}$ cm^{-1}, $\nu_{do}=1639$ Mc, $\nu_{so}=46581$ Mc, then $|\alpha_s|$ amounts to $10^{-6}\sim10^{-7}$ cm^{-1}. This is of detectable intensity, though it is not enough for net amplification or oscillation. More intensive emission from this type of maser will be attained by the use of another molecular levels.

§ 7. Conclusion

The multiple quantum transitions and other phenomena in the gas masers studied here are the typical aspects of the nonlinear properties in the interaction between radiations and a molecular system. They extend the functions of the maser for both spectroscopic and other purposes such as generation, amplification and detection of radiations. The success of the present experiment on an emission spectrum at microwave frequency will open a way of studying and applying these phenomena at higher frequencies in the various fields of quantum electronics. The extremely strong radiations which can be produced by the infrared and optical masers will be quite useful for the study of the above mentioned phenomena at these higher frequencies.

Acknowledgement

The author would like to express his hearty thanks to Prof. K. Shimoda for his kind guidance and continued encouragement in the course of this work. He is also indebted to Mr. H. Takuma for his helpful advice on the experimental technique and to Mr. K. Takagi for his assistance in the measurement.

Plasma oscillations are considered under uniformly applied electric and magnetic fields. When the external field is so weak that the particle runaway is not yet appreciable and the drift motion between electrons and ions is regarded as quasi-stationary compared with the oscillation frequency and particle gyrations, the usual Laplace transform method can be approximately employed. The dispersion relation thus obtained describes the excitation of ion waves. Behaviors of these waves are discussed, their temporal developments being taken into account.

§ 1. Introduction

Plasma oscillations have been studied extensively both in the absence of external fields and in the presence of a static magnetic field. In these cases a stationary state independent of time has been taken and a time-dependent fluctuation has been treated as a perturbation which grows up under suitable conditions.

When an electrostatic field is applied to the plasma, electrons and ions begin to flow in opposite directions, resulting the so-called current-carrying plasma. It is well known that the mutual motion between electron and ion gases causes electrostatic oscillations, or ion plasma waves. Many works have been carried out concerning ion wave instabilities brought about under a constant relative drift motion[1)–6)].

There have been a few papers in which the relative velocity between electrons and ions varying with time by an applied electric field is taken into consideration. Such cases were discussed by Fried et al.[7)] in special situations and by Kovrizhnykh[8)] in the strong field limit where collisions are neglected. A general treatment of this problem, however, would be very complicated, because runaway and oscillatory phenomena arise simultaneously and are related with each other. It would be, therefore, of significance to provide a simpler treatment of the same problem before the particle runaway is developed remarkably. In fact, as will be seen later, the drift between electrons and ions that changes gradually with time due to the electric field would be regarded as quasi-stationary and hence oscillations would take place adiabatically, provided following two conditions are fulfilled:

a) The externally applied electric field is so weak that the velocity increment gained by an electron during one cycle of excited oscillation is very small compared to the mean thermal speed of electrons

b) The period of excited oscillations is much shorter than the mean collision time between electrons and ions.

Then it will be shown that results obtained on plasma oscillations in the absence of electric field can be applied formally in the presence of an electric field. Ion waves excited will be discussed at every stage of increasing drift velocity. Thus it will be possible to trace the temporal change of ion plasma waves under an external electric field.

§ 2. Fundamental Equations

We consider a uniform plasma composed of electrons and ions of one kind, extending to infinity under external electric and magnetic fields.

We take the Boltzmann-Vlasov equations for distribution functions of velocity of electrons and ions

$$\frac{\partial f_e}{\partial t}+\boldsymbol{v}\frac{\partial f_e}{\partial \boldsymbol{x}}-\frac{e}{m}(\boldsymbol{E}+\boldsymbol{v}\times\boldsymbol{B})\frac{\partial f_e}{\partial \boldsymbol{v}}=\left.\frac{\delta f_e}{\delta t}\right|_{\mathrm{coll}}, \tag{2.1}$$

$$\frac{\partial f_i}{\partial t}+\boldsymbol{v}\frac{\partial f_i}{\partial \boldsymbol{x}}+\frac{Ze}{M}(\boldsymbol{E}+\boldsymbol{v}\times\boldsymbol{B})\frac{\partial f_i}{\partial \boldsymbol{v}}=\left.\frac{\delta f_i}{\delta t}\right|_{\mathrm{coll}}, \tag{2.2}$$

where suffixes e and i refer, respectively, to electrons with mass m, charge $-e$ and ions with mass M, charge Ze. The long-range interaction between particles is included in the fluctuating part of the electric field $\boldsymbol{E}$, and the short-range interaction arising from encounters closer than the Debye radius is represented by the collision terms on the right. In this paper we will mainly discuss plasma oscillations, so that the fluctuating magnetic field produced by the fluctuating convection current and displacement current is neglected. Hence the Maxwell equations are reduced to the Poisson equation

$$\frac{\partial \boldsymbol{E}}{\partial \boldsymbol{x}}=\frac{e}{\varepsilon_0}\int(Zf_i-f_e)d\boldsymbol{v}\,. \tag{2.3}$$

To solve these fundamental equations, the distribution functions and the electric field are Fourier-analysed in space as

$$f_j(\boldsymbol{v},\boldsymbol{x},t)=f_{j0}(\boldsymbol{v},t)+\int f_{jk}(\boldsymbol{v},t)e^{i\boldsymbol{k}\boldsymbol{x}}d\boldsymbol{k}\,,\qquad (j=e,\,i) \tag{2.4}$$

$$\boldsymbol{E}(\boldsymbol{x},t)=\boldsymbol{E}_0(t)+\int \boldsymbol{E}_k(t)e^{i\boldsymbol{k}\boldsymbol{x}}d\boldsymbol{k}\,, \tag{2.5}$$

where $\boldsymbol{E}_0(t)$ is the uniformly applied electric field.

The uniform parts of (2.1) and (2.2) are now given by

$$\frac{\partial f_{e0}}{\partial t}-\frac{e}{m}(\boldsymbol{E}_0+\boldsymbol{v}\times\boldsymbol{B}_0)\frac{\partial f_{e0}}{\partial \boldsymbol{v}}-\frac{e}{m}\int \boldsymbol{E}_k\frac{\partial f_{ek}}{\partial \boldsymbol{v}}d\boldsymbol{k}=\left.\frac{\delta f_{e0}}{\delta t}\right|_{\mathrm{coll}}, \tag{2.6}$$

$$\frac{\partial f_{i0}}{\partial t}+\frac{Ze}{M}(\boldsymbol{E}_0+\boldsymbol{v}\times\boldsymbol{B}_0)\frac{\partial f_{i0}}{\partial \boldsymbol{v}}+\frac{Ze}{M}\int \boldsymbol{E}_k\frac{\partial f_{ik}}{\partial \boldsymbol{v}}d\boldsymbol{k}=\left.\frac{\delta f_{ik}}{\delta t}\right|_{\mathrm{coll}}, \tag{2.7}$$

where the third terms on the left-hand side of both equations represent non-linear contributions which may be negligible in small amplitude oscillations. When the uniform electric field has a perpendicular component to the magnetic field and both fields are either static or varied slowly compared with plasma oscillations and particle gyrations, there occurs a flow of the plasma with a velocity $\boldsymbol{v}_D=(\boldsymbol{E}_0\times\boldsymbol{B}_0)/B_0^2$, which is perpendicular to both the electric and the magnetic fields. So far as the plasma oscillation is concerned, this drift merely causes the Doppler shift of oscillating frequency. We may therefore choose the electric field parallel to the magnetic field without loss of general feature of oscillations. (2.6) and (2.7) are thus simplified to the following equations:

$$\frac{\partial f_{e0}}{\partial t}-\frac{e}{m}E_0\frac{\partial f_{e0}}{\partial v_{/\!/}}+\omega_{ce}\frac{\partial f_{e0}}{\partial \varphi}=\left.\frac{\delta f_{e0}}{\delta t}\right|_{\mathrm{coll}},$$

$$\frac{\partial f_{i0}}{\partial t}+\frac{Ze}{M}E_0\frac{\partial f_{i0}}{\partial v_{/\!/}}-\omega_{ci}\frac{\partial f_{i0}}{\partial \varphi}=\left.\frac{\delta f_{i0}}{\delta t}\right|_{\mathrm{coll}},$$

where the velocity vector $\boldsymbol{v}$ is expressed by three components $(v_\perp\cos\varphi,\ v_\perp\sin\varphi,\ v_{/\!/})$, and $\omega_{ce}=eB_0/m$ and $\omega_{ci}=ZeB_0/M$ are the cyclotron frequencies of electrons and ions respectively. If we assume, furthermore, the cylindrical symmetry in velocity space, both $\partial f_{e0}/\partial\varphi$ and $\partial f_{i0}/\partial\varphi$ vanish. Then we get

$$\frac{\partial f_{e0}}{\partial t}-\frac{e}{m}E_0\frac{\partial f_{e0}}{\partial v_{/\!/}}=\left.\frac{\delta f_{e0}}{\delta t}\right|_{\mathrm{coll}}, \tag{2.8}$$

$$\frac{\partial f_{i0}}{\partial t}+\frac{Ze}{M}E_0\frac{\partial f_{i0}}{\partial v_{/\!/}}=\left.\frac{\delta f_{i0}}{\delta t}\right|_{\text{coll}}. \tag{2.9}$$

These equations describe the time variation of the uniform part of distribution functions under the uniformly applied electric field and are considered as basic equations for the so-called runaway phenomena.

In the extreme case of collisionless plasma, we obtain at once from (2.8) and (2.9)

$$f_{e0}=f_{e0}\left(v_\perp,\, v_{/\!/}+\frac{e}{m}\int^t E_0(t)dt\right),$$

$$f_{i0}=f_{i0}\left(v_\perp,\, v_{/\!/}-\frac{Ze}{M}\int^t E_0(t)dt\right).$$

If we have initially the Maxwellian distributions, we get displaced Maxwellian forms in which the mean velocity varies with time by the applied field; electrons and ions are accelerated in opposite directions, giving rise to an electric current in the plasma.

When collisions are introduced, electron-ion encounters randomize the directed motion imparted by the field, thus bringing about the Joule heating, electron-electron and ion-ion encounters, on the other hand, tend to make the respective velocity distribution of electrons and ions a Maxwellian form in a very short time because of much larger transfer of momentum between like particles. As is well known, however, in the case of strong field, all particles can be runaway and the Maxwellian form of particle distribution deforms appreciably almost in one electron-ion mean collision time[8]. In the case of weak field, a particle having a speed exceeding the mean random speeds of both electrons and ions must be runaway owing to the decreasing dynamical frictions for such a particle, and a particle slower than the mean random speed cannot enter the runaway state by the acceleration alone owing to the increasing dynamical friction with the particle speed, but can diffuse gradually into the runaway state by very close collisions and by the gradual decrease of the dynamical friction with the rise of electron temperature due to the Joule heating. Hence the distribution becomes non-Maxwellian in time even in the weak field.

For electrons we may employ the displaced Maxwellian distribution until νt becomes roughly $(E_c/E_0)^2$ when $(E_0/E_c)\lesssim 1$, where E_0 is assumed time-independent, ν the mean electron-ion collision frequency and E_c the critical field connected with ν as

$$\nu=\frac{eE_c}{mv_e}=\frac{\omega_e^4}{4\pi n_e v_e^3}\ln\Lambda\,,$$

where n_e=the electron number density, $\omega_e^2=n_e e^2/m\varepsilon_0$, $\Lambda=d/p$, d=the Debye length, and p=the minimum impact parameter.

For ions, we shall later neglect their drift velocity because of their large mass and we may therefore take the Maxwellian distribution. Then the displaced velocity $u(t)$ becomes the relative drift velocity between electron and ion gasses.

Neglecting the non-linear and collisional terms, we can describe the fluctuating parts of (2.1) and (2.2) as

$$\frac{\partial f_{ek}}{\partial t}+i\boldsymbol{k}\cdot\boldsymbol{v}f_{ek}-\frac{e}{m}(\boldsymbol{E}_0+\boldsymbol{v}\times\boldsymbol{B}_0)\frac{\partial f_{ek}}{\partial \boldsymbol{v}}-\frac{e}{m}\boldsymbol{E}_k\frac{\partial f_{e0}}{\partial \boldsymbol{v}}=0\,, \tag{2.10}$$

$$\frac{\partial f_{ik}}{\partial t}+i\boldsymbol{k}\cdot\boldsymbol{v}f_{ik}+\frac{Ze}{M}(\boldsymbol{E}_0+\boldsymbol{v}\times\boldsymbol{B}_0)\frac{\partial f_{ik}}{\partial \boldsymbol{v}}+\frac{Ze}{M}\boldsymbol{E}_k\frac{\partial f_{i0}}{\partial \boldsymbol{v}}=0\,. \tag{2.11}$$

When the electric field $\boldsymbol{E}_0$ is parallel to the magnetic field $\boldsymbol{B}_0$, (2.10) and (2.11) can be written as

$$\frac{\partial f_{ek}}{\partial t}+i\boldsymbol{k}\cdot\boldsymbol{v}f_{ek}-\frac{e}{m}E_0\frac{\partial f_{ek}}{\partial v_{/\!/}}+\omega_{ce}\frac{\partial f_{ek}}{\partial \varphi}-\frac{e}{m}\boldsymbol{E}_k\frac{\partial f_{e0}}{\partial \boldsymbol{v}}=0, \tag{2.12}$$

$$\frac{\partial f_{ik}}{\partial t}+i\boldsymbol{k}\cdot\boldsymbol{v}f_{ik}+\frac{Ze}{M}E_0\frac{\partial f_{ik}}{\partial v_{\parallel}}-\omega_{ci}\frac{\partial f_{ik}}{\partial\varphi}+\frac{Ze}{M}\boldsymbol{E}_k\frac{\partial f_{i0}}{\partial\boldsymbol{v}}=0\,. \tag{2.13}$$

For the electric field $\boldsymbol{E}_k$, we require the Poisson equation

$$i\boldsymbol{k}\cdot\boldsymbol{E}_k=\frac{e}{\varepsilon_0}\int(Zf_{ik}-f_{ek})d\boldsymbol{v}\,. \tag{2.14}$$

By use of three equations (2.12)-(2.14), oscillation phenomena will be discussed in the following section.

§ 3. Derivation of the Dispersion Relation

In the usual problem of plasma oscillations, the uniform distribution functions f_{e0} and f_{i0} are independent of time and we can solve the equations by the Laplace transform method. In the presence of an electric field, on the contrary, f_{e0} and f_{i0} become time-dependent and we cannot directly adopt a similar method as before. For a weak field, however, it is likely that f_{e0} and f_{i0} are so slowly varying functions of time as compared with oscillating frequencies that they may be regarded as quasi-stationary. Oscillations will take place adiabatically under the circumstance determined by f_{e0} and f_{i0} changing with time. Thus we may put

$$\frac{1}{f_{e0}}\frac{\partial f_{e0}}{\partial t}\ll\omega \quad\text{and}\quad \frac{1}{f_{i0}}\frac{\partial f_{i0}}{\partial t}\ll\omega\,, \tag{3.1}$$

where ω is the angular frequency of oscillation. If (3.1) holds, it would be reasonable to replace f_{e0} and f_{i0} by time-dependent functions in a dispersion relation, which is obtained by considering f_{e0} and f_{i0} as time-independent and by employing the usual Laplace transformation. The dispersion relation so obtained will describe characteristics of the oscillation in an approximate way.

Now we suppose that $f_{e0}(\boldsymbol{v}, t)$ and $f_{i0}(\boldsymbol{v}, t)$ satisfy the relation (3.1), these functions thus being regarded time-independent for the present in solving the equations (2.12)-(2.14). So far as the form of the dispersion relation is concerned, the Laplace transform method is equivalent to taking all the oscillating quantities with a time factor of $\exp(-i\omega t)$. Hence we get from (2.12)

$$\frac{\partial f_{ek}}{\partial\varphi}-\frac{eE_0}{m\omega_{ce}}\frac{\partial f_{ek}}{\partial v_{\parallel}}-\frac{i}{\omega_{ce}}(\omega-k_{\parallel}v_{\parallel}-k_{\perp}v_{\perp}\cos\varphi)f_{ek}=\frac{e}{m\omega_{ce}}\boldsymbol{E}_k\frac{\partial f_{e0}}{\partial\boldsymbol{v}}\,. \tag{3.2}$$

To get a solution as a power series in a parameter proportional to E_0, we write the zeroth approximation of f_{ek} as[9]

$$f_{ek}^{(0)}=\int_{-\infty}^{\varphi}G_e(\omega, \varphi, \varphi')\frac{e}{m\omega_{ce}}\boldsymbol{E}_k\frac{\partial f_{e0}}{\partial\boldsymbol{v}'}d\varphi'\,, \tag{3.3}$$

where $\boldsymbol{v}'=(v_{\perp}\cos\varphi', v_{\perp}\sin\varphi', v_{\parallel})$, $Im(\omega)>0$ and

$$G_e(\omega, \varphi, \varphi')=\exp\left[\frac{i}{\omega_{ce}}\{(\omega-k_{\parallel}v_{\parallel})(\varphi-\varphi')-k_{\perp}v_{\perp}(\sin\varphi-\sin\varphi')\}\right]. \tag{3.4}$$

By virtue of (3.3), the equation (3.2) becomes, to the first approximation of f_{ek},

$$\frac{\partial f_{ek}^{(1)}}{\partial\varphi}-\frac{i}{\omega_{ce}}(\omega-k_{\parallel}v_{\parallel}-k_{\perp}v_{\perp}\cos\varphi)f_{ek}^{(1)}=\frac{e}{m\omega_{ce}}\left(\boldsymbol{E}_k\frac{\partial f_{e0}}{\partial\boldsymbol{v}}+E_0\frac{\partial f_{ek}^{(0)}}{\partial v_{\parallel}}\right). \tag{3.5}$$

This gives

$$f_{ek}^{(1)}=-\frac{ie}{m\omega_{ce}}\int_{-\infty}^{\varphi}G_e(\omega, \varphi, \varphi')\left[\boldsymbol{k}\frac{\partial f_{e0}}{\partial\boldsymbol{v}'}+\frac{eE_0}{m}\frac{\partial}{\partial v_{\parallel}}\int_{-\infty}^{\varphi'}G_e(\omega, \varphi', \varphi'')\boldsymbol{k}\frac{\partial f_{e0}}{\partial\boldsymbol{v}''}\,d\varphi''\right]d\varphi'\psi_k\,, \tag{3.6}$$

where the electric field is expressed by the electric potential as $E_k=-ik\psi_k$ and $\boldsymbol{v}''=(v_\perp\cos\varphi'', v_\perp\sin\varphi', v_{/\!/})$.

Similarly, we obtain from (2.13) the ion component to the same approximation

$$f_{ik}^{(1)}=-\frac{iZe}{M\omega_{ci}}\int_{-\infty}^{\varphi}G_i(\omega,\varphi,\varphi')\left[\boldsymbol{k}\frac{\partial f_{i0}}{\partial\boldsymbol{v}'}-\frac{ZeE_0}{M}\frac{\partial}{\partial v_{/\!/}}\int_{-\infty}^{\varphi'}G_i(\omega,\varphi',\varphi'')\boldsymbol{k}\frac{\partial f_{i0}}{\partial\boldsymbol{v}''}\,d\varphi''\right]d\varphi'\psi_k\,, \tag{3.7}$$

where

$$G_i(\omega,\varphi,\varphi')=\exp\left[-\frac{i}{\omega_{ci}}\{(\omega-k_{/\!/}v_{/\!/})(\varphi-\varphi')-k_\perp v_\perp(\sin\varphi-\sin\varphi')\}\right]. \tag{3.8}$$

(3.6) and (3.7) are inserted into the Poisson equation (2.14), which yields the dispersion relation to this approximation

$$\begin{aligned}D(\boldsymbol{k},\omega)=k^2-i\Bigg[&\frac{e^2}{m\varepsilon_0\omega_{ce}}\int d\boldsymbol{v}\int_{-\infty}^{\varphi}G_e(\omega,\varphi,\varphi')\left\{\boldsymbol{k}\frac{\partial f_{e0}}{\partial\boldsymbol{v}'}+\frac{eE_0}{m\omega_{ce}}\frac{\partial}{\partial v_{/\!/}}\int_{-\infty}^{\varphi'}G_e(\omega,\varphi',\varphi'')\boldsymbol{k}\frac{\partial f_{e0}}{\partial\boldsymbol{v}''}\,d\varphi''\right\}d\varphi'\\&-\frac{(Ze)^2}{M\varepsilon_0\omega_{ci}}\int d\boldsymbol{v}\int_{-\infty}^{\varphi}G_i(\omega,\varphi,\varphi')\left\{\boldsymbol{k}\frac{\partial f_{i0}}{\partial\boldsymbol{v}'}+\frac{ZeE_0}{M\omega_{ci}}\frac{\partial}{\partial v_{/\!/}}\int_{-\infty}^{\varphi''}G_i(\omega,\varphi',\varphi'')\boldsymbol{k}\frac{\partial f_{i0}}{\partial\boldsymbol{v}''}\,d\varphi''\right\}d\varphi'\Bigg]=0\,.\end{aligned} \tag{3.9}$$

The Laplace transform method leads the identical relation with (3.9). One should note that this relation is valid only for $Im(\omega)>0$. After making use of some formulas of integrals and recurrence formulas of the Bessel functions, we can rewrite (3.9) in the form valid over the whole region of complex ω plane. Then we get

$$\begin{aligned}1+2\pi\sum_{l=-\infty}^{\infty}\Bigg[&\frac{1}{n_e}\left(\frac{\omega_e}{k}\right)^2\int_{C_{el}}\frac{dv_{/\!/}}{\omega-k_{/\!/}v_{/\!/}-l\omega_{ce}}\left\{1-\frac{ieE_0k_{/\!/}}{m(\omega-k_{/\!/}v_{/\!/}-l\omega_{ce})^2}\right\}\\&\qquad\times\int_0^\infty\left(k_{/\!/}\frac{\partial f_{e0}}{\partial v_{/\!/}}+\frac{l\omega_{ce}}{v_\perp}\frac{\partial f_{e0}}{\partial v_\perp}\right)J_l^2\left(\frac{k_\perp v_\perp}{\omega_{ce}}\right)v_\perp dv_\perp\\&+\frac{1}{n_i}\left(\frac{\omega_i}{k}\right)^2\int_{C_{il}}\frac{dv_{/\!/}}{\omega-k_{/\!/}v_{/\!/}+l\omega_{ci}}\left\{1+\frac{iZeE_0k_{/\!/}}{M(\omega-k_{/\!/}v_{/\!/}+l\omega_{ci})^2}\right\}\\&\qquad\times\int_0^\infty\left(k_{/\!/}\frac{\partial f_{i0}}{\partial v_{/\!/}}-\frac{l\omega_{ci}}{v_\perp}\frac{\partial f_{i0}}{\partial v_\perp}\right)J_l^2\left(\frac{k_\perp v_\perp}{\omega_{ci}}\right)v_\perp dv_\perp\Bigg]=0\,.\end{aligned} \tag{3.10}$$

Here n_i=the ion number density, $\omega_i=n_i(Ze)^2/M\varepsilon_0$; the contour C_{el} and C_{il} are chosen so as to go from negative infinity to positive infinity on the real axis, passing the lower side of all singularities of the integrand on the complex $v_{/\!/}$ plane. Instability of the oscillation will arise, in particular, when (3.10) has a solution for $I_m(\omega)>0$.

When the distribution functions are separable with respect to variables, they can be written as

$$f_{e0}(\boldsymbol{v})=n_eg_{e\perp}(v_\perp)g_{e/\!/}(v_{/\!/});\ \ f_{i0}(\boldsymbol{v})=n_ig_{i\perp}(v_\perp)g_{i/\!/}(v_{/\!/})\,. \tag{3.11}$$

Then (3.10) becomes

$$\begin{aligned}1+2\pi\sum_{l=-\infty}^{\infty}\Bigg[&\left(\frac{\omega_e}{k}\right)^2\int_{C_{el}}\frac{dv_{/\!/}}{\omega-k_{/\!/}v_{/\!/}-l\omega_{ce}}\left\{1-\frac{ieE_0k_{/\!/}}{m(\omega-k_{/\!/}v_{/\!/}-l\omega_{ce})^2}\right\}\\&\qquad\times\left\{k_{/\!/}\frac{dg_{e/\!/}}{dv_{/\!/}}\int_0^\infty g_{e\perp}J_l^2\left(\frac{k_\perp v_\perp}{\omega_{ce}}\right)v_\perp dv_\perp+l\omega_{ce}g_{e/\!/}\int_0^\infty\frac{dg_{e\perp}}{dv_\perp}J_l^2\left(\frac{k_{/\!/}v_{/\!/}}{\omega_{ce}}\right)dv_\perp\right\}\\&+\left(\frac{\omega_i}{k}\right)^2\int_{C_{il}}\frac{dv_{/\!/}}{\omega-k_{/\!/}v_{/\!/}+l\omega_{ci}}\left\{1+\frac{iZeE_0k_{/\!/}}{M(\omega-k_{/\!/}v_{/\!/}+l\omega_{ci})^2}\right\}\\&\qquad\times\left\{k_{/\!/}\frac{dg_{i/\!/}}{dv_{/\!/}}\int^\infty g_{i\perp}J_l^2\left(\frac{k_\perp v_\perp}{\omega_{ci}}\right)v_\perp dv_\perp-l\omega_{ci}g_{i/\!/}\int_0^\infty\frac{dg_{i\perp}}{dv_\perp}J_l^2\left(\frac{k_\perp v_\perp}{\omega_{ci}}\right)dv_\perp\right\}\Bigg]=0\,.\end{aligned} \tag{3.12}$$

The dispersion relation (3.10) or (3.12) has been derived under the assumption that the distribution functions are stationary. If the distribution functions change with time in accordance with the condition (3.1), the dispersion relation we are looking for is given by simply considering f_{e0} and f_{i0} as time-varying. Then the relation between the complex frequency and the wave vector obtained from the dispersion relation becomes also slowly varying with time.

We shall next specify the distribution functions to investigate the more realistic case. As was discussed in the last section, it may be allowed to take the distribution functions as Maxwellian before the particle runaway becomes remarkable. Hence in (3.12) we put

$$g_{e\perp}(v_\perp)=\frac{1}{\pi v_e^2}\exp\left[-\left(\frac{v_\perp}{v_e}\right)^2\right], \qquad g_{e\parallel}(v_\parallel, t)=\frac{1}{\sqrt{\pi}\, v_e}\exp\left[-\left\{\frac{v_\parallel-u(t)}{v_e}\right\}^2\right], \tag{3.13}$$

$$g_{i\perp}(v_\perp)=\frac{1}{\pi v_i^2}\exp\left[-\left(\frac{v_\perp}{v_i}\right)^2\right], \qquad g_{i\parallel}(v_\parallel)=\frac{1}{\sqrt{\pi}\, v_i}\exp\left[-\left(\frac{v_\parallel}{v_i}\right)^2\right], \tag{3.14}$$

where $u(t)$ denotes the relative drift speed between electron and ion gases, $v_e=(2\kappa T_e/m)^{1/2}$ and $v_i=(2\kappa T_i/M)^{1/2}$, T_e and T_i, temperatures of electrons and ions respectively, being also functions of time because of Joule heating. If the electrons flow in the positive direction, or $u(t)>0$, the electric field must be in the negative direction and therefore $E_0=-|E_0|$. (3.12) becomes

$$\begin{aligned}1+2\sum_{l=-\infty}^{\infty}\Bigg[&\left(\frac{\omega_e}{kv_e}\right)^2\exp\left\{-\frac{1}{2}\left(\frac{k_\perp v_e}{\omega_{ce}}\right)^2\right\} I_{|l|}\left(\frac{k_\perp{}^2 v_e{}^2}{2\omega_{ce}{}^2}\right)\\ &\times\left\{1+i\left(\sqrt{\pi}\,\Omega_{e0}\exp(-\Omega_{el}{}^2)[1+\Phi(i\Omega_{el})]+\frac{2e|E_0|}{mk_\parallel v_e{}^2}[1+Q_{el}(k_\parallel, \omega)]\right)\right\}\\ &+\left(\frac{\omega_i}{kv_i}\right)^2\exp\left\{-\frac{1}{2}\left(\frac{k_\perp v_i}{\omega_{ci}}\right)^2\right\} I_{|l|}\left(\frac{k_\perp{}^2 v_i{}^2}{2\omega_{ci}{}^2}\right)\\ &\times\{1+i\sqrt{\pi}\,\Omega_{i0}\exp(-\Omega_{il}{}^2)[1+\Phi(i\Omega_{il})]\}\Bigg]=0\,,\end{aligned} \tag{3.15}$$

where

$$\left.\begin{aligned}Q_{el}(k_\parallel, \omega)=&-\Omega_{e0}\Omega_{el}+i\frac{\sqrt{\pi}}{2}\left\{\Omega_{el}(3-2\Omega_{el}{}^2)+\frac{l\omega_{ce}}{k_\parallel v_e}(1-2\Omega_{el})\right\}\\ &\times\exp(-\Omega_{el}{}^2)[1+\Phi(i\Omega_{el})]\,,\\ \Omega_{el}=&\frac{(\omega-k_\parallel v_\parallel-l\omega_{ce})}{k_\parallel v_e}\,,\\ \Omega_{il}=&\frac{(\omega+l\omega_{ci})}{k_\parallel v_i}\,,\\ \Phi(x)=&\frac{2}{\sqrt{\pi}}\int_0^x e^{-t^2}dt\,.\end{aligned}\right\} \tag{3.16}$$

§4. Ion Plasma Oscillation

In this section we discuss in detail the plasma oscillation which is excited by the mutual drifting motion between electron and ion gases and is characterized by the dispersion relation (3.15).

Let us consider the case in which the dispersion relation (3.15) is reduced to a simpler form. One of such cases is realized by assuming

$$\left.\begin{aligned}&\text{a)}\ \ |\omega-k_\parallel u|/k_\parallel v_e\ll 1\,, \qquad &&\text{b)}\ \ |\omega|/k_\parallel v_i\gg 1\,,\\ &\text{c)}\ \ k_\perp v_e/\omega_{ce}\ll 1\,, &&\text{d)}\ \ k_\perp v_i/\omega_{ci}\ll 1\,.\end{aligned}\right\} \tag{4.1}$$

The assumptions (4.1) imply that a) the phase velocity of the wave parallel to the magnetic field is much slower than the electron thermal velocity v_e as seen by drifting electrons, while b) it is faster than the ion thermal velocity; c) and d) represent that the wave-length of the wave component perpendicular to the magnetic field is much greater than the gyration radius of electrons and ions, since $k_\perp$ is inversely proportional to the wavelength and v_e/ω_{ce} or v_i/ω_{ci} is the gyration radius of electrons or ions respectively.

In this approximation (3.15) becomes

$$1+2\left(\frac{\omega_e}{kv_e}\right)^2\left(1+i\sqrt{\pi}\frac{\omega-k_{\parallel}u}{k_{\parallel}v_e}+\frac{ie|E_0|}{2mk_{\parallel}v_e^2}\right)-\left(\frac{\omega_i}{kv_i}\right)^2\left\{\left(\frac{k_{\parallel}v_i}{\omega}\right)^2-\frac{1}{2}\left(\frac{k_\perp v_i}{\omega_{ci}}\right)^2\right\}=0\,.$$

From this we find

$$\left(\frac{\omega}{\omega_i}\right)^2=(k_{\parallel}\lambda_e)^2\left[1+(k\lambda_e)^2+\frac{ZT_e}{2T_i}(k_\perp R_i)^2-i\sqrt{\pi}\left\{\frac{u}{v_e}-\frac{\omega}{k_{\parallel}v_e}\left(1+\frac{e|E_0|}{2\sqrt{\pi}\,m\omega v_e}\right)\right\}\right]^{-1}, \tag{4.2}$$

where $\lambda_e=v_e/\sqrt{2}\,\omega_e$ and $R_i=v_i/\sqrt{2}\,\omega_{ci}$. If the electric field E_0 is so weak that the velocity increment of an electron during one cycle of oscillation is much smaller than the thermal velocity of electrons, we can put

$$\left|\frac{eE_0}{mv_e\omega}\right|\ll 1. \tag{4.3}$$

This has a relation with (3.1), which will be examined in the last section. When (4.3) is satisfied, the last term in the last bracket of the denominator of (4.2) can be neglected. Taking into account of the first inequality a) in (4.1), we get from (4.2)

$$\frac{\omega}{\omega_i}=\frac{\pm k_{\parallel}\lambda_e}{[1+(k\lambda_e)^2+(ZT_e/2T_i)(k_\perp R_i)^2]^{1/2}}\left[1+\frac{i\sqrt{\pi}}{2}\frac{\{(u/v_e)-(\omega/k_{\parallel}v_e)\}}{\{(1+(k\lambda_e)^2+(ZT_e/2T_i)(k_\perp R_i)^2\}}\right]. \tag{4.4}$$

Thus writing $\omega=\omega_0+i\gamma$ and neglecting higher order terms, we have

$$\frac{\omega_0}{\omega_i}=\frac{k_{\parallel}\lambda_e}{[1+(k\lambda_e)^2+(ZT_e/2T_i)(k_\perp R_i)^2]^{1/2}}\,, \tag{4.5}$$

$$\frac{\gamma}{\omega_i}=\frac{\sqrt{\pi}\,k_{\parallel}\lambda_e}{2[1+(k\lambda_e)^2+(ZT_e/2T_i)(k_\perp R_i)^2]^{3/2}}\left[\frac{u}{v_e}-\frac{(m/2M)^{1/2}}{\{1+(k\lambda_e)^2+(ZT_e/2T_i)(k_\perp R_i)^2\}}\right], \tag{4.6}$$

where only the positive root is retained by the physical reasoning that the wave velocity must be positive for $u(t)>0$. This is formally the same results as that obtained by Bernstein et al[4], except that the electron drift velocity and the temperatures of electrons and ions are supposed time-varying in our case.

It should be noted that (4.4) must be consistent with b) in (4.1). Hence we obtain from (4.4)

$$\left|\frac{\omega}{k_{\parallel}v_i}\right|\approx\frac{(T_e/2T_i)^{1/2}}{[1+(k\lambda_e)^2+(ZT_e/2T_i)(k_\perp R_i)^2]^{1/2}}\gg 1\,. \tag{4.7}$$

It is clear from this that

$$(T_e/T_i)^{1/2}\gg 1 \tag{4.8}$$

is necessary for such approximations. When the ion temperature is finite to the extent that (4.8) holds, the inequality (4.7) becomes invalid for too large value of $k\lambda_e$; in fact the accurate calculation shows that the system becomes stable for $k\lambda_e$ greater than some critical value[2),3)]. On the other hand, in the limit of zero temperature of ions (4.7) is valid for all values of $k\lambda_e$, exhibiting the existence of excited oscillations for any wave number.

When the wave vector is not parallel to the magnetic field and makes the angle θ with it, we can put $k_{\parallel}=k\cos\theta$ and $k_\perp=k\sin\theta$. We see from (4.5) and (4.6) that the wave do not propagate in the direction perpendicular to the magnetic field and that the frequency and the growth rate are nearly proportional to $\cos\theta$.

We consider for the present an extreme

case in which $T_e/T_i \to \infty$ and $k_\perp \to 0$, that is, the ion temperature is negligible compared to the electron temperature and the wave propagates in the direction of magnetic field. Then the frequency of the oscillation becomes

$$\omega_0 \approx \begin{cases} kv_e(m/2M)^{1/2} & \text{for} \quad k\lambda_e \ll 1\,, \\ \omega_i & \text{for} \quad k\lambda_e \gg 1\,. \end{cases} \tag{4.9}$$

This means that the excited wave is the so-called ion waves. The instability condition is that the growth rate γ becomes positive, namely from (4.6)

$$\frac{u}{v_e} > \frac{(m/2M)^{1/2}}{[1+(k\lambda_e)^2]^{1/2}}\,. \tag{4.10}$$

If u is smaller than $v_e(m/2M)^{1/2}$, the wave corresponding to $k\lambda_e > [(v_e/u)(m/2M)^{1/2}-1]$ becomes unstable and the wave in the range $0 < k\lambda_e < [(v_e/u)(m/2M)^{1/2}-1]$ is stable. If u becomes greater than $v_e(m/2M)^{1/2}$, then the waves for all k are unstable. The maximum growth rate lies $k\lambda_e \approx \sqrt{2}\,y$ for $y \equiv (v_e/u)(m/2M)^{1/2} \gtrsim 1$ and near $k\lambda_e \approx 1/\sqrt{2}$ for $y \ll 1$. Since we find $|\omega|/kv_e \lesssim (m/2M)^{1/2} \ll 1$ from (4.4), the condition a) in (4.1) is fulfilled when u/v_e is much smaller than unity. Features of oscillation in this range are shown in Fig. 1.

When u/v_e becomes comparable with unity, a) in (4.1) must be replaced by

$$|\omega - ku|/kv_e \lesssim 1\,. \tag{4.1}$$

Keeping other conditions b), c) and d) in (4.1) unaltered, we find, instead of (4.2), in the limit of $k_\perp \to 0$ or $k_{/\!/} \to k$,

$$\left(\frac{\omega}{\omega_i}\right)^2 = \frac{(k\lambda_e)^2}{(k\lambda_e)^2 + G(z)}\,, \tag{4.12}$$

where $G(z) = 1 + i\sqrt{\pi}\,ze^{-z^2}[1+\Phi(iz)]$, $z = (\omega - ku)/kv_e$. When $|z| \sim 1$ as seen in (4.11), we get $|G(z)| \sim 1$. From (4.12) we have also in this case,

$$\left|\frac{\omega}{kv_e}\right| \lesssim \left(\frac{m}{2M}\right)^{1/2}, \tag{4.13}$$

for any $k\lambda_e$. Hence (4.11) gives

$$1 \gtrsim (u/v_e) \gg |\omega|/kv_e\,. \tag{4.14}$$

Therefore we may take approximately the variable z as real or $z = -(u/v_e)$, which gives easily the real and imaginary parts of $G(z)$ as

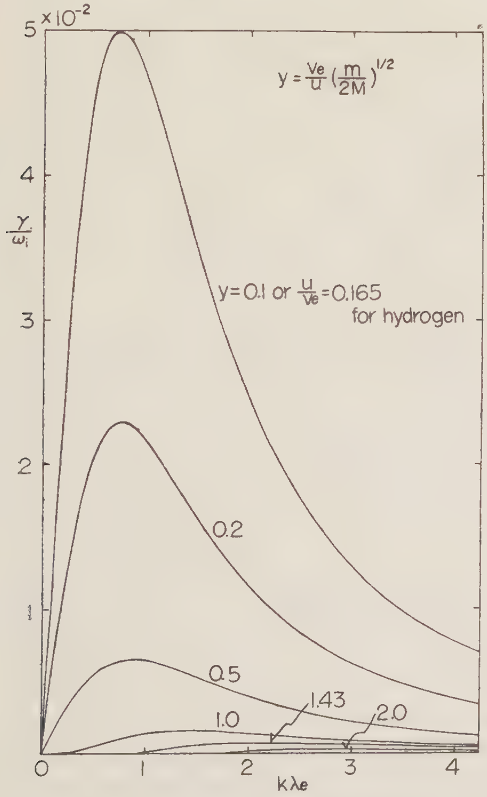

Fig. 1. The growth rate of ion wave propagating in the direction of magnetic field versus the wave number when $u/v_e \ll 1$.

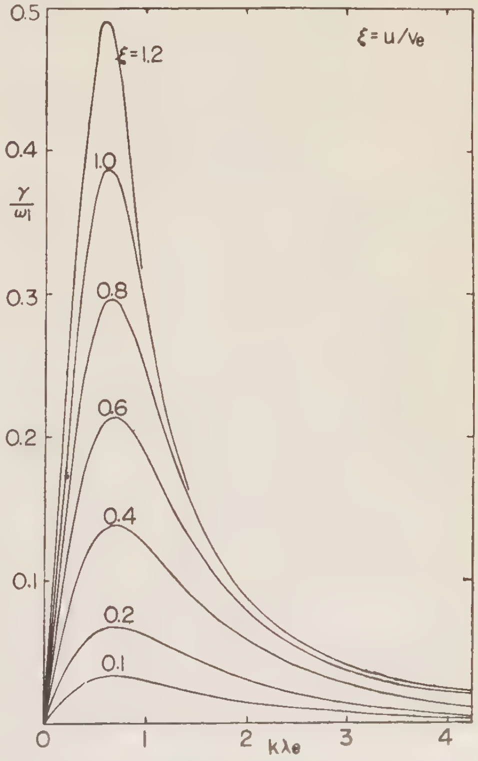

Fig. 2. The growth rate of ion wave propagating in the direction of magnetic field versus the wave number when $1 \gtrsim u/v_e$.

$$ReG(z)=1-2\xi w(\xi)\ ,$$
$$ImG(z)=-\sqrt{\pi}\,\xi e^{-\xi^2}\ ,$$

where $\xi\equiv u/v_e$, $w(\xi)=-i(\sqrt{\pi}/2)e^{-\xi^2}\Phi(i\xi)=e^{-\xi^2}\int_0^\xi e^{t^2}dt$ and its numerical table is available[11]. In terms of variables

$$a\equiv(k\lambda_e)^2+1-2\xi w(\xi)\ ,$$
$$b\equiv-\sqrt{\pi}\,\xi e^{-\xi^2}\ ,$$

we find from (4.12)

$$\frac{\omega_0}{\omega_i}=k\lambda_e\left(\frac{\sqrt{a^2+b^2}+a}{a^2+b^2}\right)^{1/2}, \qquad (4.15)$$

$$\frac{\gamma}{\omega_i}=k\lambda_e\left(\frac{\sqrt{a^2+b^2}-a}{a^2+b^2}\right)^{1/2}. \qquad (4.16)$$

When $b^2/a^2\ll1$, these are reduced to $\omega_0/\omega_i=k\lambda_e/(2a)^{1/2}$ and $\gamma/\omega_i=k\lambda_e/(2a)^{3/2}$ which coincide with (4.5) and (4.6) respectively. Figs. 2 and 3 are obtained for $1\gtrsim\xi\gg(m/M)^{1/2}$ by use of (4.15) and (4.16).

For $\xi>1$, the error caused by presuming z as real becomes remarkable with increasing ξ.

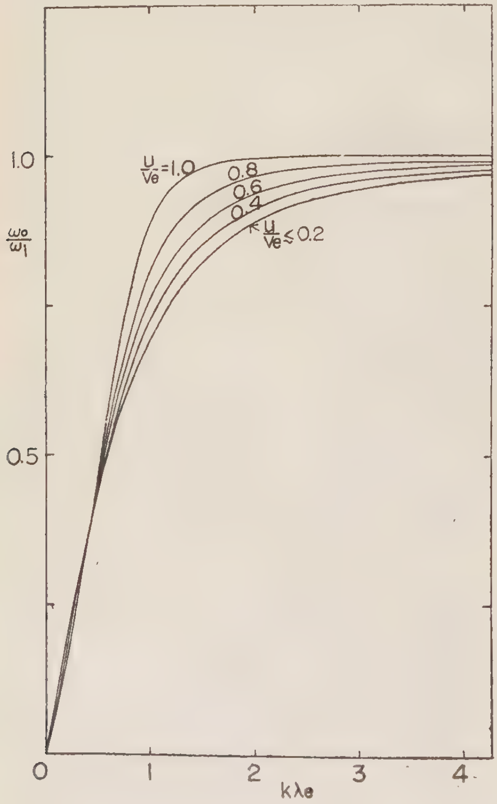

Fig. 3. The frequency of ion wave propagating in the direction of magnetic field versus the wave number when $1\geqq u/v_e$.

In the extreme case of $\xi\gg1$, we have $|z|\gg1$ and again a simple form of dispersion relation for a wave propagating parallel to the magnetic field

$$1=\left(\frac{\omega_e}{\omega-ku}\right)^2+\left(\frac{\omega_i}{\omega}\right)^2. \qquad (4.17)$$

This type of waves has been discussed in many papers. It is, however, quite analogous to the excitation of electron plasma waves by an injected electron beam. The system represented by (4.17) correspond to the system consisting of a medium plasma with a very low density n_p and a beam with a very high density n_b such that the ratio n_b/n_p is equal $(\omega_e/\omega_i)^2=M/Zm$. The detailed features of excited waves in such a system have been investigated by the present author[12]. But we are not interested in such details here, since runaway electrons deform the Maxwellian distribution in the region of large drift velocities. Then the electron distribution would have second maximum and hence electron plasma waves would be excited, the frequency of which is the order of magnitude of ω_e.

As shown above, in the limit of $T_e/T_i\rightarrow\infty$, even an infinitecimal drift velocity excites a wave with $k\rightarrow\infty$. When T_i becomes finite, the drift velocity must exceed some minimum value for instability, which increases with the ion temperature. In the case of $T_e/T_i\gtrsim1$, this minimum drift speed is about the mean thermal speed of electrons, $u\approx v_e$[2)-4)].

§ 5. Excitation of Ion Waves

Now we shall investigate behaviors of ion waves excited by an applied electric field. It was shown in the previous section that characteristics of ion waves are varied with the drift velocity. As the drift velocity increases with time, we find that the growth rate of ion wave rises gradually in time. The waves thus excited would have characteristics corresponding to $k\lambda_e\approx1/\sqrt{2}$ after some appreciable time, since the growth rate exhibits a maximum almost at that point. We know from Fig. 3 that the frequency of the wave is not sensitive to the drift velocity and is slightly below the ion-plasma frequency at $k\lambda_e\approx1/\sqrt{2}$. According to Dreicer[9], the drift velocity has been plotted against νt, the time normalized by the mean collision time. To make a rough estimation for $(E_0/E_c)^2\ll1$, the drift velocity u/v_e may be approximated as linearly proportional to νt. In addition, we see in Fig. 2 that the growth rate γ/ω_i at $k\lambda_e \approx 1/\sqrt{2}$ is nearly proportional to the drift velocity u/v_e. Thus we can assume γ/ω_i proportional to νt. For a given wave number k, we have the component of electric field

$$E_k(t) = E_k(0) \exp\left[\int^t \{\gamma_k(t) + i\omega_{0k}(t)\} dt\right] \quad (5.1)$$

where γ_k and ω_{0k} are obtained in Figs. 1–3. By the assumption just mentioned,

$$\gamma_k(t)/\omega_i \approx A(k)\nu t \, .$$

Hence

$$\int_0^t \gamma_k(t) dt = A(k)\frac{\omega_i}{\nu}\int_0^{\nu t} \nu t\, d(\nu t) = \frac{A(k)\omega_i}{2\nu}(vt)^2 \, .$$

The electric field is written as

$$E(z,\,t) = \int E_k(0) \exp\left[\frac{\omega_i}{2\nu}(\nu t)^2 A(k) + i(kz - \omega_{0k}t)\right] dk, \quad (5.2)$$

where a slight change of ω_{0k} with time is neglected. Since $A(k)$ has its maximum at $k\lambda_e \approx 1/\sqrt{2}$, the saddle point method yields the result for a large value of νt,

$$E(z,\,t) \approx E_k(0)\left[\frac{4\pi\nu}{-\omega_i A''(k_m)}\right]^{1/2} \frac{1}{\nu t} \times \exp\left[\frac{\omega_i}{2\nu} A(k_m)(\nu t)^2\right] \exp[i(k_m z - \omega_{0k_m} t)] \, , \quad (5.3)$$

where k_m is the value of k which is close to $1/\sqrt{2}\lambda_e$ and corresponds to the maximum of γ and where $A''(k) = d^2A(k)/dk^2$. Thus for a sufficiently large νt, $E(z, t)$ is grown up to an exceedingly high level, in which the linear theory employed here breaks down. We have to go back to the fundamental equations, taking into account of the non-linear terms. If the growth of oscillation would be permissible up to very large amplitude, it would have an important effect on the consequences of runaway phenomena.

Finally let us examine the condition hitherto employed for the approximate treatment of the present paper. The conditions are

(i) $\dfrac{1}{f_{e0}}\dfrac{\partial f_{e0}}{\partial t} \ll \omega$, (3.1)

(ii) $\left|\dfrac{eE_0}{mv_e\omega}\right| \ll 1$, (4.3)

(iii) $\nu \ll |\omega|$.

The last one is necessary for collisional terms in (2.11) and (2.12) to be negligible and also necessary for oscillations to sustain over many cycles. (i) is a necessary condition for quasi-stationary approximation, while it will turn out that (ii) gives a sufficient condition in a wide range of electron velocity.

In the limit of neglecting collisions, we obtain f_{e0}, for which the Maxwellian form

$$f_{e0} = \frac{n_e}{\sqrt{\pi}\, v_e} \exp\left[-\left\{\frac{v - u(t)}{v_e}\right\}^2\right],$$

is assumed initially, where $u(t) = e|E_0|t/m$ and E_0 is constant. Hence

$$\frac{1}{f_{e0}}\frac{\partial f_{e0}}{\partial t} = -\frac{2\{v - u(t)\}}{v_e}\frac{e|E_0|}{mv_e} \, .$$

As we are considering the case of $u(t) \lesssim v_e$, the condition (i) is satisfied if (ii) holds except for the velocity range of $v \gg v_e$. The particle number belonging to the range of $v \gg v_e$ is so small that their effect would be resonably discarded.

Owing to the effect of collisions, the temporal change of $u(t)$ becomes slower than that in the absence of collisions. Thus we may take (ii) as a still more sufficient condition. The condition (iii) is independent of (i) and (ii), but it is related with the parameter E_0/E_c representing the strength of applied electric field. In fact (ii) is written as

$$\left|\frac{\nu E_0}{\omega E_c}\right| \frac{eE_c}{mv_e\nu} \ll 1 \, .$$

By the definition of E_c, (2.10), it becomes

$$\left|\frac{\nu E_0}{\omega E_c}\right| \ll 1 \, .$$

Since $\nu/|\omega| \ll 1$, the condition (ii) is consistent with (iii) at least for $|E_0|E_c \lesssim 1$. If $\nu/|\omega|$ is extremely small compared to unity, a consistent case exists even for $|E_0|/E_c \gg 1$.

Strong oscillations observed in the Stellarator[13] may probably be instabilities of this type. Kovrizhnykh remarked[8] that instabilities he discussed correspond to the short-life time in the Stellarator. However it should be noted that the electric field applied in the Stellarator was not so strong as to allow the treatment by Kovrizhnykh, but it was so weak as to satisfy the criterion presented in this investigation.

Characteristics of an Ammonia Beam Maser

By Koichi SHIMODA

Department of Physics, Faculty of Science, University of Tokyo, Tokyo

(Received May 29, 1961)

Design, construction and operating characteristics of an ammonia beam-type maser are described with particular emphasis on the $J=3$, $K=2$ line. The maser with an eight-pole focuser of 40 cm lengh starts oscillation on the 3, 2 line at a focuser voltage of 5.6 kV when the maximum available source flux of about 1.2×10^{18} molecules per second is used.

Threshold conditions of oscillation as functions of the focuser voltage, lengths of the focuser and of the cavity are calculated by the theory on the Maxwell velocity distribution.

The observed frequency-change with the cavity tuning and with the focuser voltage is compared with theory in some detail. The effect of traveling wave component in the cavity and the pulling due to cavity tuning are calculated. It is shown that the frequency shift with the focuser voltage becomes very small, when the beam flux is reduced.

§1. Introduction

Ammonia molecules which are effused from a beam source travel through a inhomogeneous field in the focuser. The focusing field selects only the molecules in the upper inversion state so that they can emit microwave energy in the cavity which is resonant at an inversion frequency of ammonia. Since the first maser¹⁾ was constructed at Columbia University, the ammonia beam maser has been studied extensively in several laboratories.

A theory on the uni-velocity assumption can explain some of the fundamental characteristics of the beam-type maser²⁾, but the distribution of molecular velocities must be taken into account in order to interpret its detailed performance. A theory of the beam-type maser on the Maxwell distribution of molecular velocities at the entrance of the focuser has been developed by using realistic assumptions³⁾,⁴⁾.

The ammonia beam maser is a very stable oscillator at a frequency near 24 Gc. A frequency stability of 1×10^{-10} or better for a period of several hours has been obtained with a carefully constructed cavity resonator and with its temperature control⁵⁾,⁶⁾. However, when the $J=3$, $K=3$ line of $N^{14}H_3$ is used, the determination of the line center is found to be uncertain⁷⁾,⁸⁾,⁹⁾ by more than ±200 cps or $\pm1\times10^{-8}$. From a theoretical investigation on the assumption of the Maxwell velocity distribution, the complicated frequency shift of the 3,3 line maser was explained as the effect of unresolved hyperfine structure due to the electric quadrupole moment of N^{14} nucleus[3].

It was suggested to use the 3,2 line, because the quadrupole hyperfine structure vanishes as $eqQ\{1-3K^2/J(J+1)\}=0$, only when $J=3$ and $K=2$[3]. The maser on the 3,2 line was first constructed by Bonanomi et. al. and showed better stability[10]. Another possibility to improve the accuracy in determining the line center is to use ammonia of concentrated $N^{15}H_3$.

The aim of the present series of papers is to describe fairly complete characteristics of ammonia beam masers. In particular, studies on the 3,2 line will be described in some detail. The previous works (2), (3) and (7) will hereafter be written as SWT, I and II, respectively.

§ 2. Description of Apparatus

The construction of the apparatus is similar to that reported in II, except for a few improvements. The vacuum chamber is a vertical tube of 9 cm diameter which is directly connected to a 4-inch oil diffusion pump. Vertical and horizontal cross-sections of the maser are shown in Fig. 1 and in Fig. 2.

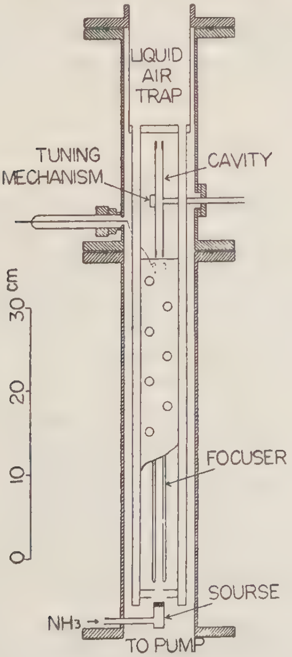

Fig. 1. Vertical cross-section of the maser

The eight-pole focuser is made of steel rods of 3 mm diameter and 40 cm length, the diameter of the focusing field being 10 mm. Neither special polishing nor cleaning of the electrode was carried out. When the high voltage is applied in push-pull to the alternate electrodes, the breakdown voltage is over 25 kV, but it is about 20 kV, when either four electrodes are grounded. Thus the maser was normally operated at a focuser voltage below 18 kV.

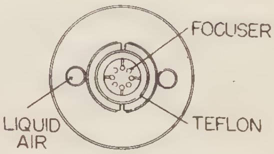

Fig. 2. Horizontal cross-section of the maser (focuser).

In order to trap the scattered molecules the focuser is surrounded by a copper cylinder of 1 mm thickness which is cooled by two straight tubes of 10 mm outer diameter which are filled with liquid nitrogen. The two tubes are connected to the bottom plate of a liquid nitrogen reservoir.

The nozzle of the beam source is constructed from a bunch of holes of 1 mm diameter. The insertion of cold diaphragms between the source and the focuser is quite effective in decreasing the scattered molecules around the focuser and in increasing the effective beam intensity. With a single diaphragm which was used for the 3,3 line maser, the maximum available source flux was about 5×10^{17} molecules per second without considerably increasing the collisions of molecules in the beam. When two diaphragms of 1 mm thickness with a separation of 10 mm as shown in Fig. 1 are used, the maximum source flux is about $1.1\sim1.2\times10^{18}$ molecules per second.

The cylindrical cavity resonator of TM_{010} mode has been exclusively used since it gives the best performance. The cavity is 12 cm in length and nearly 10 mm in diameter. The inlet and outlet holes for the beam are 8 mm in diameter and 10 mm in length. A coupling hole to the waveguide is about 2.1 mm in diameter through the cavity wall of 0.5 mm thickness.

The cylinder is slotted lengthwise to allow a rapid tuning by thermal expansion of the wolfram wire of $0.2\sim0.25$ mm diameter. The cross-section of the cavity to show the method of thermal tuning is illustrated in Fig. 3. The length of the wolfram wire was so chosen that the thermal expansion of the copper cylinder due to a change of the ambient temperature can be compensated by the small expansion of wolfram. The wolfram wire is heated by an 800 cps feedback bridge oscillator which stabilizes the temperature of the wolfram wire, since its resistance increases with temperature. A schematic diagram is shown in Fig. 4.

The measured value of the loaded Q of the cavity was between 7000 and 9000 depending on the size of the coupling hole. The maser starts oscillation on the 3,2 line with a minimum focuser voltage of 5.6 kV at the maximum source flux of about 1.2×10^{18} molecules per second. The cavity can be tuned in the frequency range of over 10 Mc. An example of the pulling of the frequency of the maser with the heating current through the wolfram wire is shown in Fig. 5.

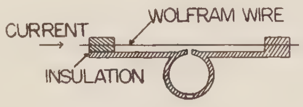

Fig. 3. Thermal tuning of the cavity.

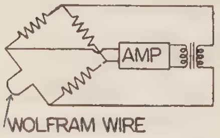

Fig. 4. Bridge oscillator for thermal tuning.

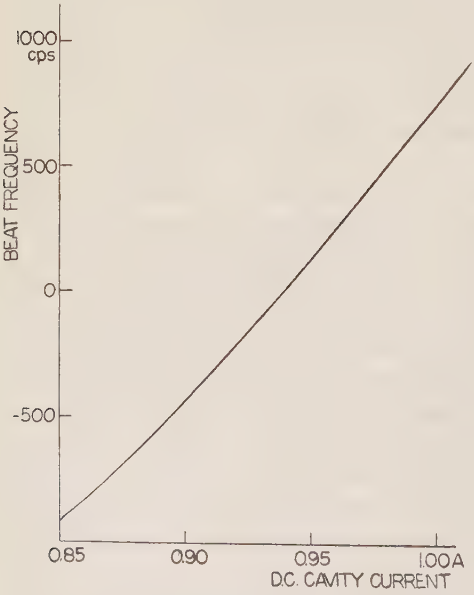

Fig. 5. Variation of the maser frequency with the heater current.

If the source pressure is increased beyond the optimum value of about 2 mmHg, the threshold focuser voltage rises because of the increase of collisions of molecules in the beam. The tank pressure was measured by an ionization gauge connected to the vacuum chamber through a tube. Therefore, the indicated pressure by the gauge must be smaller than the actual gas pressure in the chamber which is still smaller than the pressure around the beam in the focuser.

§ 3. Beam Source

Several quantities which describe the intensity of the beam are defined and their relations are discussed in the following.

The number of molecules which flow out of the source in a unit time into a small solid angle $d\Omega$ is written as $S(\Omega)d\Omega$. The directivity of the source is expressed by the angular dependence of $S(\Omega)$, which usually takes a maximum value $S(0)$ along the axis of the focuser.

The total source flux is therefore given by $S=\int S(\Omega)d\Omega$. This is equal to the number of molecules which must be supplied to the source in a unit time. When the molecule is effused from the source surface which is perpendicular to the axis, it will take any direction with the same probability so that

$$S=\int S(0)\cos\theta d\Omega$$

$$=\int_0^{\pi/2} 2\pi S(0)\cos\theta\sin\theta d\theta=\pi S(0)\,. \qquad (1)$$

If the diaphragm is placed between the nozzle and the focuser, the source that is the starting point of the molecular trajectory should be taken in the hole on the diaphragm. The source flux $S(\Omega)$ will therefore be considered as a number of molecules coming out through a hole on the diaphragm in a unit time irrespective of their rotational states.

On the assumption that the velocities of molecules in the hole on the diaphragm is given by the Maxwell-Boltzmann distribution*, the density of molecules in a particular rotational state designated by J and K is

---

* It is not correct nor necessary to assume that the Maxwell distribution holds for molecules with velocities at a large angle from the axis.

$$N(J, K)=\frac{\sqrt{\pi}\,S}{\alpha A_s}f(J, K)=\frac{\pi^{3/2}S(0)}{\alpha A_s}f(J, K)\,, \tag{2}$$

where $f(J, K)$ is the fraction of molecules in the upper or lower level of the inversion doublet, A_s the source area and α the most probable velocity. The $N(J, K)$ may be called the density of molecules in the source. The values of $f(J, K)$ for ammonia at a room temperature are $f(3,3)=3.24\%$ and $f(3, 2)=1.47\%$.

§ 4. Focusing or State-Separation

Molecules in the upper inversion state are deflected towards the axis by the electrostatic field in the focuser, while those in the lower state are deflected away. Thus the focuser acts as a state-separator. The flux of state-separated beam which enters the cavity has been calculated in I. Since the state-separation is not complete for molecules having large velocities, the difference of the beam flux of the upper state molecules and that of lower state molecules must be considered. Calculation of the excess flux of molecules in the upper state has been carried out[3] by using a simple and practical criterion for the velocity selection as given by (2.9) in I.

As was discussed in I, slower molecules have larger probability of making transitions while they stay in the cavity, and the effective beam intensity, n_{eff}, may be defined by

$$n_{\text{eff}}=\frac{n}{\langle v\rangle^2}\alpha^2\,, \tag{3}$$

where n is the state-separated beam flux, and $\langle v\rangle$ the effective average velocity.

According to Eqs. (2.14) and (2.15 *a* or *b*) in I, the effective beam intensity can be calculated in a reasonable approximation as

$$n_{\text{eff}}=\frac{NR^2}{\sqrt{\pi}\,L^2}A_l\alpha[1.5772-\exp(-a^2)-(1+a^2)$$
$$\times\mathrm{Ei}(-a^2)+\ln a^2+a^2\,\mathrm{Ei}(-b^2)]\,, \tag{4}$$

where A_l is the area of inlet hole of the cavity, L the length, R the radius of the cavity. Two parameters are

$$a=\frac{L}{R}\frac{v_c}{\alpha} \quad\text{and}\quad b=\frac{2}{\pi}\frac{l}{R'}\frac{v_c}{\alpha}\,,$$

where v_c is the critical radial velocity, l the length and R' the radius of the focuser. Equation (4) may be rewritten from (2) in the form

$$n_{\text{eff}}=\frac{A_l}{A_s}\frac{R^2}{L^2}Sf(J, K)\,y(a, b)\,, \tag{5}$$

$$y(a, b)=1.5772-\exp(-a^2)-(1+a^2)\,\mathrm{Ei}(-a^2)+\ln a^2+a^2\,\mathrm{Ei}(-b^2)\,. \tag{6}$$

The threshold value of the effective beam intensity to start oscillation in the cavity which has a quality factor Q has been given by Eq. (3.6) in I.

$$n_{\text{th}}=\frac{n_0}{\langle v_0\rangle^2}\alpha^2=\frac{h\alpha^2A}{4\pi^2\bar{\mu}^2QL} \tag{7}$$

This equation is essentially the same as Eq. (30) in SWT. Then a variable θ which is defined by

$$\theta=\sqrt{(\omega-\omega_0)^2+x^2}\,\frac{L}{2\langle v\rangle} \tag{8}$$

is related to the effective beam intensity in the form given by Eq. (3.8) in I as

$$\frac{n_{\text{eff}}}{n_{\text{th}}}=\frac{\theta^2}{\sin^2\theta}\,. \tag{9}$$

Now the theory is compared with experimental results. The observed amplitude of oscillation on the 3,2 line is shown in Fig. 6 as a function of the focuser voltage. The result in Fig. 6 was obtained when the cavity is tuned to the frequency of the line so that $\omega-\omega_0\ll x$. If the molecular velocity is constant, the value of θ must be proportional to the observed amplitude which is the relative magnitude of the rf field in the cavity. The theoretical saturation curve given by Eq. (31) in SWT or Eq. (9) does not fit the experimental results, if a change in the effective

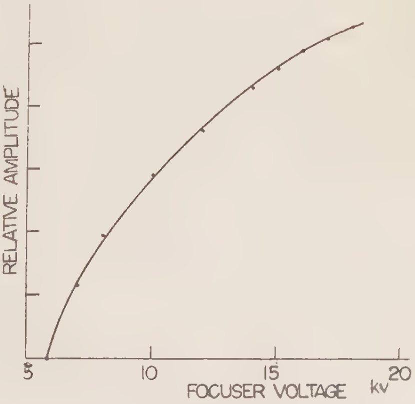

Fig. 6. Amplitude of oscillation on the 3, 2 line plotted against the eight-pole focuser voltage.

average velocity with the focuser voltage is not taken into account. The value of θ for $\omega-\omega_0 \ll x$ is

$$\theta=\frac{xL}{2\langle v\rangle}=\frac{\bar{\mu}L}{2\hbar\langle v\rangle}E\,. \qquad (10)$$

The effective average velocity was given by Eq. (2.24) in I in a fairly good approximation as

$$\langle v\rangle=\frac{\pi L+2l}{2\pi R}v_c\,,$$

where $R=R'$ is assumed. Calculated values of v_c from a weighted average of M^2 are shown in Fig. 7 for the $J=3$, $K=2$ state in an eight-pole focuser.

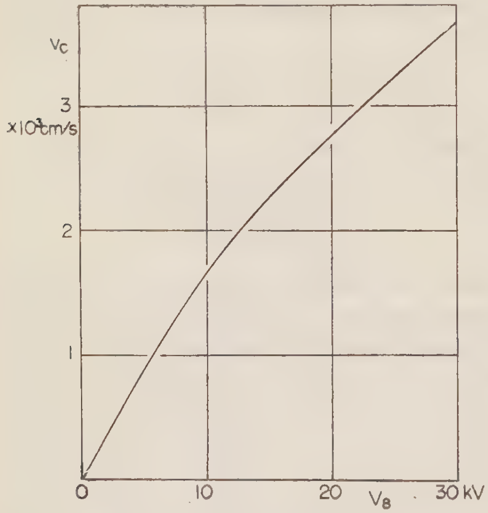

Fig. 7. Critical radial velocity of ammonia for $J=3$, $K=2$, $<M^2>=7$ in an eight-pole focuser with $R=0.5$ cm.

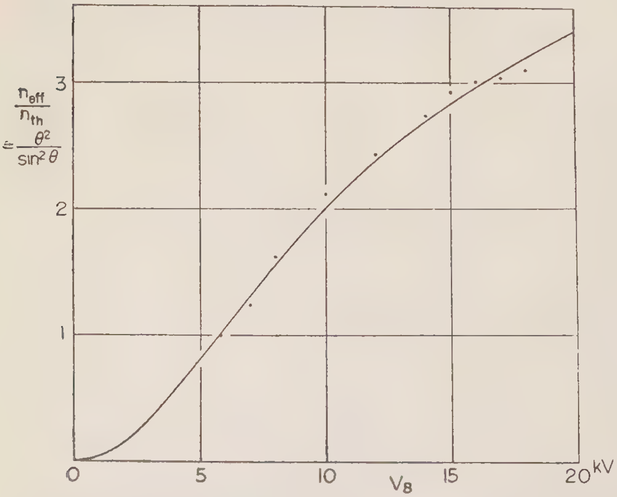

Fig. 8. Theoretical values of n_{eff}/n_{th} and experimental values of $\theta^2/\sin^2\theta$.

By assuming a proportionality factor between the observed amplitude and x, values of $\theta^2/\sin^2\theta$ can be computed. They are shown in Fig. 8 together with a theoretical curve of $n_{\text{eff}}/n_{\text{th}}$ calculated from Eqs. (5) and (7). Theoretical values were calculated for a threshold focuser voltage of 5.8 kV.

The threshold value of the effective beam intensity for the 3,2 line is calculated from Eq. (7) when $Q=8000$, $L=12$ cm and $\alpha=5.3\times10^4$ cm/s to be

$$n_{\text{th}}=n_0\frac{\alpha^2}{\langle v_0\rangle^2}\simeq1.65\times10^{13}\text{ molecules/sec.}$$

Then the source flux which fits the experimental results in Fig. 7 or Fig. 8 is calculated as $S=1.1\times10^{18}$ molecules per second in consistent with the observed flow rate which was only crudely measured.

§ 5. Design Considerations

In order to get oscillation on a weak line the maser must be carefully designed. Since the velocity distribution theory has been found to be good as described in the former section and in II, design considerations according to this theory are given below.

There have been some discussions about the choice of the number of poles of the focuser. The maximum electric fiield on the electrode and the transparency that is the relative area of the gap between electrodes have been discussed. However, it must be remarked that the scattering of molecules is the most important factor in obtaining a strong beam intensity.

When the Stark energy is proportional to the square of the electric field, the focusing force in a quadrupole focuser is proportional to the radial distance r of the molecule. Therefore, molecules which leave the source at a point other than that on the axis are not well focused.

The force in a $2n$-pole focuser is expressed by

$$F\propto r^{2n-3}\,.$$

Hence the focusing force in an eight-pole forcuser is proportional to r^5 and it is very small (less than 8%) in the region where $r<0.6R$. Then, the focuser can accept broader beam from the source and the distribution of upper-state molecules in the focused beam is broader than in the quadrupole focuser for which the molecules are more concentrated on the axis. For the same total beam flux, therefore, the maximum density of molecules is smaller in the eight-pole focuser and also the gas pressure at the entrance of the focuser is more reduced.

Because a focuser of too large number of poles produces essentially no electric field in the region near the axis, the molecules in the lower state cannot be removed from the beam. The effective beam flux is reduced by the presence of lower state molecules and by the increase of scattering by collisions between molecules.

The best number of poles depends on the focuser voltage and the Stark behavior of the molecule, but the eight-pole focuser is considered to be near the optimum in most cases. The six- or ten-pole focuser would be as good.

It is true that the focusing criterion of velocities given in I as

$$v_r < v_c \qquad \text{and} \qquad v_z < \frac{2}{\pi}\frac{l}{R'}v_c$$

must be somewhat modified for a $2n$-pole focuser with $2n \neq 4$. As far as the limiting trajectory is concerned, one might suppose that the factor $2/\pi$ should be replaced by unity, when $2n$ is large. However, a more plausible estimate for the average molecules becomes rather close to $2/\pi$, when the distributions of the starting points and of the directions of the molecular velocities are considered. Therefore, expressions obtained in II and in § 4 may be used for multipole focusers as well.

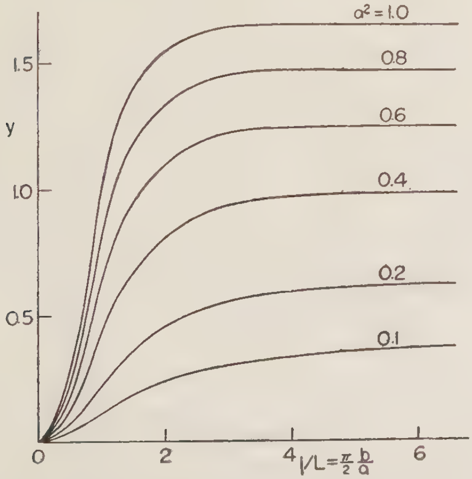

Fig. 9. Effective beam intensity vs. length of the focuser.

The theory allows an evaluation of the change in the effective beam intensity with the length of the focuser, l. Calculated values of $y(a, b)$ which is proportional to the effective beam intensity as given by Eq. (5) are shown in Fig. 9.

Although Eq. (6) was obtained on the assumption of $a<b$, the result may be extrapolated to $l=L$. Besides, another simple estimate is employed to draw curves in the range between $l=0$ and L. It can be concluded from these curves that the focuser length of 2 to 4 times as long as the length of the cavity is usually sufficient. It is noted that the saturation with the length of the focuser is slower at the lower focuser voltage.

Now the performance of the maser against the length of the cavity L is considered. Although the threshold beam intensity decreases with the increase of the cavity length, a very long cavity is not useful, because the velocities of molecules in the beam are not parallel but divergent. The threshold source flux against the cavity length L is calculated from Eqs. (5) and (7) in the form

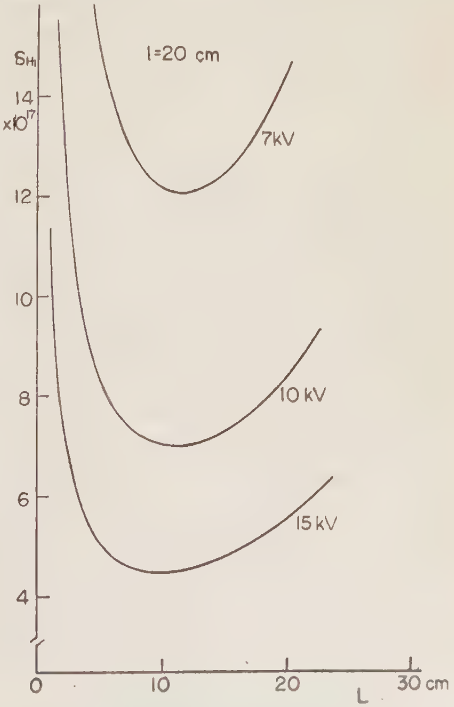

Fig. 10. Threshold source flux for the 3, 2 line vs. cavity length when l=20 cm.

$$S_{\mathrm{th}}=\frac{g}{fR^2}\frac{L}{y}\,, \tag{11}$$

where $A_i=A_s$ is assumed and

$$g=\frac{h\alpha^2A}{4\pi^2\bar{\mu}^2Q}$$

is a constant, if a small change in Q of the cavity with its length is neglected. Some examples for the 3,2 line of ammonia are illustrated in Figs. 10, 11, and 12. They are culculated for $Q=8000$, $\alpha=5.3\times10^4$ cm/s, $R=0.5$ cm, and $l=20$, 30, 40 cm respectively.

These curves show very clearly the optimum length of the cavity. The higher the focuser voltage the larger the beam divergence, hence the cavity length must be smaller. The above calculation has neglected collisions of molecules which become more frequent in a long cavity. Therefore, the optimum cavity length in an actual case would be somewhat shorter than that can be found from these curves.

In conclusion, it may be noted that the experimental apparatus described in § 1 ($l=40$ cm and $L=12$ cm) is very near the optimum design.

Finally, the evaluation for the 3,3 line is mentioned. Because the Stark shift is determined by the value of $\mu KME/J(J+1)$, three curves corresponding to focuser voltages of $V_8=7$, 10, and 15 kV for the 3,2 line must have the same form for the 3,3 line at voltages 2/3 times the above values, those are 4.7, 6.7 and 10 kV respectively. The ordinate must be multiplied by a factor

$$\frac{f(3{,}2)}{f(3{,}3)}\cdot\frac{g(3{,}3)}{g(3{,}2)}=0.112\,,$$

when the quality factor of the cavities are equal.

The threshold flux as a function of the eight-pole focuser voltage is shown in Fig. 13 for the 3,3 line. The observed threshold voltage of $V_8=2.4$ kV reported in II with an estimated source flux of 5×10^{17} molecules per second is in good agreement with theory.

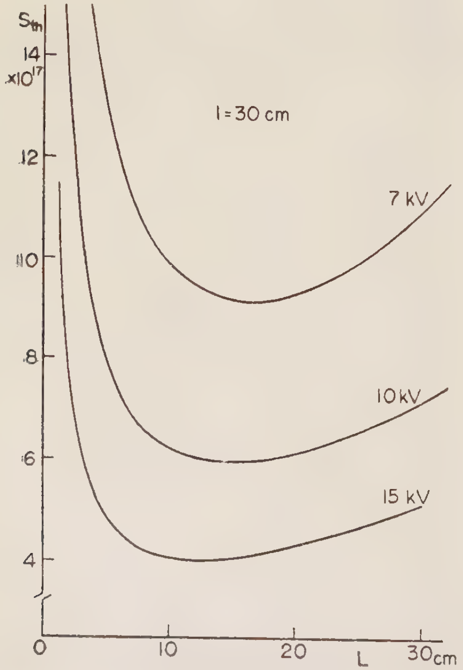

Fig. 11. Threshold source flux for $l=30$ cm.

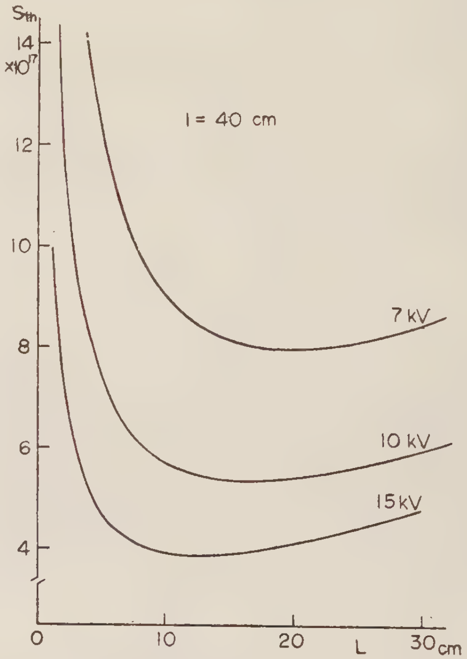

Fig. 12. Threshold source flux for $l=40$ cm.

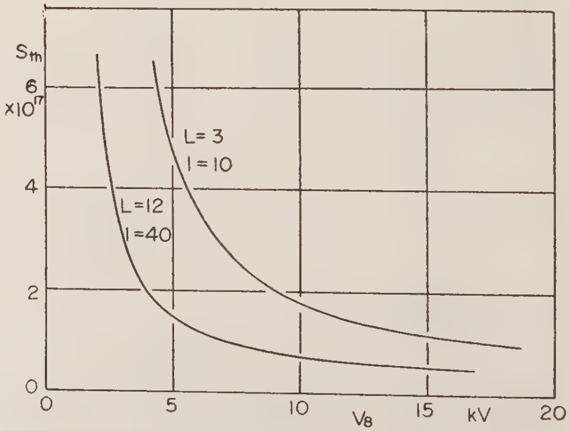

Fig. 13. Threshold condition for the 3, 3 line.

Another example obtained by a small maser of $l=10$ cm and $L=3.2$ cm gave the minimum threshold voltage of 4.85 kV[11], which is also consistent with the theoretical evaluation.

§ 6. Frequency Shifts

The frequency shift of the 3,2 line maser was measured by beating with another similar maser. Comparison of its frequency with the frequency standards will be reported shortly.

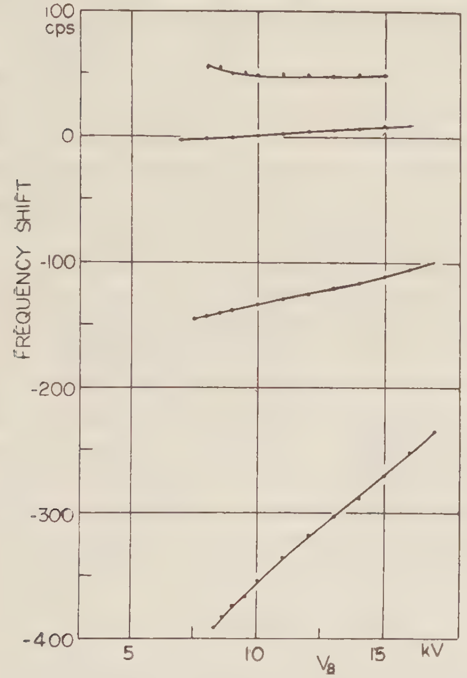

Fig. 14. Frequency shift vs. forcuser voltage, $S\doteqdot 9\times10^{17}\,\mathrm{s}^{-1}$.

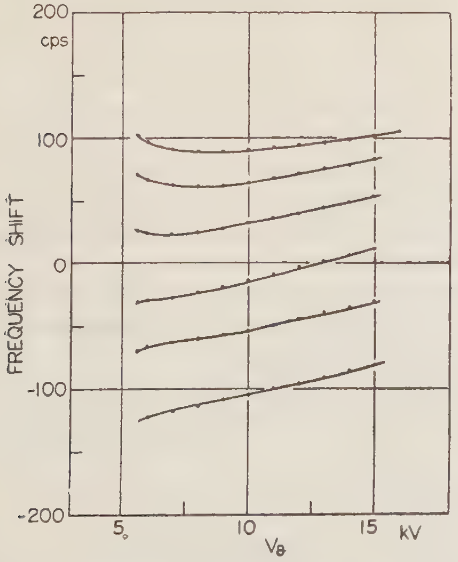

Fig. 15. Frequency shift vs. focuser voltage, $S=1.2\times10^{18}\,\mathrm{s}^{-1}$.

Typical results of the frequency shift with the focuser voltage and with the cavity tuning are shown in Fig. 14 and Fig. 15, where each curve corresponds to a different cavity tuning. Fig. 15 was obtained with the maximum source flux of about 1.2×10^{18} molecules per second and Fig. 14 was for a somewhat reduced source flux.

Comparison of these curves with Fig. 11 in II shows that the 3,2 line allows a more accurate setting of the line center. However, the presence of frequency shift due to the traveling wave component in the cavity make it difficult to find the line center within an accuracy of better than $\pm1\times10^{-9}$ from such results. A theoretical explanation will be given in § 7.

Some additional causes of the frequency shift of the maser were observed. The one is the frequency shift caused by the Stark effect due to the stray electrostatic field of the focuser. It is true that the fringing field of the focuser does not intrude inside the cavity, but an appreciable amount of the rf field is protruding out of the inlet hole of the cavity, where the electrostatic field produced by the focuser is not negligible. Thus molecules which emit rf energies near the inlet hole of the cavity tend to shift the frequency of oscillation.

This type of Stark shift is estimated to be much smaller than the traveling wave effect, but it was experimentally measured by using a dummy focuser which was placed at a distance 3 mm from the cavity. The observed increase of frequency with the dummy focuser voltage is shown in Fig. 16. This shift is proportional to the square of the focuser voltage as expected.

Since the operating focuser is actually about

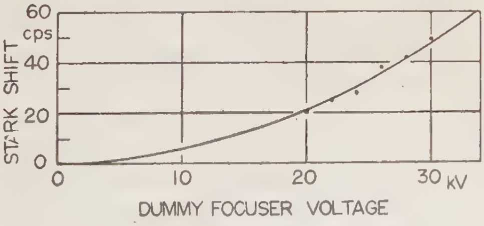

Fig. 16. Stark shift of the maser oscillation due to the fringing field.

9 mm away from the cavity, the Stark shift at a focuser voltage of 15 kV is estimated as +2 cps. This Stark shift can be made smaller, if the potentials of the alternate electrodes of the focuser are $+V/2$ and $-V/2$. Insertion of a shielding diaphragm between the cavity and the focuser would considerably reduce this effect.

The other type of the observed frequency shift is the effect of the background pressure. The change in the oscillating frequency caused by the leakage of air into the vacuum tank was measured in the pressure range between 3×10^{-7} mm Hg and 1×10^{-5} mm Hg on the reading of an ionization gauge.

The observed frequency shift was found to be approximately proportional to the tank pressure and to the amount of frequency pulling f_m-f_0, where f_m is the oscillating frequency and f_0 the line center. An empirical equation for the frequency change Δf_p caused by a pressure increase of p mm Hg was obtained in the form

$$\Delta f_p=2\times10^4(f_m-f_0)p \tag{12}$$

in cycles per second.

This type of frequency shift can be explained by the increase of the cavity pulling due to the decrease of the amplitude of oscillation through the reduction of the beam intensity by scattering of molecules. Eq. (12) is not accurate, since the observed tank pressure may be in error, and because it could not be kept constant while the frequency was measured under a deteriorated vacuum. Besides, frequency changes of less than a few cycles per second corresponding to small amounts of pulling were not measured.

Another type of frequency shift is a small change in frequency due to the collision between ammonia molecules, and it will be discussed in a paper which will appear shortly.

§7. Calculation of Traveling Wave Effect

The presence of traveling wave component corresponding to a small net power flow in the cavity produces a frequency shift due to its Doppler effect. A basic analysis of this type of frequency shift has been given by SWT. Even when the output waveguide is coupled to the cavity at the middle of its length, the power emitted by molecules flows against the direction of the beam when the rf amplitude is small, whereas it flows in the forward direction when the amplitude is large so that most of the molecules deliver their energy in the former part of the cavity. Therefore, the frequency shift due to the traveling wave effect is negative for the case of little saturation, and positive for high saturation.

Now the variation of traveling wave component with saturation is calculated. A crude calculation reported before[12] is reformed as follows. The rf power lost by the cavity wall is distributed along the length of the cavity depending on the distribution of the rf field. The output power is of course lost from the cavity through the coupling hole. The average position of the power dissipation is written as Z, a distance measured from the inlet hole of the cavity. Hence for a cavity of symmetrical mode with output waveguide at the middle of its length Z is equal to $L/2$.

The power delivered by molecules at a distance z from the inlet hole flows in the average to the forward or backward direction according as the sign of $Z-z$. Besides, the magnitude of power flow is proportional to $Z-z$. Therefore, the total power flow in the cavity is given by

$$P_t=K\int_0^L(Z-z)\sin\frac{2\theta z}{L}\,dz\ , \tag{13}$$

because the power emitted by molecules between z and $z+dz$ is proportional to

$$\sin\frac{2\theta x}{L}\,dz\ ,$$

in the TM_{010} cavity[2]. The stored energy is

$$W=K\frac{QL}{\omega_0}\int_0^L\sin\frac{2\theta z}{L}\,dz\ , \tag{14}$$

where K is the same constant as in Eq. (13) and the resonant frequency of the cavity $\omega_0/2\pi$ is taken equal to the transition frequency of the molecule.

Then the amount of the traveling wave component expressed by Q_t is calculated from Eqs. (13) and (14) as

$$\frac{1}{Q_t}=\frac{P_t}{\omega_0 W}=\frac{1}{Q}\left\{\frac{Z-L}{L}+\frac{2\theta-\sin2\theta}{2\theta(1-\cos2\theta)}\right\}. \tag{15}$$

Equation (15) may be rewritten as

$$\frac{Q}{Q_t}=\frac{1}{f_2(\theta)}-d\ , \tag{16}$$

where

$$d=\frac{L-Z}{L}$$

and

$$f_2(\theta)=\frac{2\theta(1-\cos 2\theta)}{2\theta-\sin 2\theta}$$

which is the function illustrated in Fig. 2 in SWT.

The frequency of oscillation ω' shifted by the traveling wave effect is calculated by Eq. (55) in SWT which can be written as

$$\frac{\omega'-\omega_0}{\omega_0}=\frac{4\pi^2 vL}{Q_t\lambda^2\omega_0}\left[1-\frac{1}{4}f_2(\theta)\right] \tag{17}$$

Substitution of Eq. (16) gives

$$\frac{\omega'-\omega_0}{\omega_0}=\frac{\pi}{2Q}\frac{v}{c}\frac{L}{\lambda}\left[4-f_2(\theta)\right]\left[\frac{1}{f_2(\theta)}-d\right] \tag{18}$$

Variations of the frequency shift due to the traveling wave effect with the values of θ and d are illustrated in Fig. 17.

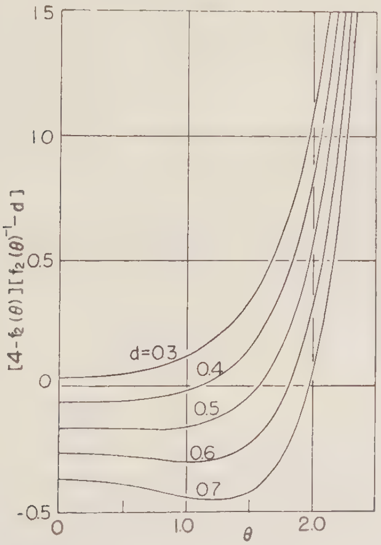

Fig. 17. Graphical representation of $[4-f_2(\theta)]\times[f_2(\theta)^{-1}-d]$.

The observed frequency of a maser on the 3,2 line or on the line of $N^{15}H_3$ includes both the traveling wave effect and the cavity pulling. The frequency pulling by the cavity was theoretically obtained by SWT after a slight modification as

$$\frac{\omega-\omega'}{\omega_0}=\frac{Q}{\pi}\frac{v}{c}\frac{\lambda}{L}f_2(\theta)\cdot\frac{\omega_c-\omega_0}{\omega_0}, \tag{19}$$

where ω is the frequency of the maser, ω_c the resonant frequency of the cavity.

From Eqs. (18) and (19) the theoretical frequency shift due to the cavity pulling together with the traveling wave effect can easily be computed. Numerical results for the values

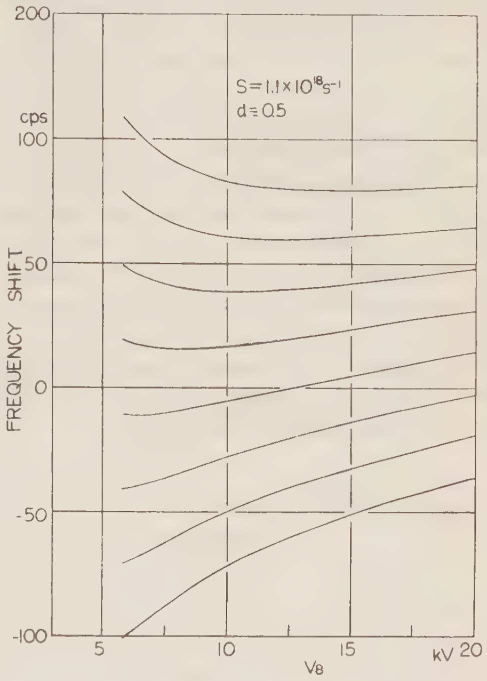

Fig. 18. Theoretical frequency shift vs. focuser voltage for d=0.5, $S=1.1\times10^{18}\,s^{-1}$, $Q=8000$, $L=12$ cm.

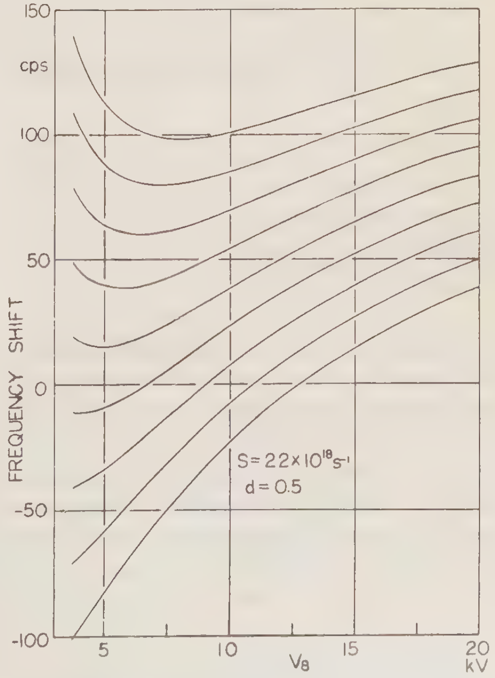

Fig. 19. Theoretical frequency shift vs. focuser voltage, $S=2.2\times10^{18}\,s^{-1}$.

of $\nu_0=22.834$ Mc, $Q=8000$, $L=12$ cm, $v=6\times10^4$ cm/s, and $d=0.5$ are shown. Fig. 18 shows the frequency shift with the focuser voltage for a source flux of $S=1.1\times10^{18}$ molecules per second corresponding to the threshold voltage of 5.8 kV. This may be compared with the experimental result of Fig. 15 which shows a little larger increase in frequency with the focuser voltage.

It is found that the character of the frequency shift strongly depends on the beam intensity. The frequency shift corresponding to the increased source flux of $S=2.2\times10^{18}$ molecules per second is larger as shown in Fig. 19. Hence it seems reasonable to conclude that the experimental characteristics of Fig. 15 for the threshold voltage of 5.6 kV is quite consistent with this theory.

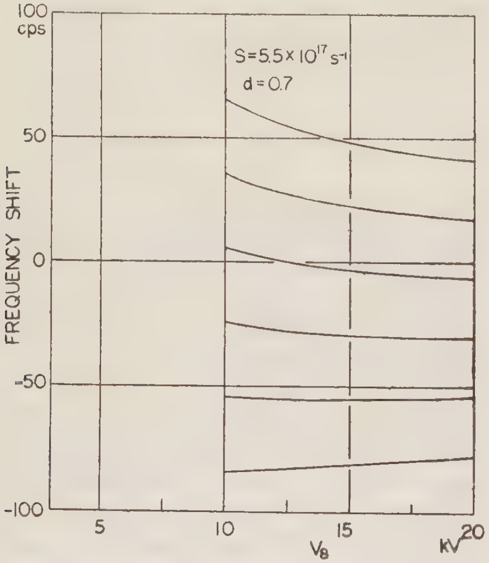

Fig. 20. Theoretical frequency shift vs. focuser voltage, $S=5.5\times10^{17}$ s^{-1}.

A reduction of beam intensity by a factor of two results in the threshold voltage of 10 kV. The frequency shift calculated for $S=5.5\times10^{17}$ molecules per second is shown in Fig. 20. It is rather surprising to see that the change of frequency becomes extremely small in this case. A middle curve in Fig. 20 shows that the frequency changes by less than ±0.3 cps in the range of focuser voltage between 11 and 19 kV.

Compared with Fig. 15, Fig. 14 shows smaller voltage dependence of the frequency. This can be considered as an exprimental evidence of the theoretical result. However, it cannot be concluded that the stability as shown by Fig. 20 is exactly realizable, since the theory did not take the velocity distribution in calculating the traveling wave effect. Also there are causes of frequency shift which were not included in the result of Fig. 20.

Concerning the stability of the absolute frequency, it may be remarked that even when the waveguide is coupled to the cavity at the middle of its length, the effective value of Z is not equal to $L/2$ because of some possible inhomogeneity of the rf field. For example, if the rf field is weaker in the part of the cavity near the focuser, the effective value of Z is smaller than $L/2$ and d is larger than 0.5. The frequency characteritic for a large value of $d=0.7$ is shown in Fig. 21, where the apparent line center is about 50 cps lower.

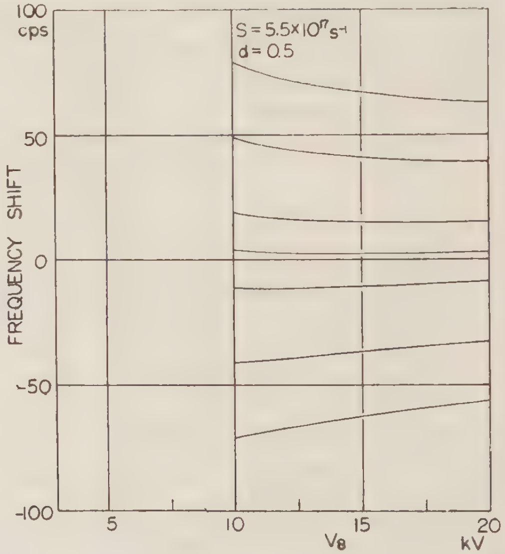

Fig. 21. Theoretical frequency shift vs. focuser voltage for $d=0.7$, $S=5.5\times10^{17}$ s^{-1}.

Determination of the line center by the magnetic perturbation method will be discussed in the paper which follows next. Experimental results on the stability, resettability and reproducibility of the 3,2 line maser will also be discussed.

Acknowledgment

The author wishes to express his appreciation to Mr. Noboru Kohno who assisted in the construction and operation of the apparatus.

Optical Study of Aniline Hydrobromide Single Crystal

By Tsuruji IWAI

Faculty of Science, Osaka University

(Received April 20, 1961)

A domain structure previously concluded by an X-ray study of aniline hydrobromide was directly confirmed by optical means. The domain walls were found to move easily by a shearing force. The temperature dependence of the extinction angle was obtained. The thermal transition of transparency was measured, and interpreted on the basis of the domain structure. The refractive indices were also measured. Although the double refraction was found to be fairly large, any anisotropy of optical absorption was not detected within the limit of experimental error.

§ 1. Introduction

According to an X-ray investigation reported by Taguchi,[1] aniline hydrobromide is orthorhombic above 27.5°C, and is monoclinic below this temperature. His conclusion is that below the transition temperature crystals which appear to be single crystals in the macroscopic observation consist, in fact, of domains having two different orientations, the *b*- and *c*-axes in common. On passing upward the transition temperature, the domains disappear and the crystals transform into orthorhombic single crystals.

The axial angle β was found to vary reversibly with temperature, in the range from the transition temperature down to about -60°C. Finally he concluded on the basis of the crystal structure below and above the transition temperature[2] that this phase transition is of the type of order-disorder associated with the hydrogen atom bound to the nitrogen atom. This point of view has recently been confirmed by a specific heat measurement.[3] A dielectric measurement seems to support this point of view.[4]

The method of the "Thermal Transition of Transparency" developed by Horie *et al.*[5)-7)] has been proved to be very useful to elucidate the temperature variation of a domain structure. In the following, a study on the domain structure of aniline hydrobromide by means of the method of the thermal transition of transparency, together with other optical properties of the same material will be given.

§ 2. Optical Observation of Domain Structure

A microscopic observation of thin specimens was carried out, in order to confirm the existence of the domain structure reported by Taguchi.[1]

1) *Domain Structure and Temperature Dependence of Extinction Angle*

Crystals of aniline hydrobromide used in this investigation were prepared by slow evaporation from a methyl alcohol solution. They show apparently the orthorhombic symmetry, predominant faces being {100} and {001}. These crystals did show any domain structure, even when viewed at right angles to the *a*- or *c*-faces under the polarizing microscope. This does not contradict to the conclusion given by the X-ray investigation, because if the domain walls are all parallel to the *bc*-plane, the extinction positions for all of the domains coincide with each other, as far as the *a*- or *c*-faces are concerned. However, a plate which was cut parallel to the *b*-plane and carefully polished did actually exhibit a polydomain structure at room temperature, and it was found that the domain walls were all parallel to the *bc*-plane. This is in good agreement with the conclusion given by the X-ray study. The domain structure is caused by the monoclinicity of the crystal and is similar to that of the monoclinic tungsten oxide, WO$_3$.[8,9] The extinction positions differ from each other for adjacent domains as shown in Photo. 1. Therefore, by measuring the angle between these two extinction positions at different temperatures, the temperature dependence of the inclination of the optic elasticity axis to the *c*-axis, φ, can be obtained. The results are shown in Fig. 1.

The variation of φ with temperature is gradual over a wide range of temperature, and it is quite similar to that of the axial angle β. Any temperature hysteresis was not observed. On heating the crystal, the domain structure disappears above 27.5°C, because each of the optic elasticity axes in any one of domains coincides with either *a*- or *c*-axis in the orthorhombic phase.

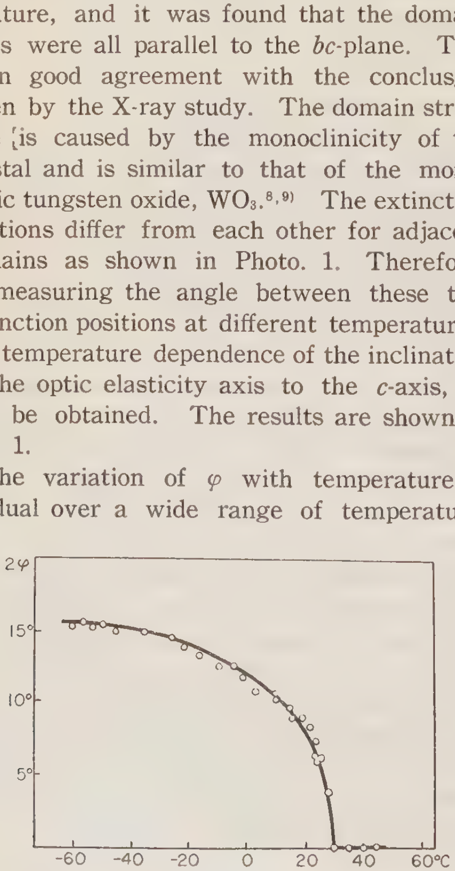

Fig. 1. Angle of twice φ *versus* temperature.
φ: the angle between the optic elasticity axis and *c*-axis.

2) *Effect of Mechanical Force on Domain Structure*

Crystals of aniline hydrobromide are composed of many domains at room temperature. As a result, the *c*-face has a zigzag structure due to the monoclinic angle. If a stress is applied in such a direction that the zigzag structure is smoothed out, the domain walls are expected to move as was reported for the case of WO$_3$.[8] In fact, the domain walls were found to move quite easily, even when a weak shearing stress was applied.

Photo. 2(a) shows the domain structure of a *b*-cut crystal placed between crossed Nicols. The planes of polarization are shown with crosses in Photos. 2, (a) to (f). The domains which look dark will be called type I and the other type II. When a shearing stress X_z is applied, the domains of type II begin to grow at the expense of those of type I, and as a result the zigzag structure becomes smooth to some extent, as shown in Photo. 2(b). On the contrary, if a stress is applied to the opposite direction, just the reverse process can be observed. A successive change in domain widths due to increasing shear is shown in Photos. 2, (c) to (d). If the shearing becomes sufficiently large, the crystal finally assumes nearly a single domain structure, as shown in Photo. 2(d). When such a crystal having a nearly single domain structure is heated above 27.5°C and then cooled down through this temperature, it shows a polydomain structure again, which is almost similar to the original one, as shown in Photo. 2(e). Some one of domains becomes a wedge-shaped one in the course of vanishment under the influence of a shearing stress. An example is shown by the arrow in Photo. 2(f).

§ 3. Temperature Dependence of Refractive Index

To measure the refractive index of a tiny crystal such as barium titanate,[10] Chaulnes' method has hitherto been used. This method, however, gives only a mean value of the refractive indices. Sawada and Danielson[11] have modified this method to determine the principal indices of refraction, by using plane-polarized light. This method was applied to *a*- and *c*-crystals of aniline hydrobromide about 300μ in thickness. A tungsten lamp was used a light source, because an ordinary monochromatic light source was insufficient in intensity for this purpose. Especially, the multi-domain structure of the monoclinic phase makes the measurement extremely difficult. However, as mentioned above, the domain walls can easily be removed away by a shearing stress. The measurement was carried out by use of a wide single domain region obtained in this way. The results are shown in Fig. 2, where the three principal indices of refraction are denoted by n_x, n_y and n_z, respectively.

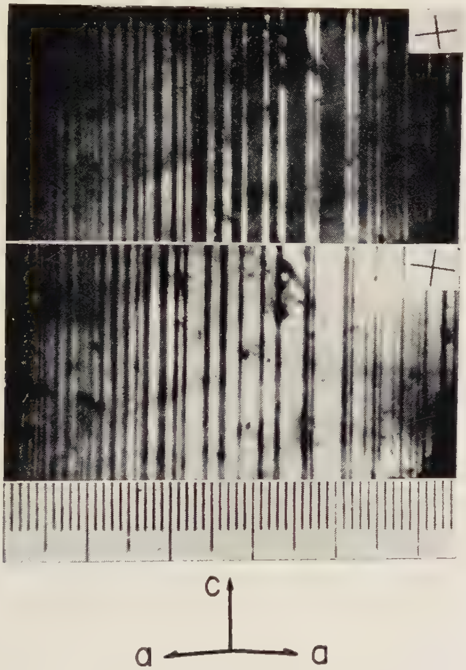

Photo. 1. Alternating extinction, accompany with different extinction positions (10^{-2} mm/div.).

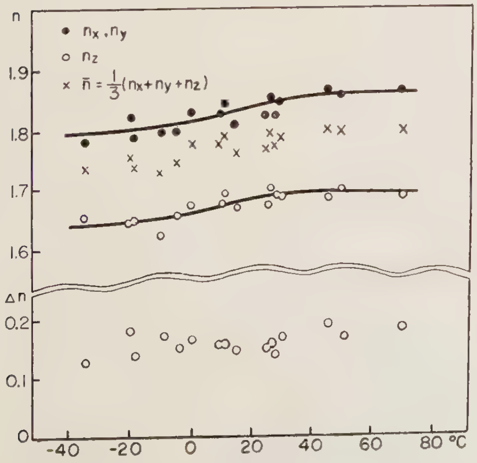

Fig. 2. Refractive indices *versus* temperature.

Any measurable difference between n_x and n_y is not detected and the birefringence $\Delta n=n_x-n_z$ remains unchanged, within the limit of experimental error over a wide temperature range from 70° to about -40°C, and besides the following relation holds throughout for the two phases: $n_x \approx n_y > n_z$. Thus, aniline hydrobromide is optically negative, in agreement with the description of Groth.[12] The temperature dependence of the refractive indices is quite small. However, the observed values decrease slightly, as the temperature is lowered. A qualitative reason for this tendency might be as follows. On cooling the crystal, the structural change occurs at 27.5°C. As the result, the local field which is acting on constituents of the crystal and effective to the refractive indices also changes.

§4. Optical Absorption

In order to see if there is any anisotropy of absorption, measurements were made by means of a microscopic spectrograph.[13] The apparatus is a combination of a microscope and a spectrograph, all of the optical elements being made of quartz. An iron arc was used

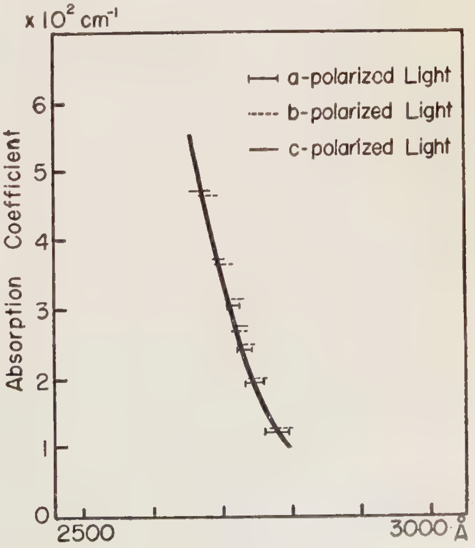

Fig. 3. Optical absorption.

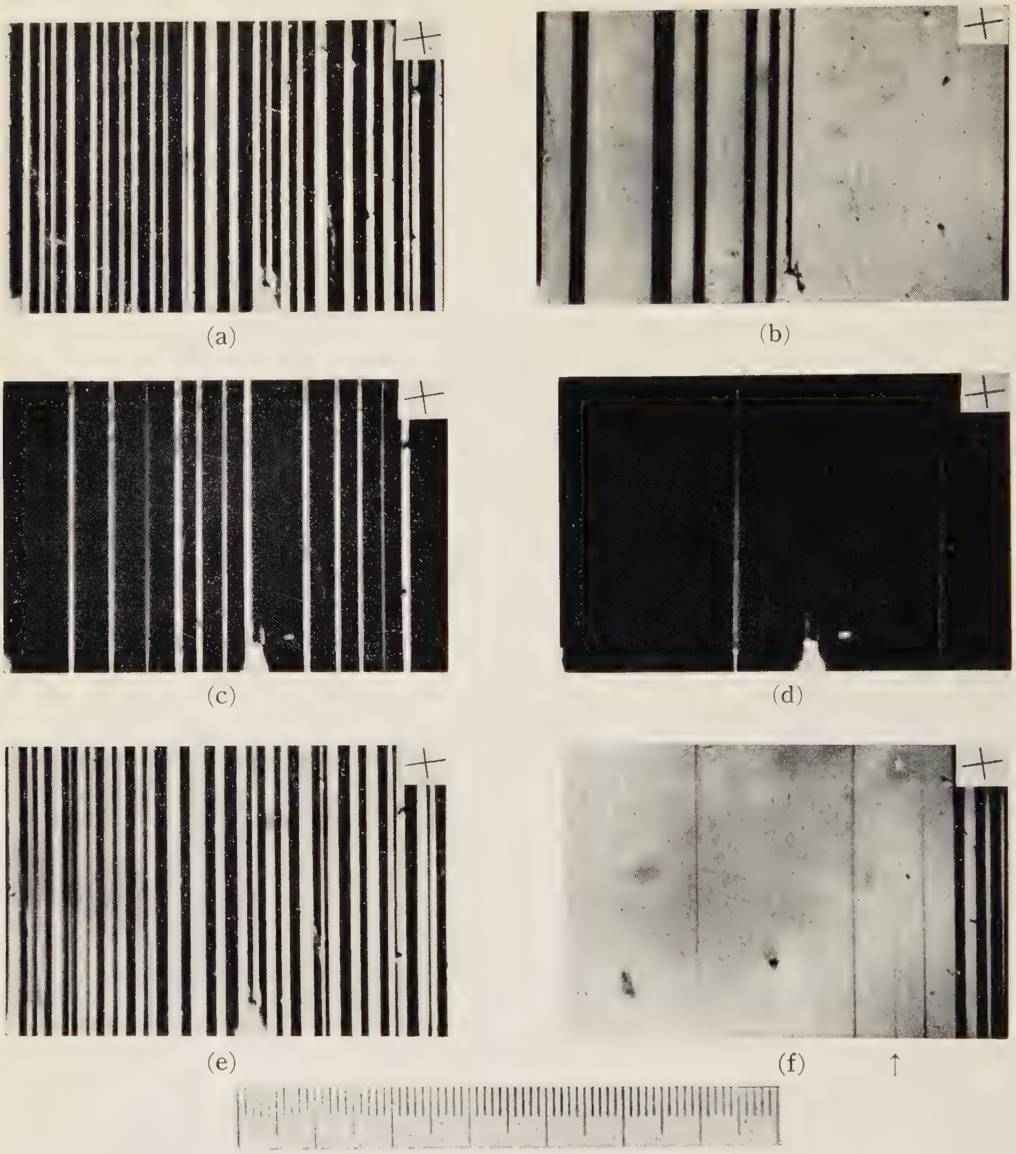

(a) (b) (c) (d) (e) (f) ↑

Photo. 2. Shearing stress effect on the domain structure (10^{-2} mm/div.).

as a light source. The *a*- and *c*-crystals about 300μ in thickness were used as specimens. The absorption spectrum for plane-polarized light was taken at 30°C. The result obtained is shown in Fig. 3, where the light polarized in the direction parallel to each of the *a*-, *b*- and *c*-axes is called *a*-, *b*- and *c*-polarized light. (The direction of polarization is given by the direction of electric vector.) The absorption curve is rather steep and the threshold lies at about 2750Å. Any distinct defference among the absorption edges for the three different polarized lights was not detected within the limit of experimental error.

In a crystal whose symmetry is lower than cubic, the crystalline field splits otherwise a degenerate electronic state into its components. This effect causes the crystal to give rise an anisotropy of absorption, as has been found in several transparent crystals.[14] In addition to this effect, another type of anisotropy arising from level splitting due to intermolecular resonance has also been reported to take place in some molecular crystals.[15] From these points of view, it may be concluded that splitting of the electronic states in aniline hydrobromide is too small to give rise to any anisotropy in its optical absorption.*

§ 5. Thermal Transition of Transparency

The thermal transition of transparency (T.T.T., for brevity) for aniline hydrobromide was observed with the aid of an experimental arrangement which has already been described in detail.[5] Natural light from a tungsten lamp was projected perpendicularly onto a virgin crystal, and its enlarged image was focussed by a microscope on a diaphragm just in front of a multiplier photo-tube, the photo-current of which was magnified by a D.C. amplifier. The temperature of the specimen was controlled by an electric heater and liquid air in a modified Dewar flask.

A virgin *c*-crystal about 300μ in thickness was used as a specimen. As has been mentioned in §2, the virgin crystal does not show any domain structure visible under a polarizing microscope. The T.T.T. obtained is shown in Fig. 4, where open circles represent the experimental plotting. On cooling the crystal down through the transition temperature, its transparency decreases at first rapidly and then tends asymptotically to a certain limit below −60°C. The temperature hysteresis loop associated with the phase transition as seen in $BaTiO_3$[5-7] was not observed.

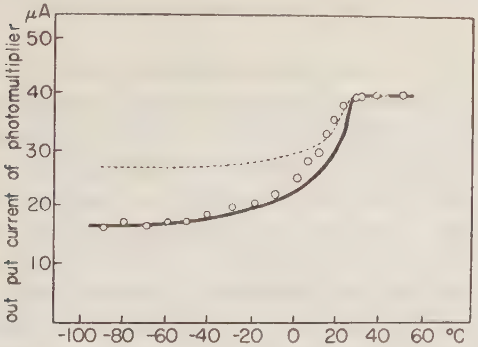

Fig. 4. Thermal transition of transparency.
- - - -: calculated value by flat boundary surface assumption.
——: calculated value by zigzag boundary surface assumption.

This T.T.T. curve is quite similar to the temperature dependence of the axial angle β.

§ 6. Interpretation of T.T.T.

The T.T.T. of barium titanate has interpreted by Horie *et al.*[5,6] on the basis of the domain structure and of crystal optics. A similar consideration is now applied to the case of aniline hydrobromide.

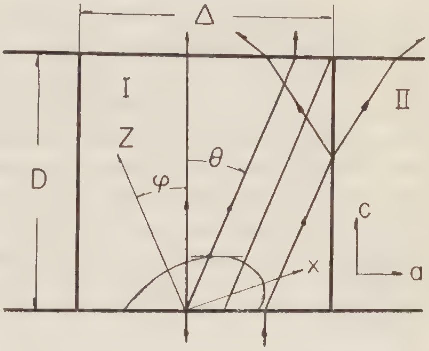

Fig. 5. Optical paths in the monoclinic phase (case of flat boundary surface).

When natural light falls perpendicularly onto a *c*-crystal, the light is decomposed into two extraordinary waves. The intersections of these wave surfaces with the *b*-plane are a circle and an ellipse. If the *c*-face is assumed to be flat, only the wave with elliptic section is deflected sideways owing to reflection and refraction at a domain boundary, as explained in Fig. 5. If the intensity of light transmitted through the crystal is called I in the orthorhombic phase, and $I-\delta I$ in the monoclinic phase, a consideration similar to that given in the case of $BaTiO_3$ leads to the following equations:

$$\delta I \approx \frac{1}{2}\cdot\frac{D|\tan\theta|}{\overline{\varDelta}} I \qquad (1)$$

and

$$\tan\theta \approx \left\{\left(\frac{n_x}{n_z}\right)^2 - 1\right\}\varphi, \qquad (2)$$

where D is the thickness of the crystal, $\overline{\varDelta}$ is the mean domain width and θ is the angle of refraction as shown in Fig. 5; and it is assumed that $\varphi \ll 1$. From the measurement of the refractive indices, n_x/n_z was found to vary only slightly with temperature. Therefore, the change in transparency, δI, is expected to depend linearly on φ. The values of n_x/n_z and φ were determined experimentally, and the values of D and $\bar{\Delta}$ were obtained by microscopic observation as follows: $D=290\mu$; $\bar{\Delta}=7.7\mu$. On substituting these values into the above equations, the curve of T.T.T. is calculated, which is shown by the dashed curve Fig. 4. However, a remarkable difference between the observed and calculated values is noticed especially at lower temperatures.

---

* In some substances such as CdS, $BaTiO_3$ and WO_3, splitting of the electronic level due to the crystalline field is estimated by several authors[14] at 0.02~0.07 ev. Splitting due to intermolecular resonance observed in some crystals of aromatic molecules is also of the order of 0.01 ev.[15] In the present experiment, the experimental error is of the order of magnitude of 0.03 ev.

Eq. (1) is derived under the assumption that the crystal surface is perfectly flat. Actually, that is not the case owing to twinning. According to the X-ray study,[1] β varies gradually with temperature and becomes 91°22′ at −110°C and the c-faces in adjacent domains make an angle of 2°44′ with each other. In such a case, the wave with circular section may also be deflected. As a result, Eqs. (1) and (2) will be modified as follows (see Appendix):

$$\delta I \approx \frac{1}{2}\cdot\frac{D(|\tan\theta_1|+|\tan\theta_2|)}{\bar{\Delta}} I, \qquad (1')$$

$$\tan\theta_1 \approx \left\{\left(\frac{n_z}{n_x}\right)^2-1\right\}\varphi + \left(\frac{n_z}{n_x}\right)^2\left(1-\frac{1}{n_x}\right)\left(\beta-\frac{\pi}{2}\right) \qquad (2')$$

and

$$\tan\theta_2 \approx \left(1-\frac{1}{n_y}\right)\left(\beta-\frac{\pi}{2}\right), \qquad (2'')$$

where the terms dependent on $\Delta\beta=\beta-\pi/2$ show the correction due to non-flatness of the c-face. The angle $\Delta\beta$ varies in a manner similar to φ with temperature, as mentioned in §2. By use of the above equations, the theoretical curve for the T.T.T. is refined as shown by the solid curve in Fig. 4. The corrected curve is in good agreement with the experimental result.

Consequently, the T.T.T. of aniline hydrobromide can be understood on the basis of the domain structure and of crystal optics. The T.T.T. method can be applied to virgin crystals without any treatment, such as cutting or polishing which is necessary to make a direct observation of the domain structure. The T.T.T. method, therefore, is proved to be a useful means to investigate the phase transition of aniline hydrobromide.

§ 7. Conclusions

(1) A microscopic observation confirms the domain structure which has been concluded by the X-ray study. The domain structure is due to the monoclinicity as seen in WO_3, and disappears in the orthorhombic phase. The domain walls are all parallel to the bc-plane. These results obtained by microscopic observation support the conclusion given by the X-ray investigation. In addition, it is observed that the domain walls move easily under the influence of a weak shearing stress.

(2) The inclination of the optic elasticity axis to the c-axis in the b-plane, φ, varies reversibly with temperature. The variation of φ is continuous and gradual over a wide temperature range, and is similar to that of the axial angle β given by the X-ray study.

(3) The transparency also varies gradually and reversibly with temperature, and its variation is similar to that of the axial angle β. Such a behavior can clearly be understood on the basis of the domain structure and of crystal optics. Accordingly, aniline hydrobromide seems to be another typical example which proves the T.T.T. method as a useful means of optical study of phase transition.

(4) The refractive indices vary slightly with temperature. The crystal of aniline hydrobromide is optically negative in both the high and low temperature modifications.

Acknowledgments

This work has been carried out under the guidance of Professor T. Horie, to whom the author wishes to express his sincere gratitude. The author wishes to express his sincere gratitude to Professor T. Watanabe for his valuable suggestions and kind advice. The author also wishes to express his sincere thanks to the late Dr. I. Taguchi for useful discussions and facilities for the preparations of specimens. He is much indebted to Dr. K. Kawabe of Kobe University and Dr. H. Akao for their useful discussions and criticisms.

Appendix

Correction for Non-Flatness of c-Face

1) *Elliptic section:* The incident and the refracted wave fronts are denoted by OA and A′P, respectively in Fig. 6. If assumed AA′=1, the coordinates (x_1, z_1) of the point A′ are given by

$$x_1 = -\frac{\cos(\varphi+\Delta\beta)}{\sin\Delta\beta}, \quad z_1 = \frac{\sin(\varphi+\Delta\beta)}{\sin\Delta\beta}. \tag{3}$$

If the coordinates of P are denoted by (X, Z), the following equation are obtained at once:

$$n_z^2X^2 + n_x^2Z^2 = 1, \quad n_z^2Xx_1 + n_x^2Zz_1 = 1\,. \tag{4}$$

Let θ_1 be the angle between the direction of the refracted ray and the z-axis. Then

$$\tan(\varphi+\theta_1) = \frac{X}{Z}\,. \tag{5}$$

From these five equations we have

$$\tan\theta_1 = \left\{\left(\frac{n_x}{n_z}\right)^2 - 1\right\}\varphi + \left(\frac{n_z}{n_x}\right)^2\left(1 - \frac{1}{n_x}\right)\Delta\beta + \mathrm{O}(\alpha^3)\,, \tag{6}$$

where $\mathrm{O}(\alpha^3)$ means the term of higher powers than the third in φ and $\Delta\beta$.

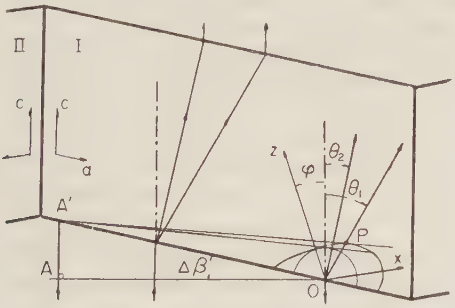

Fig. 6. Optical paths in the monoclinic phase (case of zig-zag boundary surface).

2) *Circular section:* If the angle between the direction of the refracted ray and the z-axis is called θ_2, a calculation similar to that mentioned just above leads to the following equation:

$$\tan\theta_2 = \left(1 - \frac{1}{n_y}\right)\Delta\beta + \mathrm{O}(\alpha^3). \tag{7}$$

The apparatus is insensitive to the beams deflected from the direction of incidence to the side by angles larger than 1°30′. According to a calculation similar to the case of barium titanate based upon crystal optics, the wave with elliptic section which encountered a domain boundary does not fall upon the detector at least below 25°C. As for the case of circular section, such a condition is satisfied at least below 20°C. Hence the relation (1′) holds at least below 20°C.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN, Vol. 16, No. 9, SEPTEMBER, 1961

On the *R* Centers in Lithium Fluoride

By Akizo OKUDA

Department of Mathematics and Physics, Ritsumeikan University, Kyoto

(Received June 2, 1961)

In colored LiF crystals, two bands at 320 and 378 mμ have been investigated and assigned as R_1 and R_2 bands by the correspondences to R bands in other alkali halides. Intensity ratio of the R_1 band to the R_2 band is almost constant irrespective of irradiation conditions of β- or γ-rays as well as of photochemical treatments. Both the bands are bleached by irradiation with either R_1 or R_2 light, where the former has a higher efficiency for the bleaching. The results support the interpretation that R_1 and R_2 bands are due to transitions in the same center. Emission spectra by excitation with R_1 and R_2 lights are distinct: the latter has a peak at 495 mμ and the former at 730 mμ or above.

By polarized R lights, dichroism is induced in the R_1, R_2 and M bands and also polarization of the emissions is observed. Then symmetries of the models which have been proposed as complexes of F centers are examined by the experimental results and it is considered that F_3-model lying in [111] plane is the most adequate for R center. In addition to characteristic M-center luminescence, which has a peak at 710 mμ and value of 0.6 for P[011], an emission band at 525 mμ is observed by M-light excitation but P-factor for this emission is less than that of the M-center luminescence.

§ 1. Introduction

In the alkali halides, it is well known that M-, R_1-, and R_2-absorption bands, which appear on long-wavelength side of F band, are due to transitions in the electron-trapped centers. Among them M band has extensively been studied by many authors and the model of M center has fairly definitely been explained.

However, two essentially different interpretations have been put for R bands. In 1946, Seitz[1] first proposed that the R_1 and R_2 bands arise from the F_2^+ and F_2 centers, respectively, consisting of one and of two electrons trapped at a pair of adjacent negative-ion vacancies. But afterwards, Herman, Wallis, and Wallis[2] observed constant intensity-ratio of R_1 and R_2 bands and considered that both R bands arise from transitions in the same center. Furthermore, from the theoretical calculations based upon Seitz's model, they concluded that F_2 center is responsible for both R bands. Van Doorn[3] proposed single F_3-model lying in the [111] plane from anisotropic behavior of R-band emissions in KCl and NaCl crystals. Recently, Pick[4] proposed a new idea for the F-center associations and suggested three distinct transition moments for R centers on the basis of the F_3-model.

On the other hand, Lambe and Compton[5] observed temporary bleaching effects of R bands in NaCl crystals under strong auxiliary lights and interpreted R_1- and R_2-absorption bands as the transitions in distinct centers. Subsequently, Compton and Klick[6] studied more extensively the temporary bleaching and concluded that R, M, and N centers are located near each other but one cannot decide from the temporary bleaching experiments whether both R_1 and R_2 bands are transitions in two distinct centers or two transitions in the same center.

In the previous paper, the author and others[7] have shown that R_1 and R_2 bands in LiF crystals are due to two transitions in the same center, the symmetry axis of which lies along the body diagonal of the crystal. In the present paper, the detailed results will be reported on correlations between R_1 and R_2 bands under various conditions in Part I, and on anisotropic behaviors of the absorption and luminescence of R bands in Part II. Hitherto the assignment for R_1 and R_2 bands in LiF crystal has not been confirmed[8] and no information concerning the luminescence of *R* centers has been reported. Therefore, the results will also be reported with these respects in Part I.

Usually *R* bands are produced by optical bleaching of *F* band in additively colored crystals or by prolonged irradiation with ionizing radiation. In the case of LiF crystals, however, the additive coloring could not be realized by ordinary procedure, so that in the course of the present work only ionizing radiations were employed for the coloration of the crystals.

§ 2. Experimental Procedure

LiF materials were purified and prepared from LiCl and NH_4HF_2 and single crystals of LiF were produced by Kyropoulos' method from the melts in a vacuum-type furnance whose inner atmosphere was circulated with dried nitrogen gas of low pressure[9]. Samples of about 0.3~1 mm in thickness were cleaved from the crystals. Most samples in this work were colored by exposure to 1-Mev electrons from a Van de Graaff accelerator. In this case, the exposure times and intensities of the flux were varied to obtain appropriate concentration of color centers, where the temperature of the samples was kept at −70°C or at room temperature before the exposure but it was raised under exposure. Some samples were colored by exposure to γ-rays from Co^{60} at room temperature.

The optical absorption for the colored samples was measured with a modified Shimadzu Model QR or Beckman Model DU spectrophotometer. For the purpose of bleaching colored samples, a xenon-arc lamp of 500 watts or a high pressure mercury lamp with quartz envelope was used through a quartz prism monochromator (aperture, $F=2.5$) or suitable filters.

Emission and excitation spectra were obtained by the arrangements shown in Fig. 1. In this figure M I is the Shimadzu Model QR monochromator and M II is the quartz prism monochromator which is used for excitation in the emission-spectrum measurement and for filtration of the luminescence in the excitation-spectrum measurement. An RCA 1P28 photomultiplier or a Toshiba 7305 photomultiplier with a D.C. amplifier was used depending upon the spectral location investigated, and in some cases a Toshiba PT-25-V1 phototube was employed as a check. As the light source for the excitation of luminescence, the xenon-arc lamp or a tangsten lamp was employed, and the emission and excitation spectra were corrected by a thermopile.

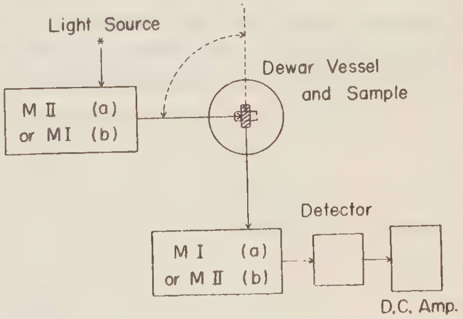

Fig. 1. Experimental arrangements used for studying the luminescence. (a) For measurement of emission spectra. (b) For measurement of excitation spectra. M: monochromator.

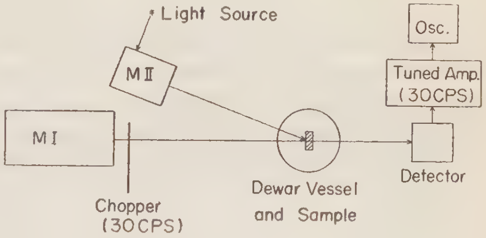

Fig. 2. Experimental arrangement used for studying the effect of temporary bleaching. M: monochromator.

Temporary bleaching effect was studied with the arrangement shown in Fig. 2. The experimental technique used in this measurement was similar to that used by Lambe and Compton except the direction of auxiliary light. The change in transmission of sample induced by irradiation with intense auxiliary light was measured at a given wavelength. The light for the transmission measurement was chopped at 30 cps and the detector was also tuned for this frequency, where the xenon-arc lamp was used as the auxiliary light source.

In order to investigate the anisotropy of color centers, dichroism induced by irradiation with polarized light was measured with a Foucault- or Nicol-prism polarizer. Further, polarization of luminescence was measured with the arrangements shown in Fig. 3. (a) is that for R_1- and R_2-band emissions, where two suitable filters are inserted in the optical path; and (b) is that for *M*-band emission, where the spectral distribution of the degree of polarization is measured through the monochromator (M I). In these cases the Foucault- or Nicol-prism, or a polaroid was employed as the polarizer depending upon the spectral location of exciting lights, and a polaroid was used as the analyzer.

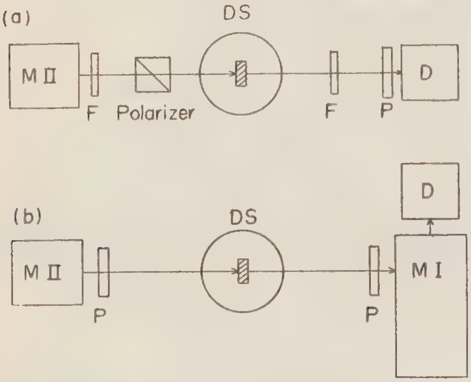

Fig. 3. Experimental arrangements used for the measurements of the polarization of luminescence. (a) For *R*-band emissions. (b) For *M*-band emission. M: monochromator, F: filter, P: polaroid, DS: dewar vessel and sample, D: detector.

In low temperature measurements, the samples were kept at liquid air temperature by using a Dewar vessel with three windows of quartz plate.

I. Absorption and Luminescence

§ 3. Experimental Results

3.1 *Absorption*

After prolonged or intense exposure to Van de Graaff electrons or γ-rays, LiF crystals showed two absorption bands at about 320mμ and at 378 mμ in the region between *F* band at 248 mμ and *M* band at 447 mμ at room temperature. Although the assignment for *R* bands in LiF crystals has not been confirmed, we tentatively assume that the two bands correspond to R_1 and R_2 bands, respectively, according to Penneman and Powers[10]. It will be shown in the next paragraph that this assignment is correct. In addition to these *R* bands, another weak and broad band with peak at 350 mμ appeared immediately after the ionizing radiations, but this band was so unstable that it was bleached out, scarcely affecting R_1- and R_2-band intensities, by brief exposure to ultraviolet light or by preserving at room temperature for a few days[11].

The relative intensities of *F*, *R* and *M* bands after electron bombardment or γ-ray

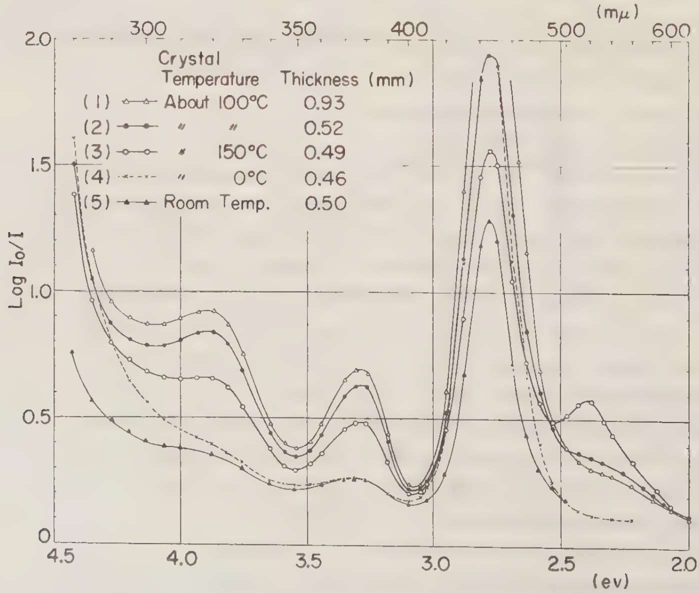

Fig. 4. Absorption spectra of several LiF crystals exposed to Van de Graaff electrons, (1)—(4), or γ-rays, (5). The measurements were made at room temperature.

irradiation differed depending upon the irradiation conditions, for instance, irradiation time or crystal temperature. In the case of electron bombardment, R bands prominently appeared at crystal temperature of about 100°C and only weakly at the temperature lower than 0°C or higher than 200°C, with about 10^8 rad exposure. In these cases it was noticed that the intensity ratios of R_1 and R_2 bands (R_1/R_2) are essentially constant irrespective of irradiation conditions, that is, of concentrations of other centers. Fig. 4 gives the absorption curves in several colored samples. The ratios in some crystals are not certain, because of overlapping of the R_1 band and F-band tail and rise of the background in this region.

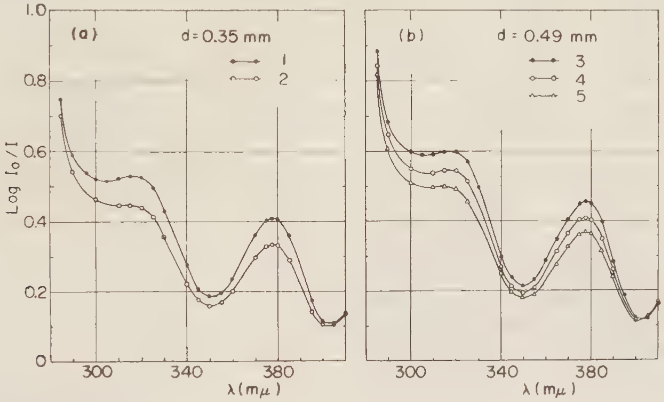

Fig. 5. Optical bleaching of R-bands in LiF crystals by irradiation (a) with R_1-light and (b) with R_2-light, at room temperature. (1) Absorption before irradiation in a crystal. (2) After irradiation with 330 mμ light. (3) Absorption before irradiation in another crystal. (4) After irradiation with 385 mμ light, and (5) further with 365 mμ light. Measurements were made at room temperature.

When a colored sample exhibiting R bands was exposed to R_1 light (330 mμ, band pass ~10 mμ) at room temperature, both R_1- and R_2-band intensities were decreased together and M-band intensity was enhanced. The same effect was observed when a sample was exposed to R_2 light (365 mμ or 385 mμ, band pass~20 mμ). These results are given in Fig. 5 and it is found that the ratios of decrements in R band intensities, $-\Delta R_1/(-\Delta R_2)$, are essentially constant as shown in Fig. 6, about 1.2. When a sample was exposed to R_1 light at 100°C and absorption was measured at room temperature, the above ratio was almost unaltered. By the successive irradiation with R_1 light at room temperature, R bands were gradually decreased maintaining the above relation, and in final stage at which the R bands were almost bleached, the ratio was still nearly uncharged and the peaks of the bands did not seem to shift in the course of bleaching. The typical absorption spectra observed at liquid air temperature will be shown just later (Fig. 9). It was observed in the above bleaching experiments that both R bands are more effectively reduced by R_1 light than by R_2 light. The relative efficiency of the bleaching for absorbed quanta is shown in Table I, making use of the results in Fig. 5, where R-light intensities are corrected by a thermopile.

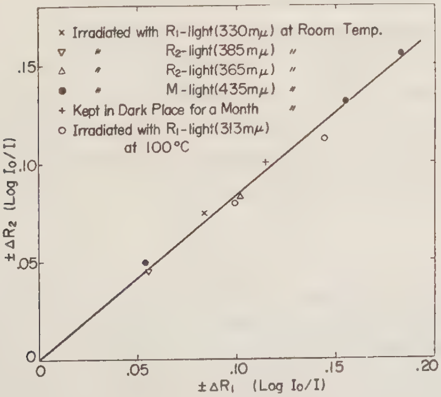

Fig. 6. Relation between the increment or decrement of R_1- and R_2-band peaks in several LiF crystals after various treatments, measured at room temperature.

Table I. Relative efficiency of the bleaching of R bands for absorbed quanta, at room temperature.

Irradiating light	Efficiency
330 mμ	1.0
365 mμ	1.8×10^{-2}
385 mμ	7.4×10^{-3}

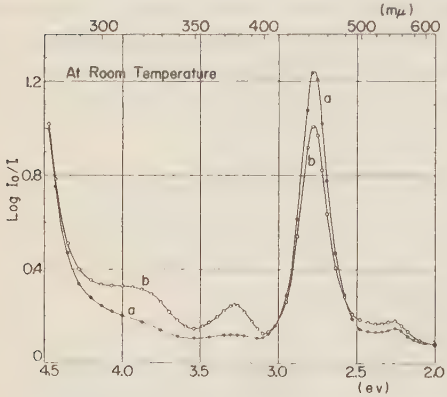

Fig. 7. Developing of R bands by irradiation with M light. (a) Absorption after irradiation with R light. (b) Absorption after subsequent irradiation with M light (435 mμ line of mercury arc), at room temperature.

Two observations were done after the R-bands bleaching with R_1 light. First, when a sample was irradiated by intense M light (435 mμ line of mercury arc) at room temperature, M-band intensity was reduced and R-band intensities were again increased as shown in Fig. 7*. Second, when a sample was kept in dark place at room temperature for a few months, the same effect was observed. In these cases the ratio of increments in R-band intensities, $\Delta R_1/(\Delta R_2)$, was again equal to that obtained in the bleaching experiments as shown in Fig. 6. The M band developed with R_1-light irradiation was more easily bleached by M-light irradiation than ordinary M band in the crystals which had not been irradiated by R light beforehand.

A colored sample exhibiting R bands was thermally pulse-annealed as follows: the sample was placed for two minutes at a high temperature and cooled quickly to room temperature at which absorption was measured. Starting from room temperature, the annealing temperature was raised by 20°C in successive processes. Then, the R_1 and R_2 bands began to bleach at the same temperature of about 200°C, as shown in Fig. 8. But in this case the ratio of decrements was uncertain because of the rise of background on the R_1-band region**.

After electron bombardment, absorption

---

* When colored crystals were irradiated simultaneously by the lights in R and M bands (for instance, carbon or mercury arc with suitable filter), a weak band with peak at about 375 mμ and a fairly strong band with peak at 550 mμ, which might correspond to N band, were developed on short-wavelength side of R band and long-wavelength side of M band, respectively.

** This may be attributed to a colloidal band with peak at 270 mμ[8].

spectra of samples showed fine structure in the R_2-band region at liquid air temperature as reported by Delbecq and Pringsheim[8]. A typical absorption spectrum is given in Fig. 9 curve (a). The appearance and regular spacing of the peaks of about 240 cm^{-1} are in accordance with those already reported. When the absorption spectrum at liquid air temperature is compared with that at room temperature given in Fig. 9 curve (a′), the peak of R_2 band does not shift in contrast with the peak of R_1 band which shifts to short-wavelength side at low temperature. When the sample was irradiated by R_1 light at room temperature like the above procedure and the absorption was measured at liquid air temperature, the fine-structure intensity was decreased in company with the decrease in the R_1- and R_2-band intensities as shown in Fig. 9 curves (b), (c) and (d). It seems that also one proportionality is maintained for the R_1, R_2 and the fine-structure intensities in each stage. Again, when the sample was irradiated by M light at room temperature and the absorption was measured at liquid air temperature, then the fine structure also appeared in company with the R_1 and R_2 bands.

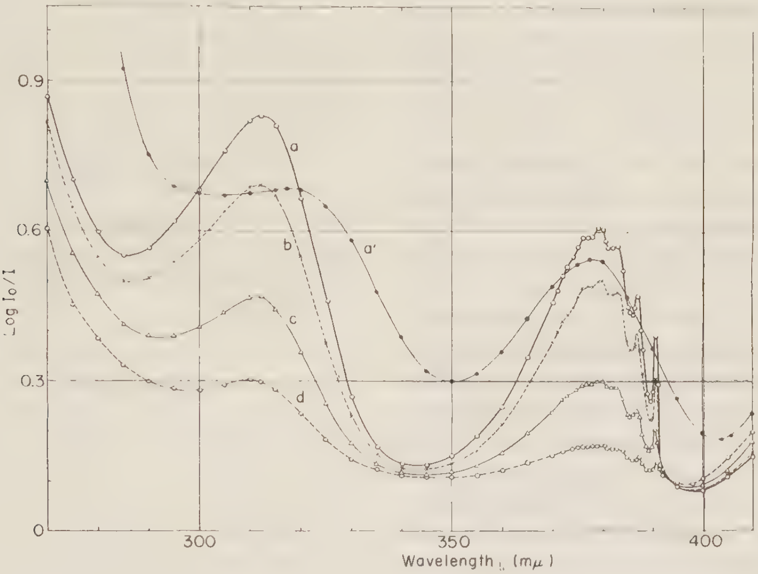

Fig. 9. Variation of the R bands and the fine structure by irradiation with R_1 light (320 mμ) at room temperature. (a) and (a′) Initial state measured at liquid air and room temperature, respectively. (b) After irradiation for 3 minutes, measured at liquid air temperature. (c) and (d) After irradiation for 13 and 53 minutes, respectively, measured at liquid air temperature.

No bleaching of R bands was observed by the irradiation with R light at liquid air temperature. On the other hand, temporary bleaching effects of crystals were observed by auxiliary R_2-light at liquid air temperature, and not by auxiliary R_1-light, which is probably due to weak intensity of R_1 light. A typical result is shown in Fig. 10. It is seen that the magnitudes of bleaching for R_1 and R_2 bands are nearly equal and also some changes in absorption are induced in other spectral region. The temporary bleaching

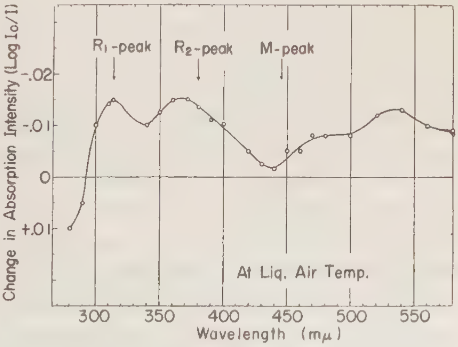

Fig. 10. Temporary change in absorption induced by irradiation with light in the R_2 band.

was not observed at room temperature.

3.2 *Luminescence*

When LiF crystals showing R bands were excited with light in R_1 or R_2 band at liquid air and room temperatures, luminescence was observed. The emission spectra observed at liquid air temperature are shown in Fig. 11. Curve (a) is that excited with R_1 light and has a peak at 730 mμ or above; curve (b) is that excited with R_2 light and has two peaks, the one at 495 mμ and the other at 710∼730 mμ, whose intensity is lower than that of the former, and by spectrographic examinations no fine structure was observed in the R_1- and R_2-band emissions. Since the red emission excited with the R_1 or R_2 light is comparatively weak and the sensitivity of the photomultiplier used in this work is depressed at longer-wavelength region than 700 mμ, locations of the emission peaks observed in this region are uncertain to some extent.

Luminescence excited with the M light was measured since the LiF crystals exhibiting the R-band luminescence showed fairly intense M-band absorptions and also intense emissions by excitation with M light. The spectrum has two peaks at 525 mμ and at 710 mμ, as shown in Fig. 11 curve (c) and the intensity ratio of the former to the latter differed in different samples.

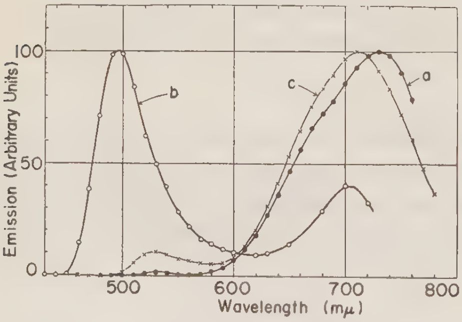

Fig. 11. Emission spectra of a LiF crystal. (a): excitation with R_1 light (315 mμ); (b): with R_2 light (380 mμ); (c): with M light (450 mμ). Measurements were made at liquid air temperature.

No significant difference was observed between the emission spectrum at liquid air temperature and that at room temperature in a crystal, but at room temperature the red emission excited by R_2 light increased partly because of the overlapping of R_2- and M-absorption bands and the resolution of two emission bands excited by M light was lowered. In general, emission excited by M, R_1 or R_2 light was quenched in the crystals containing very high concentration of centers both at room and low temperatures.

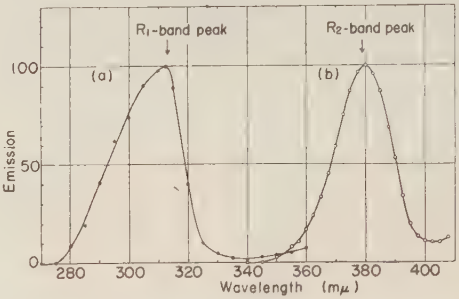

Fig. 12. Excitation spectra for R_1- and R_2-band emissions at liquid air temperature. (a) For R_1-band emission (650 mμ). (b) For R_2-band emission (495 mμ).

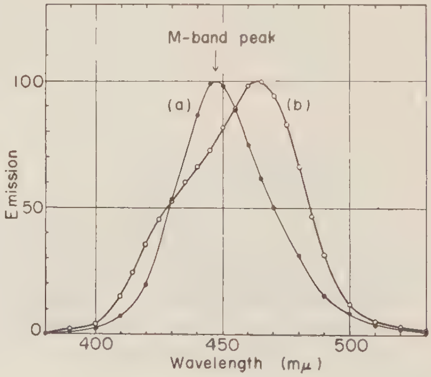

Fig. 13. Excitation spectra for M-band emission at liquid air temperature. (a) For 650 mμ emission. (b) For 525 mμ emission.

Excitation spectra for the luminescence were measured at liquid air temperature. In Fig. 12, (a) gives excitatian spectrum of R_1-absorption region for 650 mμ emission (band pass∼40 mμ) which is the peak of the R_1 emission with the detector used*. It is seen that the peak of the spectrum almost coincides with that of R_1-absorption but the long-wavelength tail is weakened in contrast with the absorption. (b) gives that of R_2-absorption region for 495 mμ emission (band pass∼25 mμ). It is seen that the peak and half width coincide with those of R_2-absorption band, but the fine structure, which is observed in absorption spectrum, is not detected. The excitation spectra of *M*-band region for 650 mμ emission (band pass$\sim$40 mμ) and for 525 mμ emission (band pass$\sim$30 mμ) are shown in Fig. 13. In the former the peak and half width almost coincide with those of *M*-absorption band, but in the latter the peak shifts to long-wavelength side of *M*-absorption peak and a small hump is also observed on short-wavelength side.

---

* Photomultiplier 7305.

As described in the foregoing section, *M* band is enhanced by irradiation with R_1 light and as mentioned above, the emission spectrum excited by *M* light has two peaks. So it is desirable to observe the change in the luminescence after the enhancement of *M* band. The result is shown in Fig. 14. It was found that after the enhancement of *M* band, the intensity of the 710 mμ emission band was increased while that of the 525 mμ emission band was almost unchanged.

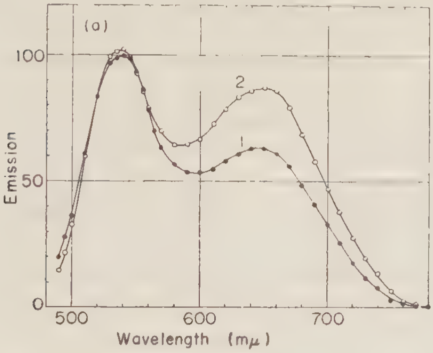

Fig. 14(a).

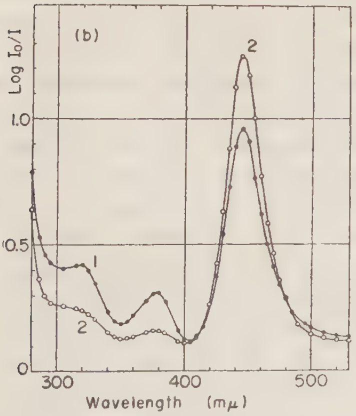

Fig. 14(b).

Fig. 14. Variation of *M*-band emission and of *M*-absorption band. (a) Emission spectra excited with *M* light (450 mμ). (b) Absorption spectra. In both figures, (1): initial state; (2): after irradiation with R_1-light at room temperature. Measurements were made at room temperature. In the emission spectra, the ordinate represents direct signal of the detector.

On the emission excited by *M* light in LiF crystals, its peak has been reported as 650 mμ by Molner[12] and as 705 mμ by Klick[13] using densitometer trace of film. Now, in the present work two emission bands were observed by excitation with *M* light and the 525 mμ emission band was comparable to the 710 mμ emission band only in such crystals that intensities of *M*-absorption band were very weak. This fact and the results of excitation spectra lead to the consideration that the 710 mμ emission band is responsible for *M*-center luminescence. This consideration will also be justified by the degree of polarization for the luminescence in Part II.

In the crystals used for measurements of *R*-band emissions, no strong absorption other than *M* and *R* bands was observed in the region of longer wavelength than 300 mμ. Therefore, on R_1-excitation, the emission with peak at 730 mμ or above may be due to R_1-luminescence—transition from R_1-excited state to ground state—but it might also contain some component of the *M*-center luminescence, since the R_1-band emission coincides on short-wavelength side with the 710 mμ emission band observed by *M*-excitation. Then, on R_2-excitation, the emission with peak at 495 mμ may be due to R_2-luminescence and the red emission to R_1-luminescence or to *M*-center luminescence.

§ 4. Discussions

4.1 *Assignments for R_1 and R_2 bands*

First, Penneman and Powers proposed the classification of absorption bands in colored LiF crystals and they designated the absorption bands at 313 mμ and 380 mμ as R_1 and R_2 bands, respectively. Afterwards, Delbecq and Pringsheim[8] suggested that these assignments were suspicious because of the peculiarity of these bands. That is, the so-called R_2 band (380 mμ band) is accompanied by the fine structure and these bands are unstable with ultraviolet light. These phenomena are not the case for *R* bands in other alkali halides[12].

In the present paper we have tentatively assumed that the absorption bands at 320 mμ

and at 378 mμ are R_1 and R_2 bands, respectively. Now the experimental results in § 3 indicate that the properties of these bands agree, in many respects, with those which have been reported for R bands in other alkali halides: a) The bands at 320 and 378 mμ lie between F and M bands, and no other absorption band is appreciable in this region except for these bands which are fairly stable under various conditions. b) The bands appear in later stages of coloration by ionizing radiation, that is, the centers, which are responsible for these bands, are produced after the production of F and M centers[1]. c) The intensity ratio of these bands seems to be essentially constant under various conditions. This phenomenon corresponds to that observed in KCl and other crystals[2),14)]. d) In the experiment of pulse annealing the bands are more unstable than F or M band. It has also been reported that R bands in additively colored KCl crystals are more unstable than F and M bands[15]. The results of the present work, however, seem to combine in some extent with the effect of bleaching of V-type centers, since some bleachings of M and F bands are observed simultaneously with that of R bands. e) After irradiation with light in the so-called R_1 band polarized along [011] direction, both bands show dichroism in directions along [011] and [0$\bar{1}$1] in the same sense, which was previously reported and will be considered again in detail in Part II. This effect has also been observed in KCl crystals[16]. Further, these bands are developed together by irradiation with the light in F band, as pointed out by Delbecq and Pringsheim[17].

The R bands in LiF crystals are unstable with R light at room temperature, contrary to those in other alkali halides. However, R bands in NaCl are temporary unstable under irradiation with R light at low temperature like those in LiF. Hence the difference in optical stability of R bands at room temperature may result from secondary effects in these crystals. Therefore, although some peculiarity still remains in the fine structure which is observed at low temperature in the R_2-band region, it may be considered that the structure is characteristic to R centers in LiF crystals.

4.2 *Correlation between R_1 and R_2 bands*

Delbecq and Pringsheim reported that the bands at 320 mμ and 380 mμ appear together after irradiation with a short-wavelength ultraviolet ($\lambda < 253.7$ mμ) and decrease with subsequent irradiation of X-rays and disappear together after irradiation with a long-wavelength ultraviolet ($\lambda = 300 \sim 400$ mμ) or after heating to 100~200°C. In the foregoing section, these bands have just been assigned as R_1 and R_2 bands, so that a very intimate relation seems to exist between R_1 and R_2 bands.

As described in § 3, it has been found that both R bands are bleached together with a constant ratio of decrements in their intensities, $-\Delta R_1/(-\Delta R_2)$, by irradiation with light in either of R_1 or R_2 band at room temperature; and especially by the R_1 light irradiation, this relation is unaffected until the greater parts of R_1 and R_2 bands are bleached. These results certainly indicate that R_2 and R_1 bands are due to transitions from the ground state to a first excited state and to a second excited state, respectively, supporting rather the suggestion by Herman *et al.* than the consideration by Lambe and Compton that two distinct R_1 and R_2 centers are intimately connected in the crystal.

Other results supporting this consideration are summarized as follows: R_1 and R_2 bands are produced with a nearly constant ratio of their intensities (R_1/R_2), irrespective of processes of the formation (exposure to γ-rays or electron bombardment, or M-light irradiation after bleaching of R centers) and of concentrations of other centers (F, M or presumably N centers). Further, in thermal treatment, both R bands begin to bleach together at the same temperature. In R bands bleaching with R lights at room temperature, the efficiency of bleaching is higher for the light in the band of higher-energy side, as shown in Table I. In this connection, it is of interest to note that in KCl crystals, Cole and Friauf[18] have reported a higher quantum efficiency of photoelectron for R_1 band than for R_2 band.

It has been found that different emission bands are observed in the LiF crystal by the excitations with R_1 and R_2 lights as decribed in § 3, while the same emission has been reported by R_1- and R_2-light excitations in KCl or NaCl crystal5),19). This fact may indicate that the correlation between the configuration coordinate curves of energy for R_1 and R_2 states in LiF crystal somewhat differs from that in KCl or NaCl crystal. Being compared with the spectral locations of M-band emissions, R_1-emission in LiF crystal might correspond to the R-emissions reported in KCl or NaCl crystal.

The absorption of R bands is complicated at low temperature. The fine structure in the region of R_2 band rises and falls together with R bands, following the destruction and formation of R centers by R_1- or M-light irradiation as described in § 3, or by F-light irradiation8). While, the structure has not been detected in the excitation spectrum of R_2-band region in the present study. Thus it is difficult to decide whether the structure is associated with the R_2 band itself or not. If the structure is not associated with the R_2 band, it may correspond to some vibrational levels in any other electronic transition than R_2 transition and it may be possible, though not yet confirmed, that the structure appears in a region outside of R_2 band in other alkali halides. On the other hand, if the structure is associated with the R_2 band, it may be expected that no structure is observed in other alkali halides with the slight difference of configuration coordinate curves described above. In this case, the configuration coordinate curves of excited R_1 and R_2 states may cross one another and only the R_2 state which does not interact with R_1 state may have clearly-resolved levels of vibration as in the case of LiF. In fact, the structure in LiF is quite obscure in high-energy side, as shown in Fig. 9.

4.3 *Correlation with other centers*

In the results of temporary bleaching, any change of absorption other than those of R bands might be contained in the R-bands region. In general, however, the magnitudes of bleaching for R_1 and R_2 bands are nearly equal in accordance with the foregoing discussion that both bands are due to transitions in the same center. Nevertheless fairly strong correlations seem to exist between the R centers and other centers, as suggested by Compton and Klick6). It is observed that intensity on higher-energy side than the R_1 band is enhanced under the irradiation with R_2 light and the same effect has also been observed in NaCl crystals. This effect is probably attributed to the production of F centers by the action of R_2 light.

M-center luminescence might be contained in the emission with R_1-light excitation, as described in § 3.2. If this is the case, the experimental result that the excitation spectrum is weak in intensity on long-wavelength side compared with R_1-absorption band might be interpreted as follows: M-center luminescence may more participate on the high-energy side of R_1 band, because M centers, in general, seem to have a high efficiency for the luminescence. However, such a hypotheticalconsi deration will need finer experiments, in which the R_1 and M luminescence could be observed separately.

After the bleaching of R bands by R_1-light irradiation at room temperature, the intensity of M band is increased and at the same time the intensity of M-band emission with peak at 710 mμ is also enhanced. It is considered, therefore, that M centers are produced with destruction of R centers in the course of the bleaching. The results and discussions concerning M band will be summarized in Part II.

II. Anisotropy of *R* Center

§ 5. Experimental Results

5.1 *Preferential bleaching*

When LiF crystals showing R bands were irradiated with the R_1 light polarized along [011] direction at room temperature, the absorption intensities of both R_1 and R_2 bands polarized along [011] were more reduced than those polarized along $[0\bar{1}1]$, as previously reported7). The decrement ratios in intensity for both directions, $-\Delta R_i[0\bar{1}1]/(-\Delta R_i/011])$, are approximately equal for R_1 and R_2 bands and estimated to be about 1/2～1/3 in early stage of the bleaching. As the irradiation with polarized R_1 light was prolonged, the absorption intensities for both directions and also the amounts of dichroism continued to reduce, as shown in Fig. 15. After dichroism was induced for both R bands in a crystal by the irradiation with [011]-polarized R_1 light, the crystal was kept in dark place for about thirty days at room temperature. Then, it was found that the absorptions in both directions were increased by the same amount in optical density, in either case of R_1 and R_2 band, as shown in Fig. 16. This fact may indicate that apparent re-orientation does not take place in the ground state of R center at room temperature. It has already been reported that when KCl crystals are irradiated with [011]-polarized R lights, weak dichroism appears in the same sense by nearly the same amount, for both R bands[16]. Being compared with the dichroism in KCl crystals, the above results of LiF crystals also give a support for the assignment of R bands in LiF crystal, as described in § 4.1.

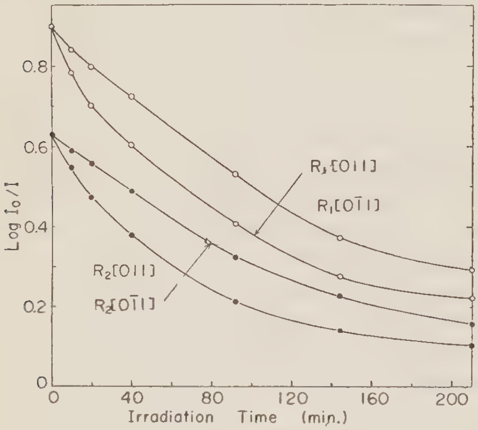

Fig. 15. Preferential bleaching of R_1 and R_2 bands in a LiF crystal by irradiation with the R_1 light polarized along [011] at room temperature.

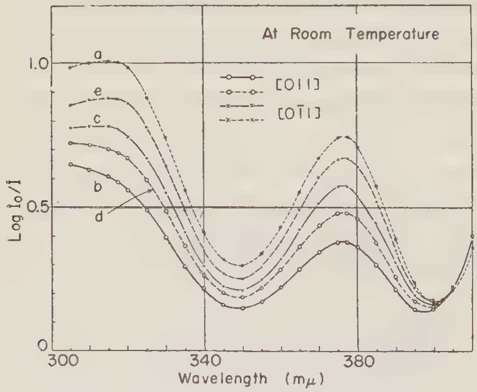

Fig. 16. Stability of the dichroism in R bands. Dotted curve, (a): initial state. Solid curves, (b) and (c): after irradiation with R_1 light polarized along [011] direction at room temperature. Dashed curves, (d) and (e): after the crystal being kept in dark place for a month at room temperature.

When LiF crystals showing R bands were irradiated with R_1 light polarized along [001] direction at room temperature, absorption intensities along [001] and [010] directions were reduced in both R bands, but no dichroism was observed in them.

After irradiation with [011]-polarized R_1 light, dichroism in [011] and [01̄1] directions also appeared in the region of M band but the sign was reverse to that of the R-band dichroism as shown by solid curves in Fig. 17. Then, the crystal was subsequently irradiated by unpolarized M light and as shown by dotted curves in Fig. 17, the dichroism of M-band region almost disappeared, while the R-band intensities along both directions increased scarcely altering the magnitudes of dichroism.

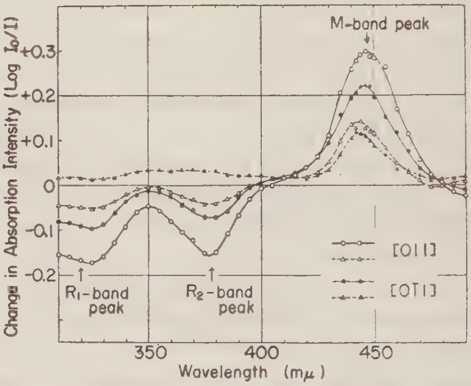

Fig. 17. Changes in absorption intensity on the region of M and R bands polarized along [011] and [01̄1], respectively. Solid curves: after irradiation with R_1 light polarized along [011]. Dotted curves: then after irradiation with unpolarized M light (450 mμ). The original M-band intensity was 1.18. The measurements and bleachings were made at room temperature.

5.2 *Polarization of luminescence*

The polarization of the luminescence of R and M bands were studied in several samples. Exciting light incident upon [100] face of the crystal was polarized first in the [011] direction and then in the [001] direction with the polarizer. Then the emission intensities $I_{\parallel}$ and $I_{\perp}$ were measured with the analyzer parallel and perpendicular to the polarizer, respectively. The degree of polarization expressed as P-factor is given by

$$P[ijk]=\frac{I_{\parallel}-I_{\perp}}{I_{\parallel}+I_{\perp}},$$

Table II. The *P*-factor of the luminescence in LiF crystals excited by polarized *R* lights, at liquid air temperature.

Exciting light	*P*[011]	*P*[001]
R_1 band	0.34～0.39	0.23～0.29
R_2 band	0.15～0.22	0.02～0.08

where [*ijk*] represents the direction of polarization for the exciting light. Results for the R_1- and R_2-band emission, which were obtained at liquid air temperature, are shown in Table II. The values vary in different samples as indicated, presumably due to the concentration of centers contained in each sample. In the above measurements of *P*-factor, it must be noted that R_1-band emission might contain *M*-center luminescence as described in § 3.2 and R_2-band emission might exclusively consist of R_2-luminescence*. Therefore, only *P*-factors of R_2-band emission are significant in the above results. These values are nearly the same as those reported in KCl and NaCl crystals$^{3),5)}$ and are quite small compared with the values which will be expected from the directions of optical dipole moments lying in the face diagonals of the crystal.

As for the *M*-band emission, spectral distribution of the *P*-factor was measured at room temperature. The result is shown in Fig. 18. It is seen that the values of *P*[011] are approximately 0.6 on long-wavelength side and gradually diminish on short-wavelength side.

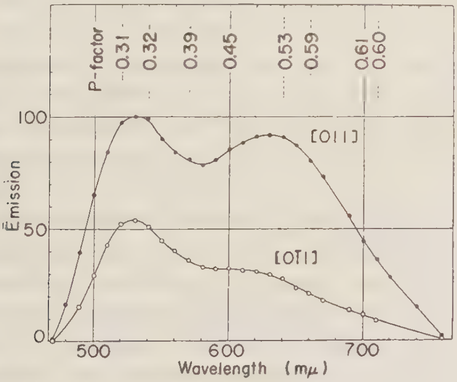

Fig. 18. Anisotropic spectra of *M*-band emission. Crystal was irradiated by *M* light (450 mμ) polarized along [011] direction at room temperature. The ordinate represents direct signal of the detector.

§ 6. Discussions and Conclusion

6.1 *Anisotropy of R center*

In Part I it has been shown that R_1 and R_2 bands in alkali halides arise from transitions in the same center. In this section, the optical dipole moments associated with the *R* absorptions will be considered in connection with the results obtained in the last paragraph and compared with the expected dipole moments of the models which have been proposed as *F*-center coagulations.

It is well known that if symmetry of a color center in an alkali halide is lower than cubic, the absorption shows some dichroism after preferential bleaching with polarized light and also the emission expected by polarized light shows some polarization. The changes introduced in absorption intensities can be calculated as shown by Compton and Klick$^{20)}$, provided that any re-orientation of the center does not take place in the course of the bleaching. Similarly, the *P*-factor of luminescence can be also calculated. These expected values are listed in Table III in the case of an optical dipole oriented along ⟨001⟩, ⟨011⟩, or ⟨111⟩.

As described in § 5, both *R* bands show dichroism in the same sense after bleaching by [011]-polarized R_1 light and no dichroism by [001]-polarized R_1 light. By comparing with Table III, it might be suggested that optical dipole associated with R_1 band is oriented along ⟨111⟩. However, the observed decrement ratios of 1/2～1/3 in the directions of face diagonal, $-\Delta R_1[0\bar{1}1]/(-\Delta R_1[011])$, are larger than the expected value. The expected value will be increased if re-orientation of the center takes place in the ground state, and lowered if it takes place in the excited state. From the experimental fact described in § 5, it may be considered that apparent re-orientation does not take place in the ground state, in the course of the bleaching with polarized R_1 light at room temperature. The above considerations may be also applicable to the dipole oriented along ⟨011⟩ direction. Besides, observed values of *P*[011] and *P*[001] for R_2 luminescence (Table II) are also dif-

---

* The photomultiplier 1P28 was used in this measurement and signal of the red emission with R_2 excitation was negligibly small compared with that of the R_2-luminescence.

Table III Anisotropy of absorption and luminescence expected from simple optical dipoles.

Direction of optical dipole moment	Irradiated with [011]-polarized light		Irradiated with [001]-polarized light	
	Initial ratio of decrements of absorption along $[0\bar{1}1]$ and $[011]$ $-\Delta[0\bar{1}1]/(-\Delta[011])$	$P[011]$	Initial ratio of decrements of absorption along $[010]$ and $[001]$ $-\Delta[010]/(-\Delta[001])$	$P[001]$
⟨001⟩	1/1	0	0	1.0
⟨011⟩	1/5	0.66	1/2	0.33
⟨111⟩	0	1.0	1/1	0

ferent from the values in Table III for the dipole oriented along ⟨111⟩ or ⟨011⟩ direction. Therefore, the experimental results may be inconsistent with the R_2-model proposed by Seitz or F_2-model, which consists of a pair of adjacent negative ion vacancies with two trapped electrons. In this model, at least one of the R bands is considered to associate with simple optical dipole oriented along ⟨011⟩. In fact, Herman *et al.* have suggested, from the theoretical consideration on hydrogen-molecular model of F_2 center, that R_1 and R_2 bands may correspond to ${}^1\Sigma_g{}^+ - {}^1\Pi_u$ and ${}^1\Sigma_g{}^+ - {}^1\Sigma_u{}^+$ transitions, respectively; the doubly degenerate ${}^1\Pi_u$ state may be splitted in the crystalline field, and the optical dipole moment of the transition ${}^1\Sigma_g{}^+ - {}^1\Sigma_u{}^+$ is oriented along the axis of the molecule—the face diagonal of the crystal—and those of the transition ${}^1\Sigma_g{}^+ - {}^1\Pi_u$ are perpendicular to the face diagonal. Therefore, it cannot be explained by the dipoles in this model that R_1 and R_2 bands show the dichroism in the same sense. Even if we assume that R_1 and R_2 bands correspond to two transitions whose upper states arise from a splitting of the degenerate ${}^1\Pi_u$ state, it may be also difficult to explain the experimental results. R_1-model proposed by Seitz or $F_2{}^+$-model, which consists of a pair of adjacent negative ion vacancies with a trapped electron, may be similarly situated as F_2-model.

These difficulties may arise from the models composed of two vacancies. Then, we consider centers composed of three vacancies. First, the center consisting of a pair of negative ion vacancies and an adjacent positive ion vacancy with a trapped electron—M-center model by Seitz[1] or Knox[21]—will be discarded from a consideration similar to the above discussion. For example, optical dipoles associated with A_1-B_1 and A_1-B_2 transitions in C_{2v} symmetry are oriented along ⟨011⟩ and ⟨001⟩ directions, respectively. Next, a center will be discussed which consists of three F centers lying in a [111] plane and has its symmetry axis along ⟨111⟩ direction. Such a model has been suggested for R center by van Doorn[3] and Pick[4].

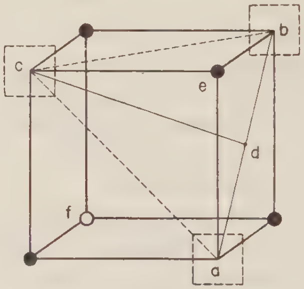

Fig. 19. F_3-model of R-center.

Fig. 19 gives the configuration of vacancies in this model, where a, b, and c mean negative ion vacancies, and the configuration has eight possible vacancy-orientations in the crystal (see, Fig. 20 in Appendix). The potential for a trapped electron in this configuration has the symmetry of C_{3v} and two types of transition may be considered; an optical dipole of one transition is oriented along the ⟨111⟩ symmetry axis of the center and that of the other transition, whose upper state is doubly degenerate, is in the [111] plane perpendicülur to the symmetry axis. Then it is assumed that the degeneracy of the upper state is removed by a distortion of the ionic arrangement with which the arrangement perhaps forms a isosceles triangle in the [111] plane and R_1 and R_2 bands correspond to transitions from the ground state to the two splitted states. The origin of the distortion

Table IV. Anisotropy of absorption and luminescence expected from the F_3-model.

	Irradiated with R_1 or R_2 light polarized along [011]		Irradiated with R_1 or R_2 light polarized along [001]	
	Initial ratio of decrements of absorption along $[0\bar{1}1]$ and [011] $-\Delta R_i[0\bar{1}1]/(-\Delta R_i[011])$	$P[011]$	Initial ratio of decrements of absorption along [010] and [001] $-\Delta R_i[010]/(-\Delta R_i[001])$	$P[001]$
R_1 band	1/1.66 (1/2~1/3)	0.25	1/1 (1/1)	0
R_2 band	1/1.66 (1/2~1/3)	0.25 (0.15~0.22)	1/1 (1/1)	0 (0.02~0.08)

Values observed in this work are indicated in parentheses.

might be attributed to a localized distribution of electron in the center. In such a situation, three ionic arrangements are producible for a vacancy orientation and the optical dipoles associated with the R_1 and R_2 bands may be approximately parallel to the face diagonal and perpendicular to it in the degenerate plane, for instance along *ab* and *cd* in Fig. 19, respectively, or *vice versa*, and potential barrier may be inconsiderable between two ionic arrangements in a vacancy orientation, in contrast with that of a vacancy re-orientation. Hence it is assumed that exchanges among three ionic arrangements (ionic re-orientation) frequently occur around the ⟨111⟩ symmetry axis in a vacancy orientation and, on the contrary, the vacancy re-orientations are scarcely realized, during the bleaching process at room temperature. Then the preferential bleaching by polarized light in such a model can be calculated by the procedure shown in Appendix. The results are listed in Table IV, indicating that the expected values in the [011] and [001] directions for both R bands are in good accordance with the experimental results. Further, provided that random ionic re-orientations occur in the excited states, P-factors of R_2 luminescence also agree with the experimental results as shown in Table IV.

It should be noted that the same anisotropy as described above will be expected if the F_3-model is associated with a positive ion vacancy, *e*, or a pair of positive and negative ion vacancies, *e* and *f*, in Fig. 19. Pick has considered perturbation of an F center within the F_3-model having C_{3v} symmetry and suggested that optical dipoles associated with R_1 and R_2 bands are parallel to the face diagonal of crystal and perpendicular to it in the [111] plane, respectively, and that the dipole associated with R_F band, which overlaps to F band, is parallel to the symmetry axis of ⟨111⟩. In the present treatments of R-center anisotropy, besides R_1 and R_2 bands, another band is also expected to appear and optical dipole associated with it may be approximately oriented along the ⟨111⟩ axis. Further, the same dichroism in both R dands will be induced by irradiation with [011]-polarized light in its band as also expected by Pick.

By making use of the F_3-model discussed above, the fine structure in R_2 band might be interpreted as follows: in the center there is a molecular-like bond inducing the distortion of C_{3v} symmetry and the bond is fairly isolated from lattice vibrations of the host crystal while it associates with a local vibration corresponding to the observed fine structure.

6.2 *Correlation with other centers*

As described in Part I, the M centers produced by R_1 light irradiation seem to be converted into R centers by M-light irradiation more easily than the M centers which have existed before R_1-light irradiation. This fact may suggest that an R center is decomposed by R_1-light irradiation into two nearly located components—an M center and some lattice defect, for instance an F center—and these components easily combine with each other by M-light irradiation and form an R center. In connection with the results of anisotropy of R center, the interaction of R center with other centers should be taken into consideration. As described in § 5, dichroism induced in the M band by [011]-polarized R_1 light almost disappears after subsequent irradiation with unpolarized M light and at the same time R bands recover scarcely altering the differences of intensities in [011] and [0$\bar{1}$1]. Hence, it is unlikely that the R-band dichroism induced by polarized R_1 light results from M centers located in the neighborhood and that also V-type centers are significant in the anisotropies of the R and M centers. Contrary to M and V-type centers, F centers might be important since high concentrations of F centers are contained in the crystals investigated. By reflecting upon the cubic symmetry of F centers, however, it may be considered that anisotropy of R centers could not be changed essentially by them. Further the dichroism in M band may be attributed to the M centers which are directly produced from R centers by polarized R_1-light irradiation and the M centers may be re-oriented in the process of recombination described above.

The interactions between R centers and other centers, however, may exist more or less, as reported in the temporary-bleaching experiment and the dichroism in KCl crystals[22], and these interactions might make the magnitude of dichroism and the value of P-factor diverge to some extent.

In addition to the 710 mμ emission band, the 525 mμ emission band is observed by excitation with M light and the excitation spectrum for this emission somewhat differs from the M-absorption spectrum. Further, the value of P[011] for this emission band is small compared with the value of 0.6 for the 710 mμ emission band*. These results support the conclusion that the 710 mμ emission band corresponds to M-center luminescence as described in §3. It is not possible to assign the origin of the 525 mμ emission but it is certain that M center possessing ⟨011⟩ symmetry does not act directly as an emitter for this emission.

6.3 *Conclusion*

It has been concluded in Part I that R_2 and R_1 bands are due to transitions from a ground state to a first excited state and to a second excited state, respectively, in the same center. Under the above conclusion, the experimental results of the dichroism and the polarization of luminescence have been examined by the models proposed so far on complexes of F centers. Then, as far as the symmetry of the center is concerned, F_3-model lying on [111] plane is more adequate for R center than F_2- or F_2^+-model, or M-center models proposed by Seitz and Knox. From the consideration of optical dipole moments in the F_3-model, however, it may be reasonable to accept the deviation of C_{3v} symmetry and the occurrence of ionic reorientation in the course of the bleaching or in the excitation.

Although the interaction between R centers and other centers might be fairly strong, it may be considered that experimental results concerning the dichroism of absorption and the polarization of luminescence are essentially due to anisotropy of R center itself.

Acknowledgements

The author wishes to express his cordial thanks to Prof. Y. Uchida and Dr. K. Fukuda of Kyoto University for their valuable discussions and encouragements throughout this work. His thanks are also due to Dr. E. Mukoyama of Toyo Rayon Co. and Mr. Y. Nakayama of Kyoto University for the facilities afforded in β-ray and γ-ray irradiations and to Mr. K. Asai for his assistance in the latter part of this work.

This work was partly supported by a grant from the Ministry of Education.

Appendix

On the F_3-model described in §6.1, the eight possible vacancy-orientations are separated into such two groups, A and B in Fig. 20, that each orientation in the group A or B has the same directional dependence of the optical dipoles upon the polarization of light.

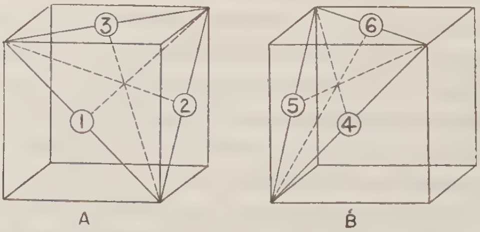

Fig. 20. Directions of optical dipoles associated with R_1 and R_2 bands in the F_3-model.

---

* The value of P[011] for the M-center luminescence has already been reported to be 0.6 by Lambe, Compton[5], and Feofilov[23].

Therefore it is sufficient to consider six ionic-arrangements in Fig. 20: 1, 2, and 3 in A; and 4, 5, and 6 in B, where dotted line in each arrangement means the symmetry axis of isosceles triangle in the distorted C_{3v}. First, we consider the case where optical dipole associated with R_1 absorption is oriented along the face diagonal of the crystal and that associated with R_2 absorption is perpendicular to it.

The R centers are oriented with equal concentration, n_0, in each ionic-arrangement in the group A and B before irradiation with polarized light. After irradiation with the [011]-polarized R_1 light, each n_0 may change into n_i, where subscript i means i-ionic arrangement in Fig. 20. If any vacancy re-orientation is not induced during the irradiation with R_1 light, the changing rate of n_i may be expressed as follows:

$$\frac{dn_1}{dt}=-n_1\beta+\frac{1}{\tau}(n_j-n_1)\,,\qquad \frac{dn_j}{dt}=-n_j\frac{\beta}{4}+\frac{1}{2\tau}(n_1-n_j)\,,$$

$$\frac{dn_4}{dt}=\frac{1}{\tau}(n_k-n_4)\,,\qquad \frac{dn_k}{dt}=-n_k\frac{\beta}{4}+\frac{1}{2\tau}(n_4-n_k)\,,$$

$$j=2,\ 3;\ k=5,\ 6$$

where $1/\tau$ is a frequency of the ionic re-orientation and β is a bleaching constant. If τ is very small, the concentrations are approximately given by

$$n_1=n_0\exp(-\beta t/2)=n_j\,,\qquad n_4=n_0\exp(-\beta t/6)=n_k\,.$$

Then, the absorption intensities of R_1 band in the [011] and [0$\bar{1}$1] directions are given as follows:

$$\kappa_1[011]=\frac{3}{2}\alpha_1 n_0\exp(-\beta t/2)+\frac{1}{2}\alpha_1 n_0\exp(-\beta t/6)\,,$$

$$\kappa_1[0\bar{1}1]=\frac{1}{2}\alpha_1 n_0\exp(-\beta t/2)+\frac{3}{2}\alpha_1 n_0\exp(-\beta t/6)\,,$$

where α_1 is a constant. By considering the angle between the direction of polarization and the direction of R_2 optical dipole, the absorption intensities of R_2 band are also calculated in both directions:

$$\kappa_2[011]=\frac{3}{2}\alpha_2 n_0\exp(-\beta t/2)+\frac{1}{2}\alpha_2 n_0\exp(-\beta t/6)\,,$$

$$\kappa_2[0\bar{1}1]=\frac{1}{2}\alpha_2 n_0\exp(-\beta t/2)+\frac{3}{2}\alpha_2 n_0\exp(-\beta t/6)\,,$$

where again α_2 is a constant. Then initial bleaching ratio in both directions can be estimated for R_1 and R_2 bands:

$$\frac{\Delta\kappa_1[0\bar{1}1]}{\Delta\kappa_1[011]}=\frac{\Delta\kappa_2[0\bar{1}1]}{\Delta\kappa_2[011]}=\frac{3}{5}\,.$$

This means the same sense dichroism for R_1 and R_2 bands.

In a similar way, after irradiation with [001]-polarized R_1 light, the absorption intensities of R_1 and R_2 bands in the [001] and [010] directions are given under the same assumptions as described above:

$$\kappa_1[001]=\kappa_1[010]=2\alpha_1 n_0\exp(-\beta t/3)\,,$$

$$\kappa_2[001]=\kappa_2[010]=2\alpha_2 n_0\exp(-\beta t/3)\,.$$

In this case, therefore, no dichroism is observable. If we exchange the direction of optical dipole of R_1 absorption for that of R_2 absorption, the same results as described above will be obtained.

Impulsive Motion of a Circular Cylinder in a Viscous Fluid at Small Reynolds Numbers

By Sinzi KUWABARA

Aeronautical Research Institute, University of Tokyo

(Received June 2, 1961)

The drag of a circular cylinder set in uniform motion impulsively from rest in a viscous fluid is calculated. On the assumption of small Reynolds numbers, Oseen's equations for unsteady motion are employed. The two limiting cases corresponding to the initial and final periods, respectively, are investigated.

§1. Introduction and Summary

Studies on steady slow motion of one or many bodies in a viscous fluid have been made by many authors, but there have been few works concerning the unsteady slow motion. Oseen has investigated the impulsive motion of a sphere on the basis of the Stokes approximation[1]. The impulsive motion of a circular cylinder has been studied by Blasius[2] and Goldstein and Rosenhead[3]. Their investigations have been based on the boundary-layer equations, hence their results are valid only for the large Reynolds numbers. In the present paper, we shall study the motion of a circular cylinder started impulsively from rest with a constant velocity in a viscous fluid.

Since we shall assume the Reynolds number to be small, it may be reasonable to make use of Oseen's equations for the unsteady motion. Also, use will be made of the Laplace transformation. Since it is difficult to solve this problem completely, we shall only treat the two limiting cases corresponding to the final and initial periods, respectively. For the final period, it is found that the drag of the circular cylinder approaches gradually the value for the steady case as the time from start increases. For the initial period, on the other hand, the drag decreases rapidly from infinity, i.e., inversely proportionally to the square root of time.

Numerical calculations have been carried out for the Reynolds numbers 0.08, 0.4 and 1, respectively. The two asymptotic solutions corresponding to the initial and the final periods, respectively, seem to continue each other fairly well.

§ 2. Basic Equations

We consider the motion of a circular cylinder which starts impulsively from rest with a constant velocity U in a viscous fluid. We assume that the Reynolds number $R=2aU/\nu$ is small compared with unity, where a is the radius of the circular cylinder and ν is the kinematic viscosity, so that we may conveniently use the Oseen approximation. Oseen's equations and the equation of continuity can be written in non-dimensional forms as follows:

$$\frac{\partial u}{\partial t}+\frac{\partial u}{\partial x}=-\frac{\partial p}{\partial x}+\frac{1}{2k}\Delta u\,, \tag{2.1}$$

$$\frac{\partial v}{\partial t}+\frac{\partial v}{\partial x}=-\frac{\partial p}{\partial y}+\frac{1}{2k}\Delta v \tag{2.2}$$

and

$$\frac{\partial u}{\partial x}+\frac{\partial v}{\partial y}=0\,, \tag{2.3}$$

where (x, y) are the cartesian coordinates, t is the time, (u, v) the velocity components, p the pressure and $2k=aU/\nu=R/2$. Here the units of length, time, velocity, and pressure have been taken as a, a/U, U and ρU^2, respectively, where ρ is the density of the fluid.

From (2.1) and (2.2), we have

$$2k\left(\frac{\partial \omega}{\partial t}+\frac{\partial \omega}{\partial x}\right)=\Delta\omega\,, \tag{2.4}$$

where ω is the non-dimensional vorticity defined as

$$\omega=\frac{\partial v}{\partial x}-\frac{\partial u}{\partial y}\,. \tag{2.5}$$

Introducing the complex variables

$$z=x+iy\,, \qquad \bar{z}=x-iy\,, \tag{2.6}$$

and

$$W=u-iv\,, \tag{2.7}$$

we have

$$\frac{\partial W}{\partial \bar{z}}=-\frac{1}{2}i\omega \tag{2.8}$$

from (2.3) and (2.5).

Let us define the Laplace transform of $f(x, y, t)$ as

$$f^*(x, y, p)=\int_0^\infty f(x, y, t)e^{-pt}\,dt\,, \tag{2.9a}$$

$$f(x, y, t)=\frac{1}{2\pi i}\int_{c-i\infty}^{c+i\infty} f^*(x, y, p)e^{pt}\,dp\,, \qquad \mathscr{R}e\, c>0\,. \tag{2.9b}$$

Then, we can transform (2.4) and (2.8) as follows:

$$2k\left(p\omega^*+\frac{\partial \omega^*}{\partial x}\right)=\Delta\omega^*\,, \tag{2.10}$$

$$\frac{\partial W^*}{\partial \bar{z}}=-\frac{1}{2}i\omega^*\,. \tag{2.11}$$

The general solution of (2.10) which vanishes at infinity is easily obtained as follows:

$$\omega^*=\tfrac{1}{2}e^{kx}\sum_{n=0}^{\infty}(C_n e^{ni\theta}+\bar{C}_n e^{-ni\theta})K_n(\kappa r)\,, \tag{2.12}$$

where (r, θ) are the polar coordinates, C_n the complex coefficients, K_n the modified Bessel functions of the first kind and $\kappa=\sqrt{k^2+2kp}$. In a manner similar to Imai's method of solving Oseen's equations[4], the general solution of (2.11) with (2.12) can be obtained as

$$W^*=-\frac{i}{4}\sum_{n=0}^{\infty}(C_n W_n+C_n W_{-n})\,, \tag{2.13}$$

where

$$\frac{\partial W_n}{\partial \bar{z}}=e^{kx}K_n(\kappa r)\,e^{ni\theta}\,. \tag{2.14}$$

Integrating (2.14), we have

$$W_n=\frac{k}{\kappa}\,W_{n-1}-\frac{2}{\kappa}e^{kx}K_{n-1}(\kappa r)\,e^{(n-1)i\theta}\,. \tag{2.15}$$

Replacing n by $-n+1$, we have

$$W_{-n}=\frac{\kappa}{k}\,W_{1-n}+\frac{2}{k}e^{kx}K_n(\kappa r)\,e^{-ni\theta}\,. \tag{2.16}$$

Repeated application of the recurrence formulae (2.15) and (2.16) gives respectively

$$W_n=\left(\frac{k}{\kappa}\right)^n W_0-\frac{2}{\kappa}e^{kx}\sum_{m=0}^{\infty}\left(\frac{k}{\kappa}\right)^{n-1-m}K_m(\kappa r)\,e^{mi\theta}\,, \tag{2.17}$$

$$W_{-n}=\left(\frac{\kappa}{k}\right)^n W_0+\frac{2}{k}e^{kx}\sum_{m=1}^{n}\left(\frac{\kappa}{k}\right)^{n-m}K_m(\kappa r)\,e^{-mi\theta}\,. \tag{2.18}$$

Inserting these into (2.13), we obtain

$$\begin{aligned}W^*=&-\frac{i}{4}\,W_0\sum_{n=0}^{\infty}\left\{\left(\frac{k}{\kappa}\right)^n C_n+\left(\frac{\kappa}{k}\right)^n\bar{C}_n\right\}\\&+\frac{i}{2k}e^{kx}\left[A_1K_0(\kappa r)+\sum_{m=1}^{\infty}(A_{m+1}\,e^{mi\theta}-\bar{B}_m\,e^{-mi\theta})K_m(\kappa r)\right]+\frac{df^*}{dz}\,.\end{aligned} \tag{2.19}$$

where

$$W_0=\frac{2}{\kappa^2 z}\exp\left(\tfrac{1}{2}kz\right)\int^{\kappa r}\exp\left(kt^2/2\kappa^2 z\right)K_0(t)t\,dt\,, \tag{2.20}$$

$$A_n=\sum_{m=n}^{\infty}\left(\frac{k}{\kappa}\right)^{m-n-1}C_m\,,\qquad B_n=\sum_{m=n}^{\infty}\left(\frac{\kappa}{k}\right)^{m-n}C_m\,, \tag{2.21}$$

and $f^*(z)$ is an arbitrary analytic function of z.

In view of the fact that W_0 is a many-valued function of (r,θ), and that the complex velocity W should be one-valued, we must have

$$\sum_{n\ 0}^{\infty}\left\{\left(\frac{k}{\kappa}\right)^n C_n+\left(\frac{\kappa}{k}\right)^n\bar{C}_n\right\}=0\,. \tag{2.22}$$

Thus, we finally obtain

$$W^*=\frac{i}{2k}\left[A_1K_0(\kappa r)+\sum_{n=1}^{\infty}(A_{n+1}\,e^{ni\theta}-\bar{B}_n\,e^{-ni\theta})\,K_n(\kappa r)\right]+\frac{df^*}{dz}\,, \tag{2.23}$$

where f^* should be expressed as

$$f^*(z)=\frac{1}{p}z+\frac{m^*+i\Gamma^*}{2\pi}\ln z+\frac{a^*}{z}+\cdots\,. \tag{2.24}$$

For the initial period, we assume that $p\gg 1$ and so $\kappa\gg 1$. From (2.21) we can see that B_n is a series in the ascending powers of the large factor κ/k, so that (2.23) is useless for the initial period.

Repeated application of the recurrence formula (2.15) only gives

$$W^*=\frac{i}{2\kappa}e^{kx}\left\{A_0'K_0(\kappa r)+\sum_{n=1}^{\infty}(A_n'e^{ni\theta}+B_n'e^{-ni\theta})K_n(\kappa r)\right\}+\frac{df^*}{dz}\,, \tag{2.25}$$

where

$$A_n' = \sum_{m=n+1}^{\infty} \left(\frac{k}{\kappa}\right)^{m-n-1} C_m\,, \qquad n=0,\,1,\,2,\,\cdots \tag{2.26a}$$

and

$$B_n' = \sum_{m=0}^{n-1} \left(\frac{k}{\kappa}\right)^{n-1-m} \bar{C}_m + \sum_{m=0}^{\infty} \left(\frac{k}{\kappa}\right)^{m+n-1} C_m\,, \qquad n=1,\,2,\,\cdots\,. \tag{2.26b}$$

This is useful for the initial period.

To the Stokes approximation of the unsteady motion, we have the vorticity equation and its general solution in transformed forms as

$$2kp\omega^* = \varDelta\omega^*\,, \tag{2.27}$$

$$\omega^* = \frac{1}{2} \sum_{n=0}^{\infty} (C_n e^{ni\theta} - \bar{C}_n e^{-ni\theta}) K_n(\kappa r)\,, \tag{2.28}$$

where C_n are the arbitrary constants and $\kappa=\sqrt{2kp}$. In a manner similar to the preceding procedure, we obtain

$$W^* = \frac{i}{2\kappa} \left\{ A_0'' K_0(\kappa r) + \sum_{n=1}^{\infty} (A_n'' e^{ni\theta} + B_n'' e^{-ni\theta}) K_n(\kappa r) \right\} + \frac{df^*}{dz}\,, \tag{2.29}$$

$$A_n'' = C_{n+1}\,, \quad n=0,\,1,\,2,\,\cdots\,; \qquad B_1'' = C_0 + \bar{C}_0\,; \qquad B_n'' = \bar{C}_{n-1}\,, \quad n\ -2,\,3,\,\cdots\,. \tag{2.30}$$

It will be seen that on puttin $k\to 0$ and $kp=$finite, (2.25) and (2.26) reduce to (2.29) and (2.30) as should be expected.

The condition of no-slip on the surface of the profile can be written as

$$W^* = 0 \qquad \text{on the profile.} \tag{2.31}$$

The forces experienced by the cylinder are calculated by integrating the stresses on the surface of the cylinder. It is easily obtained from Imai's formula[5]:

$$C_D - iC_L = -\frac{4}{R} \oint_C \frac{\partial\omega}{\partial\bar{z}} \bar{z}\, d\bar{z} = -\frac{8i}{R} \oint_C \frac{\partial^2 W}{\partial\bar{z}^2} \bar{z}\, d\bar{z}\,, \tag{2.32a}$$

or its transformed form

$$C_D^* - iC_L^* = -\frac{4}{R} \oint \frac{\partial\omega^*}{\partial\bar{z}} \bar{z}\, d\bar{z}\,, \tag{2.32b}$$

where $C_D = X/(\frac{1}{2}\rho U^2\cdot 2a)$ and $C_L = Y/(\frac{1}{2}\rho U^2\cdot 2a)$ are the drag and lift coefficients, and $(X,\,Y)$ are the force components, and integration being taken along the profile C. This formula has originally been derived for the case of steady motion but it can easily be shown that the formula is valid for the unsteady case as well, provided the profile is chosen as the path of integration.

§ 3. The Final Period

For the final period, we can put $p \ll 1$ and hence $\kappa \fallingdotseq k \ll 1$, so that

$$C_n = O(k^n) \tag{3.1}$$

in view of the form of ω^* as given by (2.12). Then, we take the transformed velocity and vorticity as

$$W^* = \frac{i}{2k} e^{kx} \left\{ \frac{k}{\kappa} C_1 K_0(\kappa r) - \bar{C}_1 K_1(\kappa r) e^{\ i\theta} \right\} + \frac{1}{p} + \frac{m^*}{2\pi} \frac{1}{z} + \cdots\,, \tag{3.2}$$

$$\omega^*=\frac{1}{2}e^{kx}(C_1e^{i\theta}+\bar{C}_1e^{-i\theta})K_1(\kappa r) \tag{3.3}$$

retaining only the terms of order of κ^2. C_1 and m^* can be determined so as to satisfy the boundary condition (2.31). Thus, we have

$$C_1=2i\kappa\Big/\left\{p\left(K_0+\frac{1}{2}\kappa K_1\right)\right\}, \tag{3.4}$$

$$\frac{m^*}{2\pi}=\kappa K_1\Big/\left\{kp\left(K_0+\frac{1}{2}\kappa K_1\right)\right\}, \tag{3.5}$$

where we have put $K_0=K_0(\kappa)$ and $K_1=K_1(\kappa)$ for brevity.

Substituting from (3.4) into (3.13), we have

$$\omega^*=-\frac{2\kappa e^{kx}K_1(\kappa r)}{p(K_0+\frac{1}{2}\kappa K_1)}\sin\theta\,. \tag{3.6}$$

Expanding the Bessel functions K_0 and K_1, and retaining only the first dominant terms, we have

$$\omega^*=-\frac{2e^{kx}\sin\theta}{pr(-\ln\frac{1}{2}\kappa-\gamma+\frac{1}{2})}, \tag{3.7}$$

which gives, by the inverse Laplace transformation,

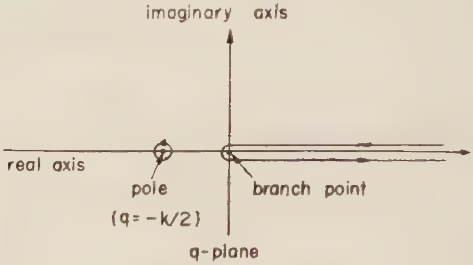

Fig. 1. The contour of integration used for (3.8).

$$\omega=-\frac{2e^{kx}\sin\theta}{2\pi i\cdot r}\exp(-kt/2)\int_C\frac{i\pi e^{-qt}\,dq}{(q+k/2)\{-\frac{1}{2}\ln 2kq+\ln 2-\gamma+\frac{1}{2})^2+\pi^2/4\}}, \tag{3.8}$$

where $q=-p+k/2$, $\gamma=0.57721\ldots$ is Euler's constant and the contour of integration is as shown in Fig. 1.

Substitution from (3.8) into (3.32a) gives

$$C_D=C_D^{(0)}+\frac{16}{R}\exp(-R^2\tau/16)\int_0^\infty\frac{e^{-s}\,ds}{(s+R^2\tau/16)\{(-\ln s+\beta)^2+\pi^2\}} \tag{3.9}$$

$$=C_D^{(0)}+\frac{16}{R}\exp(-R^2\tau/16)\int_0^1\frac{d\eta}{(-\ln\eta+R^2\tau/16)\{(-\ln(-\ln\eta)+\beta)^2+\pi^2\}}, \tag{3.10}$$

where

$$C_D^{(0)}=8\pi/\{R(S+\tfrac{1}{2})\}, \tag{3.11}$$

$\tau=2t/R$ and $\beta=\ln\tau+\ln 4-2\gamma+1$. $C_D^{(0)}$ is the drag coefficient for the steady motion.

§ 4. The Initial Period

For the initial period, we put $p\gg1$ and so $\kappa\gg1$. Also we assume that C_n in (2.12) are all of the same order of magnitude. Then remembering (2.25) and (2.24), we write the transformed velocity as

$$\begin{aligned}W^*=&\frac{i}{2\kappa}e^{kx}[C_1K_0(\kappa r)+C_2K_1(\kappa r)e^{i\theta}+C_3K_2(\kappa r)e^{2i\theta}+\cdots\\&+(C_0+\bar{C}_0)K_1(\kappa r)e^{-i\theta}+\bar{C}_1K_2(\kappa r)e^{-2i\theta}+\cdots]\\&+\frac{1}{p}+\frac{m^*}{2\pi}\frac{1}{z}+\frac{a^*}{z^2}+\cdots,\end{aligned} \tag{4.1}$$

where only the lowest order terms in k/κ are retained. Introducing (4.1) into the boundary condition (2.31), we have

$$C_0+\bar{C}_0=\frac{m^*ki}{\pi}\,; \qquad C_1=2i\kappa/(pK_0)\,; \qquad C_n=0\,, \quad n\geq 2\,. \tag{4.2}$$

Since ω^* should be an odd function of θ for the case of a circular cylinder, we have from (2.12)

$$C_0+\bar{C}_0=0 \tag{4.3}$$

so that

$$m^*=0\,. \tag{4.4}$$

Substituting from (4.2) and (4.4) into (2.12), we have

$$\omega^*=-\frac{\kappa}{q-k/2}\,e^{kx}\frac{K_1(\kappa r)}{K_0(\kappa)}\sin\theta\,, \tag{4.5}$$

where we have put $q=p+k/2$ so that $\kappa=\sqrt{2kq}$. Using the asymptotic expansions of Bessel functions, we obtain

$$\begin{aligned}\omega^*=&-\sqrt{\frac{2kq}{r}}\,\frac{\exp\,[kx-\sqrt{2kq}\,(r-1)]}{q-k/2}\\ &\times\left\{1+\frac{3}{8}\frac{1}{\sqrt{2kq}\cdot r}-\frac{5}{128}\frac{1}{2kq\cdot r^2}+\frac{105}{1024}\frac{1}{(2kq)^{3/2}r^3}+\cdots\right\}\\ &\times\left\{1-\frac{1}{8}\frac{1}{\sqrt{2kq}}+\frac{9}{128}\frac{1}{2kq}-\frac{75}{1024}\frac{1}{(2kq)^{3/2}}+\cdots\right\}^{-1}\sin\theta\,.\end{aligned} \tag{4.6}$$

Application of (2.32b) and its inverse transformation fails owing to the divergence of the integral appearing in the inverse transformation. To avoid this difficulty, we take as the contour of integration C in (2.32b) a circle of radius r (>1). Thus we have

$$\begin{aligned}\oint\frac{\partial\omega^*}{\partial\bar{z}}\,\bar{z}\,d\bar{z}&=-\frac{2\pi kqr}{q-k/2}\,\frac{K_2(\kappa r)}{K_0(\kappa)}\\ &=-\frac{2\pi kqr^2}{q-k/2}\left\{1+\frac{15}{8}\frac{1}{\sqrt{2kqr}}+\frac{105}{128}\frac{1}{2kq\cdot r^2}-\frac{315}{1024}\frac{1}{(2kq)^{3/2}\cdot r^3}+\cdots\right\}\\ &\quad\times\left\{1-\frac{1}{8}\frac{1}{\sqrt{2kq}}+\frac{9}{128}\frac{1}{2kq}-\frac{75}{1024}\frac{1}{(2kq)^{3/2}}+\cdots\right\}^{-1}.\end{aligned} \tag{4.7}$$

For the calculation of ω and $\oint\frac{\partial\omega}{\partial\bar{z}}\,\bar{z}\,d\bar{z}$ by inverse Laplace transformation, we have adopted a method of successive approximation, that is, retaining the first term of the asymptotic expansion of each of K_0, K_1 and K_2 for the zero-th approximation, the first two terms of the expansion for the first approximation and so on.

i) The zero-th approximation. We put

$$\omega^*=-\sqrt{\frac{2k}{q}}\,\exp\,[kx-\sqrt{2kq}\,(r-1)]\sin\theta\,, \tag{4.8}$$

$$\oint\frac{\partial\omega^*}{\partial\bar{z}}\,\bar{z}\,d\bar{z}=-2\pi kr^{3/2}\exp\,[kx-\sqrt{2kq}\,(r-1)]\,, \tag{4.9}$$

for the zero-th approximation as mentioned above. We can carry out easily the inverse transformation and have

$$\omega=-\frac{2}{\sqrt{\pi\tau r}}\exp\left(-\frac{1}{4\tau}(r-1)^2\right)\sin\theta\,, \tag{4.10}$$

$$\oint\frac{\partial\omega}{\partial\bar{z}}\,\bar{z}\,d\bar{z}=-\frac{\sqrt{\pi}}{2}\,r^{3/2}(r-1)\tau^{-3/2}\exp\left(-\frac{1}{4}(r-1)^2/\tau\right) \tag{4.11}$$

where $\tau=t/2k$ and we have omitted the factor $\exp(-kx-k^2\tau)$ as well as in the higher approximations, because we restrict our consideration to the region near the cylinder and the initial period. This omission makes our approximation equivalent to the Stokes type. The same result would be obtained from (2.29) and (2.30).

Substitution from (4.11) to (2.32a) gives

$$C_D=0\,. \tag{4.13}$$

ii) The first approximation. In this approximation, we put

$$\omega^*=-2\sqrt{\frac{2k}{qr}}\exp\left[-\sqrt{2kq}\,(r-1)\right]\frac{\sqrt{q}+3/(8\sqrt{2k}\cdot r)}{\sqrt{q}-1/(8\sqrt{2k})}\sin\theta\,, \tag{4.14}$$

$$\oint\frac{\partial\omega^*}{\partial\bar{z}}\,\bar{z}\,d\bar{z}=-2\pi kr^{3/2}\exp\left[-\sqrt{2kq}\,(r-1)\right]\frac{\sqrt{q}+15/(8\sqrt{2k}\cdot r)}{\sqrt{q}-1/(8\sqrt{2k})}\,. \tag{4.15}$$

Then, we have

$$\begin{aligned}\omega=-\frac{2}{\sqrt{r}}\Bigg[&\frac{1}{\sqrt{\pi\tau}}\exp\left(-\frac{1}{4\tau}(r-1)^2\right)+\frac{1}{8}\left(1+\frac{3}{r}\right)\exp\left(-\frac{1}{8}(r-1)+\tau^2/64\right)\\&\times\mathrm{Erfc}\left(\frac{r-1}{2\sqrt{\tau}}-\frac{1}{8}\sqrt{\tau}\right)\Bigg]\sin\theta\,,\end{aligned} \tag{4.16}$$

$$\begin{aligned}\oint\frac{\partial\omega}{\partial\bar{z}}\,\bar{z}\,d\bar{z}=-\pi r^{3/2}\Bigg[&\frac{1}{2\sqrt{\pi}}(r-1)\tau^{-3/2}\exp\left(-\frac{1}{4}(r-1)^2/\tau\right)\\&+\frac{1}{8}\left(1+\frac{15}{r}\right)\left\{\frac{1}{\sqrt{\pi\tau}}\exp\left(-\frac{1}{4}(r-1)^2/\tau\right)+\frac{1}{8}\exp\left(-\frac{1}{8}(r-1)+\tau/64\right)\right.\\&\left.\times\mathrm{Erfc}\left(\frac{1}{2}(r-1)\Big/\sqrt{\tau}-\frac{1}{8}\sqrt{\tau}\right)\right\}\Bigg]\,,\end{aligned} \tag{4.17}$$

where

$$\mathrm{Erfc}\,x=\frac{2}{\sqrt{\pi}}\int_x^\infty\exp(-t^2)\,dt\,.$$

Substitution from (4.17) into (2.32a) gives

$$C_D=\frac{8\pi}{R}\left\{\frac{1}{\sqrt{\pi\tau}}+\cdots\right\}. \tag{4.18}$$

iii) The second approximation gives

$$\begin{aligned}\omega=-\frac{2}{\sqrt{r}}\Bigg[&\frac{1}{\sqrt{\pi\tau}}\exp\left(-\frac{1}{4\tau}(r-1)^2\right)+D\exp\left(-\xi(r-1)+\xi^2\tau\right)\mathrm{Erfc}\left(\frac{r-1}{2\sqrt{\tau}}-\xi\sqrt{\tau}\right)\\&+\bar{D}\exp\left(-\bar{\xi}(r-1)+\bar{\xi}^2\tau\right)\mathrm{Erfc}\left(\frac{r-1}{2\sqrt{\tau}}-\bar{\xi}\sqrt{\tau}\right)\Bigg]\sin\theta\,,\end{aligned} \tag{4.19}$$

where

$$D=-\frac{8i}{\sqrt{17}}\left\{\frac{\xi}{8}\left(1+\frac{3}{r}\right)-\frac{3}{128}\left(3+\frac{5}{r^2}\right)\right\} \tag{4.20}$$

and

$$\xi=\frac{1}{16}(1+i\sqrt{17})\,,\qquad \bar{\xi}=\frac{1}{16}(1-i\sqrt{17})\,. \tag{4.21}$$

We have

$$C_D=\frac{8\pi}{R}\left\{\frac{1}{\sqrt{\pi\tau}}+\frac{1}{2}+\cdots\right\}. \tag{4.22}$$

iv) The third approximation gives

$$\omega=\omega_0+\omega_1+\omega_2+\omega_3\ , \tag{4.23}$$

where

$$\omega_0=-\frac{2}{\sqrt{\pi\tau r}}\exp\left(-\frac{1}{4\tau}(r-1)^2\right)\sin\theta\ , \tag{4.24}$$

$$\omega_i=\frac{2}{\sqrt{r}}\,\frac{D_1\xi_i^2-D_2\xi_i+D_3}{(\xi_k-\xi_i)(\xi_i-\xi_j)}\exp\left[-\xi_i(r-1)+\xi_i^2\tau\right]\mathrm{Erfc}\left(\frac{r-1}{2\sqrt{\tau}}-\xi_i\sqrt{\tau}\right)\sin\theta\ , \tag{4.25}$$

(i, j, k) being even permutation of $(1, 2, 3)$, with

$$D_1=\frac{1}{8}\left(1+\frac{3}{r}\right),\qquad D_2=\frac{3}{128}\left(3+\frac{5}{r^2}\right),\qquad D_3=\frac{5}{1024}\left(5+\frac{7}{r^3}\right) \tag{4.26}$$

and

$$\xi_1=0.401830\ ,\qquad \xi_2=-0.138415+i0.402980\ ,\qquad \bar{\xi}_3=\xi_2\ , \tag{4.27}$$

which are the roots of the cubic equation

$$\xi^3-\frac{1}{8}\xi^2+\frac{9}{128}\xi-\frac{75}{1024}=0\ . \tag{4.28}$$

Also we have

$$C_D=\frac{8\pi}{R}\left[\frac{1}{\sqrt{\pi\tau}}+\frac{1}{2}-\frac{1}{4}\sqrt{\frac{\tau}{\pi}}+\cdots\right]. \tag{4.29}$$

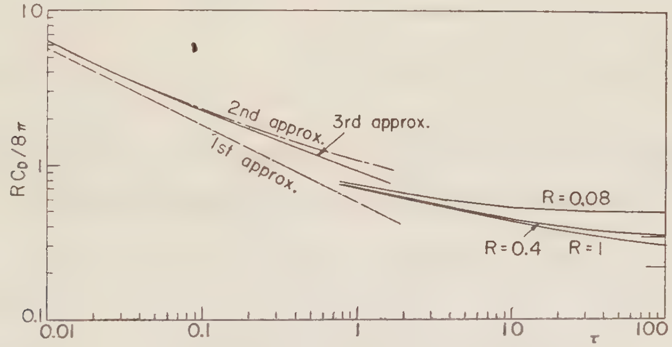

Fig. 2. $RC_D/8\pi$ vs. τ. The horizontal lines drawn on the right edge show the asymptotic values, which correspond to the steady case.

Table I. Calculated values of $RC_D/8\pi$ for various values of τ.

1) Final period solution (3.10)

R \ τ	1	2	5	10	20	50	100	∞
0.08	0.6970	0.5993	0.4948	0.4323	0.3823	0.3305	0.2997	0.2209
0.4	0.7037	0.6077	0.5061	0.4482	0.4047	0.3665	0.3508	0.3426
1	0.7435	0.6542	0.5689	0.5290	0.5080	——	——	0.4994

2) Initial period solution (4.29)

Approx. \ τ	0.01	0.02	0.05	0.1	0.2	0.5	1
1st	5.642	3.989	2.523	1.784	1.262	0.7979	0.5642
2nd	6.142	4.489	3.023	2.284	1.762	1.298	1.064
3rd	6.128	4.469	2.992	2.240	1.693	1.198	0.9231

Being equivalent to Stokes' approximation, the values of $RC_D/8\pi$ are independent of R.

§ 5. Numerical Discussions

Numerical calculations have been carried out for $R=0.08$, 0.4 and 1. Fig. 2 and Table I show the numerical values of $RC_D/8\pi$ for various values of τ. The asymptotic solution corresponding to $\tau\to\infty$ has been obtained by the numerical integration of (3.10).

The asymptotic functional form of $RC_D/8\pi$ corresponding to $\tau\to 0$ is not dependent on R but only on τ as in natural in the Stokes approximation. From (4.13) we find that the zero-th approximation does not contribute to the drag coefficient. The asymptotic solutions for $\tau\to 0$ and $\tau\to\infty$ seem to continue to each other fairly well in the intermediate region of τ.

Acknowledgement

The author wishes to express his sincere thanks to Professor Isao Imai for his continual guidance and encouragement throughout this study. He is also indebted to Professor Hidenori Hasimoto and Professor Yorisaburo Takaisi for their invaluable discussions. Study of Temperature Variation of Ultrasonic Velocity and Adiabatic Compressibility in Some Liquids—Part I

By P.R.K.L. PADMINI and B. RAMACHANDRA RAO
Ultrasonic Laboratories, Physics Department, Andhra University, Waltair, INDIA

(Received May 27, 1961)

Temperature variation of ultrasonic velocity and density is studied in some organic liquids, low melting point organic solids in melt state, and corrosive inorganic liquids. It is found that in all the cases the ultrasonic velocity decreased linearly with increase of temperature. The temperature independence of Rao's molar sound velocity was studied for the first time in corrosive inorganic liquids and is established. The new relations put forward by Kishimoto and Nomoto for temperature coefficients of velocity, density and adiabatic compressibility in terms of boiling point are examined and confirmed. The relation put forward by Lagemann $M^{1/2}$. $\Delta V/\Delta T$ was also examined.

§ 1. Introduction

Considerable work has already been done on the study of temperature variation of ultrasonic velocity in liquid state by Freyer, Hubbard and Andrews[1], Lagemann, McMillan and Woolf[2], Bär[3], Bhagavantam and Joga Rao[4], Suryaprakasam[5], Willard[6], Iyengar[7], Sette[8] and others. These investigators found that ultrasonic velocity decreased linearly with increase of temperature in all the liquids except water. From a systematic study of the temperature coefficient of ultrasonic velocity in liquids, Lagemann[9] and his collaborators concluded that the successive substitution of a heavier atom in a molecule leads to successively smaller temperature coefficients. They have also obtained the following empirical relation connecting the molecular weight and the temperature gradient of the ultrasonic velocity,

$$\frac{\varDelta V}{\varDelta T}M^{1/2}=39.09\ . \tag{1}$$

They have also noticed that this relation does not hold good for highly associated liquid like water, acetonitrile etc.

From a systematic study of the temperature variation of ultrasonic velocity and density, M.R. Rao[10] observed that the ratio of temperature coefficient of velecity to density is nearly constant and is approximately equal to 3. From this he deduced the relation

$$M/\rho(V)^{1/3}=R\ , \tag{2}$$

where R is a constant independent of temperature which is known as Rao's constant, V is ultrasonic velocity and M/ρ is molar volume. Following Rao's equation, Wada[11] has deduced the following relation connecting adiabatic compressibility and density

$$\frac{1}{\beta_s}\frac{d\beta_s}{dt}=7\alpha \tag{3}$$

where β_s is adiabatic compressibility and "α" is the coefficient of expansion.

Nomoto and Kishimoto[12] deduced Rao's relation theoretically using Lennard-Jones and Devonshires[13] liquid model improved by Wentorf-Buchler, Hirschfelder and Curtiss[14] by taking into consideration the effect of the second and third layer molecules. Kishimoto and Nomoto[15] recently deduced from the above equation the following relation, at temperatures corresponding to $0.9\,T_b$ where T_b is the boiling point

$$\frac{1}{\beta_T}\frac{d\beta_T}{dt}=6.5\alpha \tag{4}$$

where β_T is isothermal compressibility and using the data available for about 28 organic liquids these authors have plotted the value of $1/\beta_s\cdot d\beta_s/dT$ versus "α" and found that there is good degree of linearity and obtained a value of 6.85 for this ratio which is in good agreement with equation (4).

Following the same lines of theoretical study Kishimoto and Nomoto[16] have shown in a comparison paper that the temperature coefficient of isothermal compressibility, ultrasonic velocity and density at temperatures corresponding to $T=0.9\,T_b$, are inversely proportional to the boiling point. However they found that the coefficients experimentally found are not in agreement with the predictions of the theory. In the present investigation the authors have investigated the temperature effect on ultrasonic velocity in several new liquids including some corrosive liquids with a view to check up Rao's relation, Lagemann's empirical formula and theoretical equations deduced by Kishimoto and Nomoto.

§ 2. Experimental Technique

The ultrasonic velocities at various temperatures are determined by the fixed path interferometer developed by B.R. Rao and K.S. Rao[17] for the study of temperature variation in liquids using a crystal oscillator. For highly corrosive liquids which attack the metal of the ultrasonic cell, an all glass—cell has been used. This glass cell is made of a wide pyrex glass tube whose ends are closed by two thin flat glass sheets which are fused all around the edges maintaining the plane parallelism. A side tube serves as the inlet as well as the out-let for the liquids under study. The thermometer is introduced through the inlet after introducing the liquid. This cell has the advantage that it can be used for any corrosive liquid or liquids giving dangerous fumes. Available data for the temperature variation of density for some of liquids studied is taken from International Critical Tables (I.C.T.). The densities at various temperature are determined for the remaining liquids for which the data is not available in I.C.T.. The liquids used are either B.D.H. or E. Merck quality and are distilled before use. As it is difficult to handle the corrosive liquids they are not distilled.

§ 3. Results and Discussion

The velocity—temperature graphs for various liquids studied are given in Figs. 1 to 5.

The parameters, $\varDelta V/\varDelta T$, $1/V\cdot dV/dT$, $1/\rho\cdot d\rho/dT$, $1/\beta_s\cdot d\beta_s/dT$ are calculated and presented in the Table I.

As expected the velocity in all the liquids studied decreased linearly with increase of temperature, a feature which is characteristic of all the liquids except water.

From a study of the data available for a large number of homologous series of organic liquids it may be easily noticed that the value of $\Delta V/\Delta T$ generally decreases with increase of molecular weight, a feature which is implicit in Lagemann's relation (1). Lagemann has pointed out that the successive substitution of a heavier atom in a molecule results in a decrease of the temperature coefficient $\Delta V/\Delta T$. Examining the data presented in table I in the light of this rule the large value of 6.02 for $\Delta V/\Delta T$ in the case of iso-propylamine may be explained as due

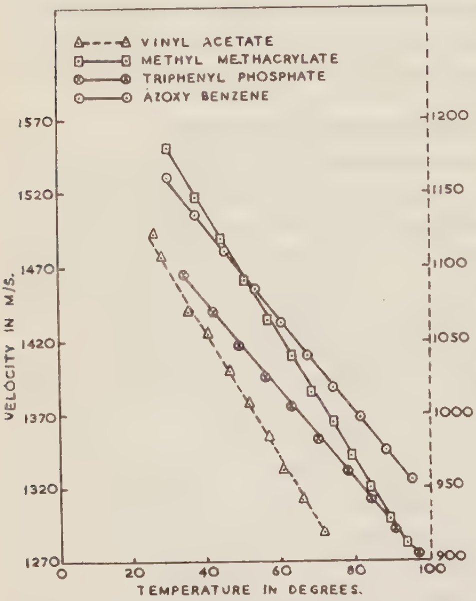

Fig. 1. Variation of ultrasonic velocity with temperature in liquids vinyl acetate, methylmethacrylate, triphenyl Phosphate and azoxybenzene.

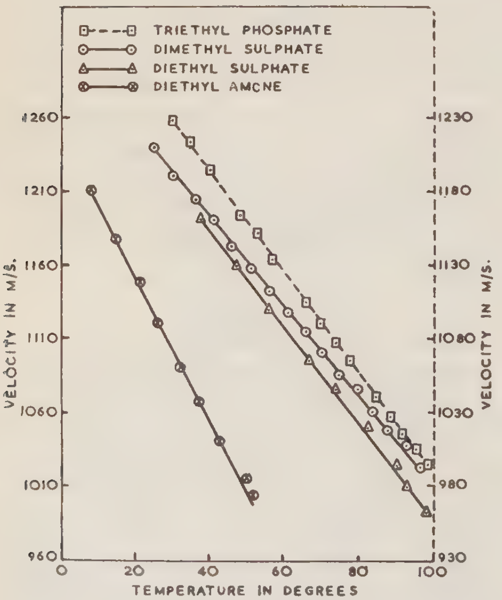

Fig. 2. Variation of ultrasonic velocity with temperature in triethylphosphate, Dimethyl sulphate. Diethylsulphate and Diethylamine.

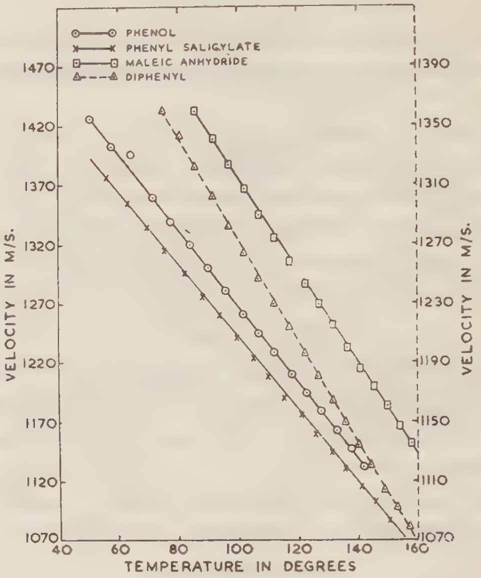

Fig. 3. Variation of ultrasonic velocity with temperature in Phenol, Phenyl Salicylate, Maleic Anhydride, and Diphenyl.

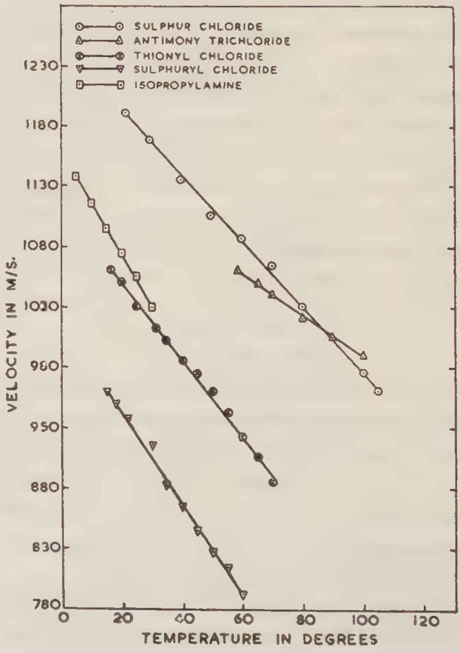

Fig. 4. Variation of ultrasonic velocity with temperature in sulphur chloirde, Antimony Trichloride, Thionyl chloride sulphuryl chloride and Isopropylamine.

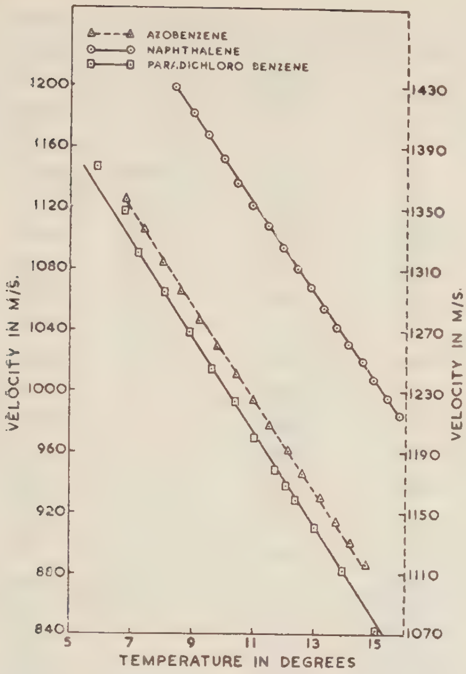

Fig. 5. Variation of ultrasonic velocity with temperature in Azobenzene, Naphthaline and Paradichlorobenzene.

to its lower molecular weight compared to diethylamine. Similar feature is noticed in the pairs of liquids ethyl and triphenyl phosphates, sulphur chloride and thionyl chloride and in the series of monomers. However the case of pairs of liquids like dimethyl diethyl sulphate, sulphur chloride and sulphuryl chloride, and azo and azoxybenzene, the results are not in accordance with the above rule in that the values of $\Delta V/\Delta T$ increased with increase of molecular weight. Although there are several exceptions to this rule, examining the data as a whole it will be seen that there is a general qualitative agreement. As for instance antimony trichloide which has a fairly high molecular weight has a low value of $\Delta V/\Delta T$, namely 2.0 whereas isopropylamine which has the lowest molecular weight among all the chemicals studied here has the highest value of 6.02 for $\Delta V/\Delta T$, the other values being intermediate. The values of $M^{1/2}\ \Delta V/\Delta T$ presented in the table I for all the liquids reveal that some liquids show large deviations from Lagemann's empirical value of 39.0.

For instance the value is higher than the Lagemann's constant by 40% in the case of triphenyl phosphate. The deviation is as much as 30% in the case of ethyl phosphate. The values obtained are very low in the case of phenol and antimony chloride, the deviations being 56% and 30% respectively. For liquids isopropylamine, sulphur chloride, sulphuryl chloride, ethyl methacrylate the deviation lies between 10 to 20%. The remaining liquids show quite a good agreement with Lagemann's formula.

From an examination of the molar sound velocity values at different temperatures for each substance, it was noticed that there was a remarkable degree of constancy over the range of temperature investigated, the maximum variation being generally not above 1% for most of the liquids. An examination of the data for ratio of temperature coefficient of velocity and density presented in Table II shows that this ratio is fairly constant giving an average value of about 3.1 which is in agreement with the value of 3 assumed by Rao for obtaining the relation (3). In a similar manner if we examine the ratio of the temperature coefficient of adiabatic compressibility and density, the ratio is found to vary between 6.3 and 8.8 the average value being about 7.2. This value is in reasonable agreement with the value of 6.85 obtained by Nomoto for the same ratio from a study of the data of large number of organic liquids. The remarkable degree of constancy of Rao's constant in the case of liquids like sulphur chloride, thionyl chloride, sulphuryl chloride and antimony trichloride, shows that Rao's relation is valid even for inorganic liquids. Further investigations in several other inorganic liquids are

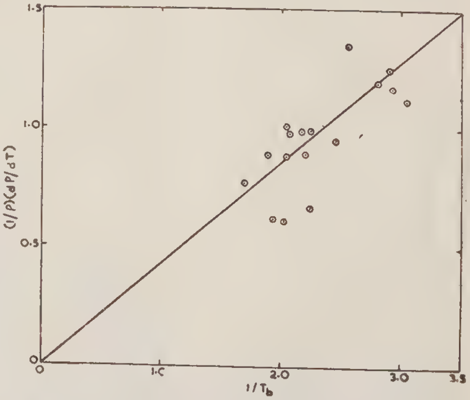

Fig. 6. Relation between $1/\rho\cdot d\rho/dT$ and boiling point.

necessary to confirm this result. In the case of substances like naphthalene, azobenzene, phenol etc. which are solids at room temperature, it is evident that Rao's relation holds good in the melt state over a fairly wide range of temperature.

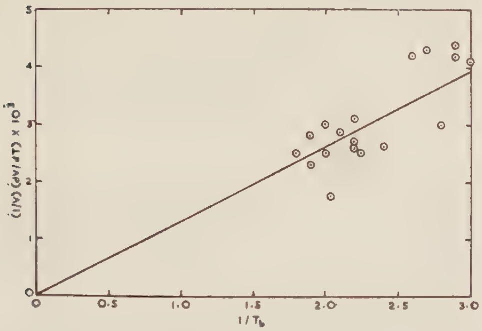

Fig. 7. Relation between $1/V\cdot dV/dT$ and boiling point.

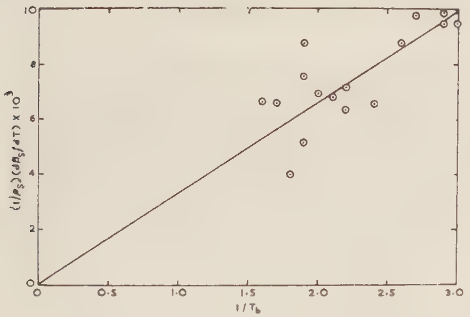

Fig. 8. Relation between $\frac{1}{\beta}\frac{d\beta}{dT}$ and boiling point.

In order to examine the relations put forward by Kishimoto and Nomoto between temperature coefficient of velocity, density, adiabatic compressibility and the boiling point, the values $1/V\cdot dV/dT$, $1/\rho\cdot d\rho/dT$ and $1/\beta_s\cdot d\beta_s/dT$, are calculated for all the new liquids studied and the results are presented in the Table II along with the boiling point T_b and its reciprocal. Thhe values thus obtained are plotted in Figs. 6, 7 and 8. For the three plots presented in these figures it may be seen that most of the points fall roughly on a line passing through the origin indicating that both the temperature coefficients of velocity, density and compressibility are nearly linear functions of reciprocal of the boiling points. From these experimental graphs the following relations are obtained.

$$\frac{1}{\rho}\frac{d\rho}{dT}=-\frac{0.41}{T_b}$$

$$\frac{1}{\beta_s}\frac{d\beta_s}{dT}=\frac{3.3}{T_b}$$

$$\frac{1}{V}\frac{dV}{dT}=-\frac{1.32}{T_b}.$$

Comparing these equations with those obtained by Kishimoto and Nomoto from a study of a large number of organic liquids for which data is available in literature it may be seen that there is fairly good agreement. The gradient of the compressibility graph which is 3.3 is higher than the value of 2.8 obtained by Kishimoto and Nomoto. Similarly the gradient of velocity boiling point graphs is about 1.32 and this is little higher than the value of 1.2 obtained by these authors. The gradient of the $\alpha-1/T_b$ graph was given as 0.41 by Kishimoto and Nomoto and this value is in excellent agreement with the average value of $T_b\cdot\alpha$ product obtained here. Thus it may be seen that the linear variation relationships given by Kishimoto and Nomoto are confirmed by the present investigation for the new liquids studied and it is evident that these relations have a wide applicability.

Scintillation from the Solid Xenon

By Sigeo TAKEMOTO, Takeo HASEGAWA
and Saburo HOMMA
*Department of Physics, Tohoku University,
Sendai, Japan*

(Received July 5, 1961)

Xenon was investigated by Sayres and Wu[1] as a gas scintillation counter. According to their experiment, the scintillation pulse height produced by Po^{210} alpha particles was very low in comparison with CsI(Tl); but when the photomultiplier was used with a wave length shifter, quaterphenyl, the pulse height increased by a factor of 106/6. Therefore the large part of the scintillation spectrum of xenon gas produced by alpha particles might be beyond the short wave length limit of the photomultiplier.

In the present experiment, the xenon gas was frozen by a liquid air and the scintillation pulse from the solid xenon due to Po^{210} alpha particles were measured with an electronic system consisted of DuMont 6291 photomultiplier, cathode follower and Iwasaki 30 MC synchroscope (vertical rise time 1.2×10^{-8} sec).

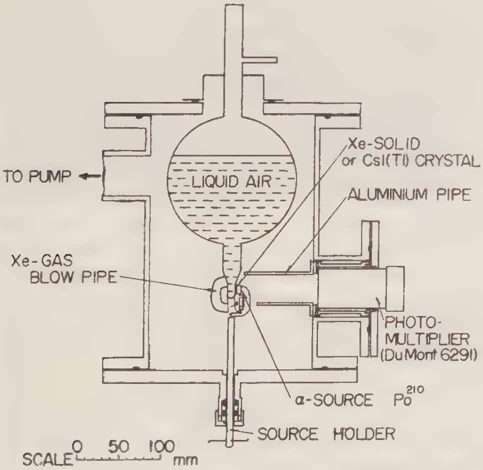

Fig. 1. The experimental apparatus for the measurement of the scintillation light from the solid xenon.

Fig. 1 shows the experimental apparatus. About 20 cc xenon gas was blown upon the flat surface of a stainless vessel in which liquid air was contained. The gas was frozen instantaneously on the stainless surface. The thickness of the frozen xenon was about 10 mg/cm², which was enough to stop the 5.3 MeV alpha particles. The scintillation light from the solid xenon entered into the photomultiplier through an aluminium pipe. A typical example of the scintillation pulses from the solid xenon is shown in Fig. 2 in comparison with CsI(Tl) (10 mmϕ ×1 mm, at room temperature). The pulse height of the solid xenon was about 1/3 times as high as that of CsI(Tl). The fluctuation of the alpha pulse height in the solid xenon scintillator might be chiefly due to the poor transparency and the inhomogeneity of the frozen material. In order to make the pulse height increase, a wave length shifter, sodium salicylate, was placed on the photomultiplier, but no remarkable improvement in the pulse height was observed. Therefore the scintillation spectrum of the solid xenon might be considered to be in the sensitive part of the photomultiplier.

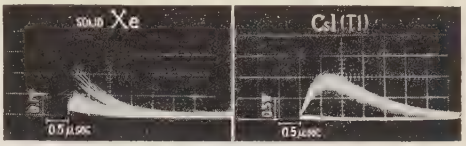

Fig. 2. A typical example of the output pulse from the cathode follower (measured with Iwasaki 30 MC synchroscope).

The decay time was also studied using the above synchroscope and was obtained to be less than 6×10^{-8} sec for the solid xenon.

From the present experiment the possibility of xenon as the liquid scintillator might be suggested.

Proton Magnetic Resonance and the Polymorphism of Triglycerides

By Haruo Nakajima
Department of Physics, Faculty of Science, Hokkaido University, Sapporo, Japan

(Received June 5, 1961)

The crystalline modifications of the saturated triglycerides have been studied by thermal, x-ray, and infra-red techniques.[1),2)] In order to investigate the molecular motion in the different crystalline forms and the mechanism of double melting, measurements of the temperature dependence of the proton magnetic resonance absorption spectrum were carried out on two of the triglycerides, tristearin $(C_{17}H_{35}COO)_3C_3H_5$ and tripalmitin $(C_{15}H_{31}COO)_3C_3H_5$, in their β- and α-form. The stable β-forms of both triglycerides were prepared by crystallizing the samples from toluene; the less stable α-forms, by quenching the molten samples in water-ice mixture.

The second moments of the resonance absorption spectrum of tristearin in both crystalline forms are plotted against temperature in Fig. 1. Their experimental error is about ±5% at room temperature and is about ±10% far below it. The similar behavior and similar numerical value are seen in the temperature dependence of the second moment of tripalmitin. The center peaks of the resonance absorption derivative, which are prominent above room temperature and are out of scale at higher temperatures, seem to be of a liquid-like nature. The second moments of the absorption derivative except the center peaks are determined above 40°C. They may be called as the second moments of the solid part. The glycerole residue is likely to play an important part in the center peaks.

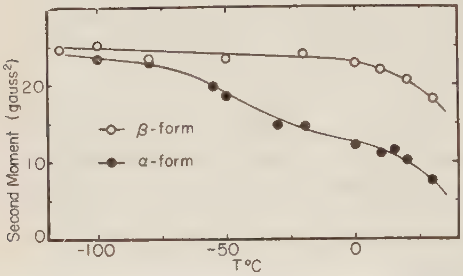

Fig. 1. Second moment versus temperature curves for β- and α-form of tristearin.

At the temperatures below about −80°C, the second moments of both crystalline forms are fairly close to the rigid structure value for a single chain of the acid-radical in the molecule. The difference in the intermolecular contribution to the second moment between both forms may be very slight at these temperatures, if they have the different crystalline structures. On the other hand, hindered rotation or oscillation of the molecule about its chain axis in the crystal may explain the decrease in the second moment of the α-form above −50 °C.[3)] This is parallel to the result of the x-ray and infra-red measurements[4)] that the α-form has hexagonal packing rather than a vitreous form[1)] at room temperature.

At the lower melting point of each triglyceride, 54°C for tristearin and 44°C for tripalmitin, a transition of the crystalline structure from the α- to the β-form is seen in the resonance absorption spectra of the solid part of the α-form. Fig. 2 represents this transition (a) in the second moment of the solid part of tristearin and (b) in the line shape of tripalmitin. The increase in the second moment with increasing temperature was reported in the case of liquid crystal.[5)] No change in the line shape of the α-form has been noticed beyond the experimental error for several weeks at room temperature.

Observation of the Tracks of Fission Fragments in Molybdenite

By Kazuhiko IZUI and F. Eiichi FUJITA*
Japan Atomic Energy Research Institute
Tokai-mura, Ibaragi-ken, Japan

(Received May 8, 1961)

Recently electron microscopy of fission fragment-irradiated materials such as mica1), evaporated film of uranium oxide2) and graphite3) has revealed the presence of the tracks of fission fragments exhibiting the thermal spike effects4) of them.

Present note reports some remarkable features of the tracks of the fission fragments in molybdenite crystal observed with an electron microscope, which would make possible to give a detailed analysis of the thermal spike region.

The thin film of molybdenite was superposed on the evaporated film of uranium and exposed to the thermal neutrons in JRR-1 reactor to the total doses of the order of $10^{16} n/\mathrm{cm}^2$ together with the uranium film and then observed with Hitachi electron microscope of HU-10 type after detaching the uranium film.

The tracks of fission fragments were observed as shown in photo. 1 where many of them appear as straight lines about 100Å wide and some of them as linear arrays of spots. The contrasts of the tracks are reversed to that of the matrix crystal in some parts of the regions where the extinction contour bands appear, which indicate that they are the diffraction contrasts caused by the variations in the Bragg conditions in the crystal. These narrow regions along the tracks seem to be small recrystallized regions produced by thermal spike effects of the fission fragments passing through the crystal, as pointed out in the case of graphite3).

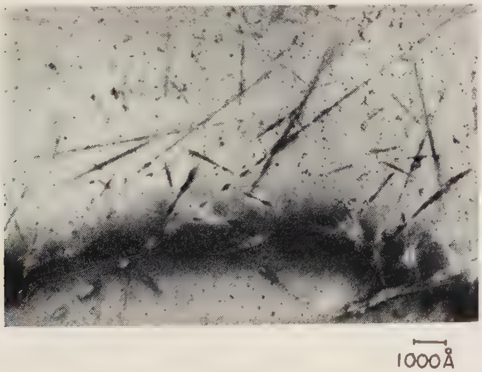

Photo. 1.

In some case the appearences of the tracks are modified by varying the diffraction condition in the crystal as shown in photo. 2(a) and 2(b) which are the photographs taken from the same area in the slightly different inclination of the specimen to the electron beam. In photo. 2(a) the track consists of a linear array of shots, while in photo. 2(b) it contains not only spots but light narrow lines about 50Å wide penetrating the centers of each spots.

It may be concluded from these facts that the structure of the thermal spike region is of the form which is illustrated in Fig. 1, where dotted lines indicate the spreading of the strain field around the spike region. The origin of such structure may be attributed to the un-uniformity in solidification of the molton material in the spike region which had initially uniform cylindrical shape.

On the Extraordinary X-ray Diffraction Intensities of Quenched TiC Powder

By Shiro FUJISHIRO

Department of Chemistry, Faculty of Science, Kyoto University, Kyoto, Japan

(Received June 19, 1961)

Titanium carbide, that has a high melting point and a great hardness, appears to be an intermetallic compound with a strong directional bonding between Ti and C[1]. The heat of formation of TiC, that is a measure of the bond strength, is about 30-40 Kcal[2],[3] at room temperature, much greater that that of ordered alloys. This fact suggests a highly ordered arrangement of Ti and C in the crystal. A rough calculation based on the quasi-chemical method[4], however, showed that the number of Ti-C bond decreases gradually with temperature, particularly above 2500°K.

The original purpose of the present experiment was, therefore, to detect the exchange of Ti and C in their sites due to thermal vibration on X-ray data. Quenched specimens of TiC have been investigated in the present experiment but no such effect was found. On the contrary, extraordinary diffraction patterns were obtained, that would not be explained only by frozen vacancies or atoms in the wrong lattice sites. Powdered titanium carbide prepared from titanium sponge was employed as the specimen. Lattice parameter was 4.321±0.001 Å. The specimen in a graphite basket was suspended from the top of a quartz furnace tube by means of a thin tungsten wire. In the bottom of the tube liquid argon was stored, which was cooled by liquid nitrogen from outside to minimize the evaporation of liquid argon. Purified argon gas was flashed and passed always through the system during a run. This procedure prevents TiC from oxidation or nitriding. High temperatures up to 2500°C were attained by means of an induction unit. After the specimen was maintained at a desired temperature for a sufficient time, the top of tungsten wire was unhooked so that the specimen fell into the pool of liquid argon. In order to determine the structure of the quenched specimen, this was immediately tested by means of a Geiger-flex X-ray diffractometer. In Fig. 1 the chart at the top shows the diffraction pattern for an ordinary TiC powder. The middle chart was obtained from TiC which had been quenched from 2500°C, in which the diffraction intensities of (111), (220) and (222) were remarkably increased. Neither line broadening nor significant change in lattice parameter occurred as a consequence of quenching. By annealing this specimen at 500°C for an hour in vacuum, the chart at the bottom was obtained. This would indicate a stage of recovery, whereas no such sign occurred when the identical specimen was aged at room temperature for a week. Repeated experiments gave the same results although the degree of increase of the intensities depended on the quenching rate, the temperature at which and the time for which the specimen was maintained.

Gilman[5] reported that in NaCl type crystals the glide {110}<110> or {100}<110> occurs, depending on the polarizability of a crystal and the temperature It seems that the anisotropic contraction due to quenching may cause this sort of slips, but if it were so, the line broadening and the shift of scattering angles must be observed[6].

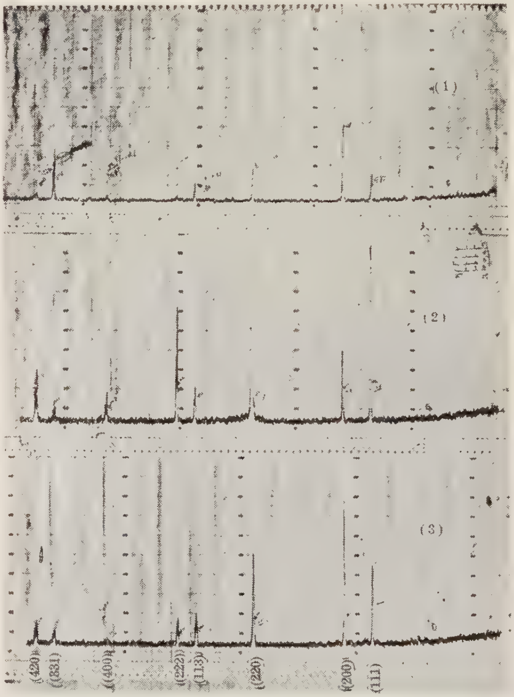

Fig. 1. X-ray analysis for TiC powder by CuKα.

A tentative calculation showed that the slip {100}<100> with a vector of half of the unit cell and with an appropriate periodicity results not in line broadening but in an increase of intensity at (111) as being expressed by $\alpha(F_{Ti}+F_C)^2$. In an ordinary crystal this is given by $\alpha(F_{Ti}-F_C)^2$. Here α is a constant, F_{Ti} and F_C are the atomic structure factors of Ti and C, respectively.

As no decisive conclusion, however, can be drawn from the above results, further investigation will be done to elucidate this phenomenon. The author wishes to express his appreciation to professors S. Kachi and R. Maddin for stimulating discussions.

The Flow of a Viscous Fluid past a Porous Flat Plate

By Mitutosi Kawaguti

Railway Technical Research Institute, Tokyo

(Received July 28, 1961)

It is of theoretical as well as practical interest to study the flow past a bluff body which has numerous gaps, such as railway bridges, snow break forests, etc. As a first step to this study, we have investigated the flow of a viscous fluid past a porous flat plate through which the fluid may pass with the velocity proportional to the pressure difference between the both sides of the plate. First, assuming that the Reynolds number of the flow is sufficiently small, we have obtained the Oseen approximate solution for the flow past a (non-porous) flat plate which is put perpendicularly to the flow, and have calculated the pressure difference between the upstream and the downstream sides of the plate. Next, we have studied the correction due to the flow through the plate.

The Oseen solution for the flow past a two-dimensional ordinary flat plate may be easily obtained with Imai's method[1]. Thus, the complex velocity at the point P (whose complex coordinate is z) can be given as

$$W=-\frac{1}{2}\frac{U}{S}\left\{\left(Z-\frac{1}{Z}\right)-\left(\frac{1}{Z}-\overline{Z}\right)\right\}\frac{Z}{Z^2+1}$$
$$+\frac{1}{2}\frac{U}{S}\ln Z\overline{Z}+O(k)\,, \tag{1}$$

where the breadth of the plate is assumed as 4, and

$$z=Z-Z^{-1}\,,\qquad S=\ln(2/k)-0.57721\cdots\,,$$
$$k=U/2\nu\,,$$

U and ν being the undisturbed velocity and the kinematic viscosity, respectively.

The pressure distribution over the surface of the plate is given as

$$p=\pm\rho\nu(U/S)(1-y^2/4)^{-1/2}+\text{const.}+O(k^2)\,,\quad (z\equiv x+iy)\,,$$
$$(+\text{: upstream side},\ -\text{: downstream side}). \tag{2}$$

Then the flow velocity through the flat plate U_t is assumed as

$$U_t=K\Delta p/\rho U=(2\nu K/S)G(y)\,, \tag{3}$$

where

$$G(y)=(1-y^2/4)^{-1/2}$$

and K is a proportional constant which may be determined theoretically or experimentally.

Now we shall approixmate the function $G(y)$ by

$$F(y)=A+B\int_{-2}^{+2}\frac{Y}{Y-y}\,dY\,. \tag{4}$$

The first and the second terms in (4) correspond to a uniform flow and the flow due to a linear distribution of vortices over the surface of flat plate respectively. A and B may be determined from appropriate conditions on $F(y)$. (For example, $A=1.564$, $B=-0.141$, if we adopt the condition that $F(y)$ and $G(y)$ coincide with each other at the points $y=0$, $y=\pm1$. It has been found that some other conceivable conditions give the values A and B much the same order of magnitude as above.)

Next, we consider the correction to the drag of the flat plate due to the presence of gaps. It is easily shown that the second term in $F(y)$ does not contribute to the drag. The contribution of the first term in $F(y)$ to the drag may be obtained, by superposing on the uniform flow U the flow that is at rest at infinity and has the velocity $u_0U=2\nu KA/S$ on the flat plate. But, such a flow may be obtained by superposition of the uniform flow of velocity $-u_0U$ past a fixed non-porous flat plate and a uniform flow u_0U.

Finally the drag of the porous flat plate has been obtained as

$$C_D=\frac{D}{\frac{1}{2}\rho U^2L}=\frac{8\pi}{RS}(1-u_0)+O(R)+O(K)$$
$$=\frac{8\pi}{RS}\left(1-\frac{8KA}{RS}\right)+O(R)+O(K), \tag{5}$$

where $R=UL/\nu$ is the Reynolds number, L being the breadth of the plate.

Observations on the Etch Patterns in Deformed KCl Crystals

By Masayoshi Sakamoto

Department of Physics,
Tokyo College of Science,
Shinjuku-ku, Tokyo, Japan

(Received June 2, 1961)

Recently Gilman and Johnston[1] proposed a mechanism of dislocation multiplication in alkali-halide crystals, which includes a double cross-glide mechanism similar to that formerly proposed by Koehler[2] and Orowan[3]. According to this mechanism, a length of a gliding screw dislocation moves by cross-glide onto a nearby plane parallel to the original glide plane and a multiplication results from prismatic loops or trails formed by jogs on moving screw dislocations. These screw dislocations must have many cusps, because of dragging force exerted by the trails. Therefore, it is especially of interest, with regard to this mechanism, to observe etch patterns of deformed KCl crystals. The present report describes the results of observations on etch patterns on surfaces, nearly parallel to {110} plane or glide plane, of mechanically deformed KCl crystal.

Specimens were subjected to a light compression or bending, and single slip bands were produced. A cut was made with wet nylon string, in the portion where density of slips is low, along a plane parallel to the glide plane as AB in Fig. 1. The surface obtained by cutting was scraped carefully about $100\sim200\mu$ in depth by chemically polishing method, followed by etching with the technique used in the previous work[4]. Many photographs of the etch patterns were taken on crystals obtained by these procedures. Each of these surfaces seems to be in tilt by a small angle against the {110} plane, taking into account the method of cutting and scraping.

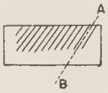

Fig. 1. Cutting of the specimen.

A typical example of the photographs is shown in Fig. 2. It may be recognized as a remarkable feature that there are several paired etch pits among many normal ones and that both trails of these paired etch pits are closing together in the [100] direction or, conversely, sometimes opening out probably in the [0$\bar{1}$1] direction oppositely, both in cusp shape, as shown in Fig. 3(a) and (a′). Some examples of the cusp-like pits are shown by arrows in the photograph.

On the other hand, mechanically deformed specimens were kept at $500\sim600$°C for several hours. It was observed on these specimens that some change in the form of paired etch pits has taken place. Fig. 3(b) shows their shape which is surrounded by straight lines instead of smooth curves on the specimen before the treatment.

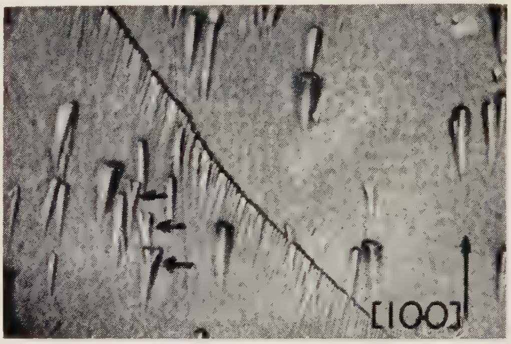

Fig. 2. Paired etch pits.

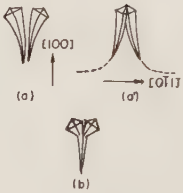

Fig. 3. Sketches of paired pits.

The two features described above are observed only on the surfaces near the {110} plane of deformed crystals. Therefore, these paired etch pits may be interpreted to be the cusps attached to the screw dislocations. The shape change of paired etch pits by the heat treatment may be conceived to result from the tension of dislocation and the interaction between oppositely signed dislocations. It must be noted that in the present work patterns of stepped trails were also observed, providing another evidence to the mechanism above.

Preparation of Gallium Phosphide Crystals and Their Etch Pattern

By Sigeru Iizima and Makoto Kikuchi
Electrotechnical Laboratory,
Tokyo, Japan

(Received July 13, 1961)

Crystals of gallium phosphide are made from the elements in an inactive atmosphere. As shown in Fig. 1, the quartz boats containing elemental gallium and phosphorus respectively are placed in a quartz tube which is closed at one end. This tube is placed in a large outer quartz tube, and heated in the flow of argon gas, so that the temperatures at the quartz boat containing gallium metal and the other containing phosphorus are controlled at 1200°C and 150–400°C, respectively. Heating and controlling of the temperatures are achieved by using Pt wire wound furnace and the potentiometer type controller. After heating for 20 hours, the furnace is switched off and cooled down to room temperature.

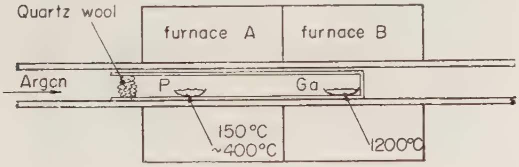

Fig. 1. Diagram of apparatus used for preparing gallium phosphide.

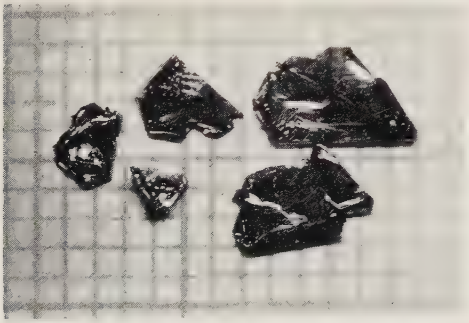

Fig. 2. Plate-shaped crystals of gallium phosphide. Scale: 1 mm a division.

Plate-shaped crystals about 0.3 mm thick are found in the gallium metal, and by treating in hot dilute HCl excess gallium can be removed (Fig. 2). On the inner wall of the inner quartz tube, there grow very thin and flexible ribbon-shaped crystals (Fig. 3).

Crystal of gallium phosphide has the structure of zinc blende type, and the flat faces of the plate-shaped crystals are {111} faces. When etched in a mixture of 1 part HNO_3 and HF for 15 minutes, on one face of the plate-shaped crystal appears a characteristic etch pattern which resembles that of germanium (111) face etched by superoxol (Fig. 4(a)). On the opposite face, no characteristic pattern can be found (Fig. 4(b)). White and Roth[1] have reported the observation of polarity of gallium arsenide crystals. Probably, a similar consideration may be admitted that the face with the characteristic pattern is correlated with White and Roth's case 2 in which the gallium atoms are on the outside of the double layer.

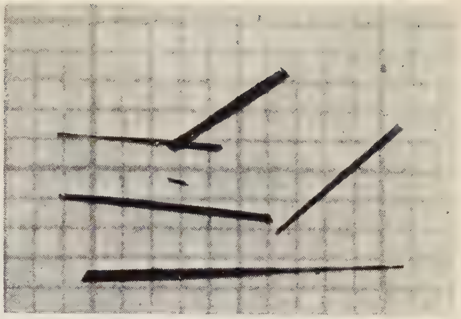

Fig. 3. Ribbon-shaped crystals of gallium phosphide. Scale: 1 mm a division.

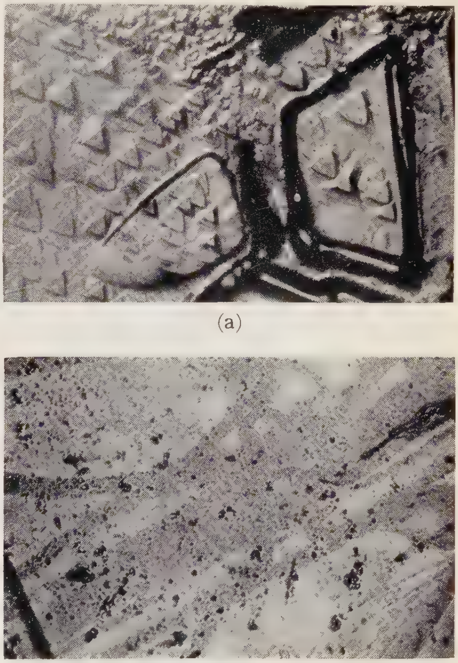

(a)

(b)

Fig. 4. (a) Characteristic etch pattern on one face. (b) The opposite face. Diagonal of the figures is about 1.5 mm.

Electroluminescence in Gallium Phosphide Single Crystals

By Sigeru Iizima and Makoto Kikuchi
Electrotechnical Laboratory,
Tokyo, Japan

(Received July 13, 1961)

Point contact V-I characteristics and electroluminescent properties of gallium phosphide crystals synthesized in argon atmosphere at elevated temperature[1] are observed. Resistivities of our crystals, which are not doped with any impurities purposely, range from 0.1 to 1 ohm-cm and the conductivity is *n*-type.

On making the large-area contact to the plate-shaped crystal with silver paint on the one side and making metal point contact on the other, good rectification effects are observed. A typical V-I characteristic is shown in Fig. 1. As is shown in the figure, breakdown voltage of our samples is about 5-10 volts. When the breakdown occurs, orange-yellow light emission is observed, as is shown in Fig. 2. It looks likely that the light emission prevails over the whole crystal, but it is probably due to the internal reflection of the light emitted at the point contact. The fact that light is emitted only when the breakdown occurs in our crystal is seen from the photograph of Fig. 3. Upper trace in the figure shows the change of the light intensity received by photomultiplier tube 7306, and lower trace shows the change of the current which flows through the contact, when ac voltage of 400 cps is applied. The absence of electroluminescence at the forward bias is probably due to the presence of the deathnium levels caused by considerable amount of impurities unintentionally introduced in our crystals.

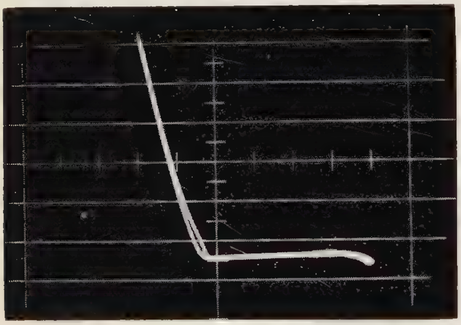

Fig. 1. Point contact V-I characteristic in our typical *n*-type crystal. Abscissa: voltage, 2 volts per division; ordinate: current, 250 μA per division.

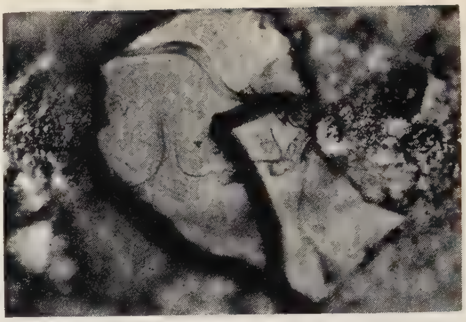
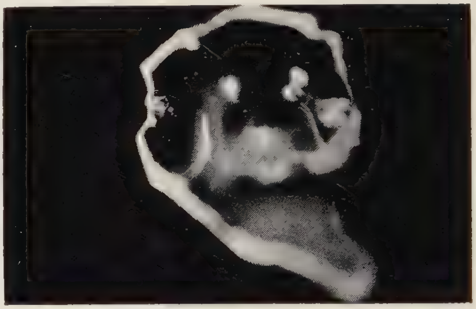
Fig. 4 shows the trace of current *vs* light intensity characteristic. From the figure, it appears that



(a)



(b)

Fig. 2. Photograph of GaP crystal with point contact, (a) by external illumination; (b) by electroluminescence.

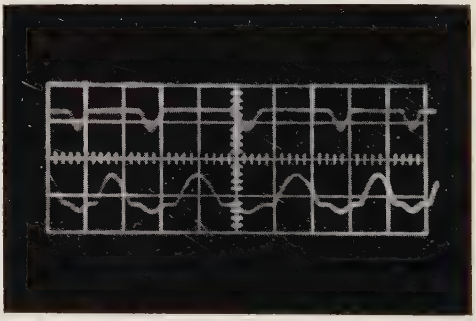


Fig. 3. Upper trace: light intensity; lower trace: current, 10 mA per division.

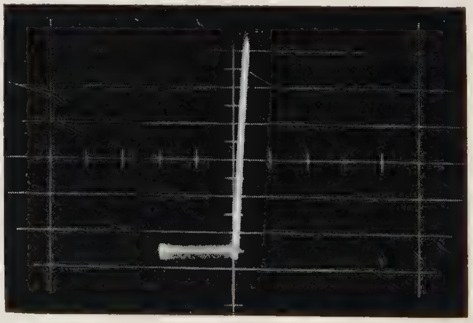

Fig. 4. Current *vs* light intensity characteristic. Abscissa: current, 2 mA per division; ordinate: light intensity, arbitrary scale.

light intensity is proportional to the backward breakdown current. This suggests that the bimolecular radiative recombination is the dominant effect when the light is emitted at the breakdown region.

Crystal Distortion of FeO on Cooling past its Néel Temperature

By Yoshiko SUZUKI and Eiichi ASADA

Government Chemical Industrial Research Institute, Tokyo

(Received May 31, 1961)

It is well known that FeO becomes antiferromagnetic on cooling past the Néel temperature and the crystal lattice exhibits a small rhombohedral distortion from its original simple NaCl-type structure[1].

The magnitude of the distortion is affected by the content of excess oxygen over FeO and this can be varied over a relatively wide rang; B.T.M. Willis and H. P. Rooksby[2] has reported that the distortion diminishes with decreasing iron concentration, that is, with increasing departure from stoichiometric FeO.

In the present, in order to investigate the crystallographic transition point and the dependence of the distortion of FeO on the temperature, X-ray diffraction measurement was made continuously over a range from room temperature to 83°K. Rate of increasing and decreasing temperature were both 2°C/min.. Ferrous oxalate was precipitated from solution of ferrous chloride which was prepared from electrolytic iron. Precipitate was decomposed by heating at 800°C in vaccuo, thus sample **I** was obtained. Because this product gave lines of free iron as well as ferrous oxide on the X-ray powder pattern, it was again heated at 1000°C for several hrs.. This was called sample **II**, and it gave no line of free iron and showed an increased lattice parameter by 0.003 Å.

Observed diffraction line was (220) in cubic index which splitted into (211) and $(10\bar{1})$ in rhombohedral indices. In sample **II**, the line was gradually broadened on initial stage of cooling below the room temperature and became splited into two lines from which rhombohedral lattice constants a and α were calculated. The split grew larger as the temperature approached to 83°K.

Fig. 1 show the half-value breadth of the line and the rhombohedral angle α versus temperature relations.

In sample **I**, the line (220) was broadened similarly as in sample **II**, but remained unsplit even at liquid-nitrogen temperature. The starting temperatures of line brodening which coincide with each other in sample **I**, and **II**, are in good accord with transition temperature determined by means of the measurements of specific heat[3] or of dilatometry[4], but not of magnetic susceptibility[5] as shown in Table I.

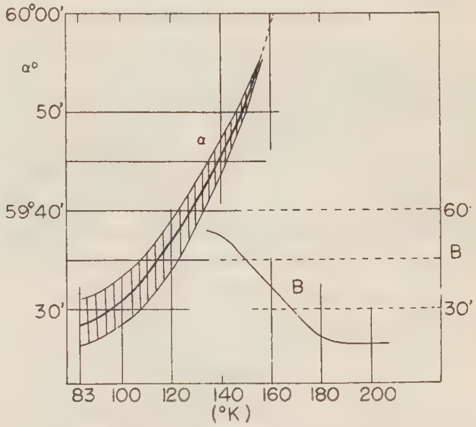

Fig. 1. Half-value breadth B of (220) and rhombohedral angle α versus temperature.

Table I.

Specific heat[3]	183-184°K
Dilatometry[4]	186°K
Magnetic susceptibility[5]	198°K
X-ray photografic[6]	203°K
X-ray diffractometer	180-185°K

R. Collongues[7] suggested that FeO with minimum iron content may distort to tetragonal symmetry. But in our present experiment, all X-ray patterns of sample **I** were in good agreement with those of the initial stage of sample **II**.

Further, with purpose to increase iron content and to make change in the Néel temperature, about 5 mole % of Fe powder (sample **III**) and Mn, Cr, Co, Cu, Zn powder etc. were mixed into sample **I**, sintered in vaccuo at 1000°C for several hrs. and quenched in water. Fig. 2 shows the differences of the distance of (111) and that of (100) for these samples.

So it is obvious that metalic ingredients, such as Mn, Cr, Co, etc. lower the crystallographic transition point as well as the magnitude of distortion at 83°K, whereas excess oxygen over FeO affects only the magnitude of distortion.

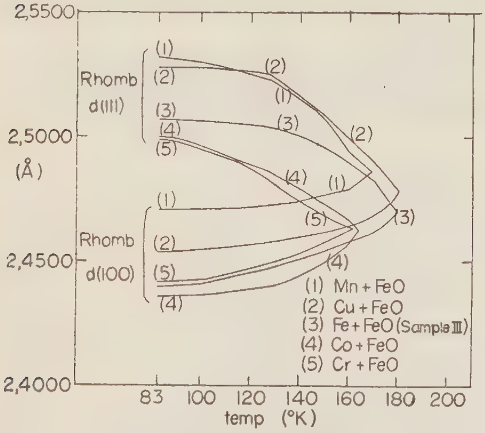

Fig. 2. Magnitude of Split of (111) Cub. → (111) Rhom. and (100) Rhom.

Note on Fe^{3+} ions in Spinel Structure

By Yoshikazu Sugiura

Sony Corporation Research Laboratory
Hodogaya, Yokokama

(Received June 3, 1961)

It was reported in the author's previous paper[1)] that the line widths of paramagnetic resonance absorption of Fe^{3+} ions in $MgAl_2O_4$ and $ZnAl_2O_4$ increased with the increasing concentration of ions, but decreased down when the concentration was further increased beyond a certain value. These phenomena were explained as the result of line broadening by dipolar interaction and narrowing by exchange interaction. It has been found, however, that if we assume that Fe^{3+} ions are randomly distributed and take the exchange interaction into consideration in the calculation of second and fourth moments based on the method of Kittel and Abrahams[2)], the maximum of line width is not expected for all concentration range.

We will give here another explanation based on the change in distribution of Fe^{3+} ions in A and B sites with their concentrations.

In the following calculation it is assumed that exchange interaction is isotropic and the terms linear in exchange interactions is neglected to their square terms. To compare with the results of experiments with polycrystalline samples the second and fourth moment are averaged over all angles. The second moments are calculated in spinel structure as follows,

$$\text{on A site:}\quad h^2\langle\Delta\nu^2\rangle=\tfrac{1}{3}S(S+1)\{0.655x^2+1.133xy)f\,\frac{g^4\beta^4}{(a/4)^6}\,,$$

$$\text{on B site:}\quad h^2\langle\Delta\nu^2\rangle=\tfrac{1}{3}S(S+1)\{1.514y^2+1.133xy\}f\,\frac{g^4\beta^4}{(a/4)^6}\,,$$

where f is the concentration of magnetic ions, and x and y are the rates of magnetic ions occupying A ane B sites, respectively. $(x+y=1)$. a is the lattice constant and β is the Bohr magneton.

When f is low, only the linear terms of f contribute to the fourth moment. Assuming that the line shape is Lorentzian with cut-off frequency[2)], the line widths are obtained from the second and fourth moments. In Fig. 1 the dotted lines show the total width between maximum slopes in the absorption curve for $x=1$ or $y=1$ neglecting A_{aa} and A_{bb}, the exchange interactions between the magnetic ions occupying the sites indicated by suffixes. The full lines show $\Delta H_{\max,\,\text{slope}}$ obtained by subtracting the width due to the crystalline field from the experimental value. In low f region Fe^{3+} ions are assumed to occupy A sites in $MgAl_2O_4$ and B sites in $ZnAl_2O_4$, consistent with the assumption used in calculating the crystalline fields on A and B sites. It is estimated from the difference between the calculated and experimental curves that $A_{aa}/g\beta=0.7\times10^3$ Oe for $MgAl_2O_4$ and $A^{bb}/g\beta=1.1\times$

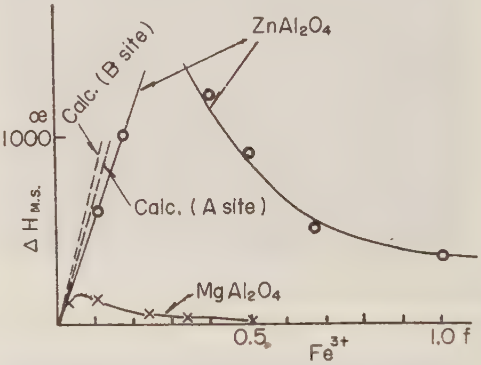

Fig. 1.

10^3 Oe for $ZnAl_2O_4$. These values are slightly smaller than the one estimated from Curie point.

In high f region, the calculated line widths increase proportional to $f^{1/2}$ and no maximum appears. So the following assumptions are proposed to explain the experimental results. In $ZnAl_2O_4$, Fe^{3+} ions occupy only B sites for low f, but the number of ions occupying A sites increase with f and the line widths decrease through the narrowing effect of large exchange interaction A_{ab} between the magnetic ions in A and B sites. In $MgAl_2O_4$ the variation of distribution has a reverse tendency.

Considering only the large exchange interaction A_{ab}, f^2 term in the fourth moment is as follows,

on A sites: $h^4\langle\Delta\nu^4\rangle=K\{43.62x^2y+59.80xy^2\}$,

on B sites: $h^4\langle\Delta\nu^4\rangle=K\{76.42xy^2+34.90x^2y\}$,

$$K=\tfrac{1}{3}\{S(S+1)^2\}f^2\frac{g^4\beta^4}{(a/4)^6}A^2_{ab}\ .$$

The distributions of Fe^{3+} ions in A and B sites estimated to fit the calculated line widths to the experimental ones with $A_{ab}/g\beta=3\times10^5$ are shown in Fig. 2. Even in limiting case $ZnFe_2O_4$, almost all Fe^{3+} ions occupy B sites and this tendency is not contradictory to the so-called normal spinel structure of $ZnFe_2O_4$. In Mg(Al, Fe)O_4, 15% of Fe^{3+} ions occupy B sites and the variation of distribution with the concentration seems to show the transition to the so-called inverse spinel structure of $MgFe_2O_4$.

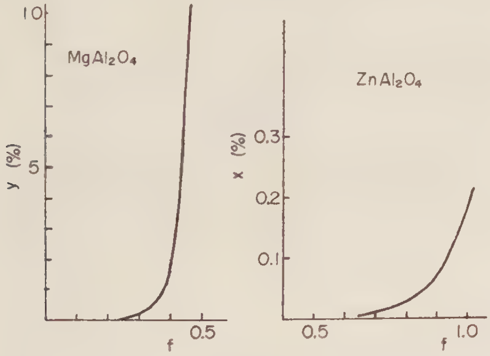

Fig. 2.

The authors wish to express their sincere thanks to Profs. R. Uyeda and K. Yoshida and Dr. H. Yoshioka for their helpful discussions.

Surface Field Effect and Noise in Ge Grain Boundary

By Yoshio Inuishi, Ken Kotani* and Ichiro Tsurumi*

College of Engineering, Osaka University, Osaka
**Kobe Kogyo Co., Kobe*

(Received June 5, 1961)

Effects of surface field on the current across the grain boundary in n type Ge, and accompanying noise were studied. 9.6° grain boundary was formed in an n type Ge crystal (5.8 Ω cm) with [100] common axis and sealed into vacuum glass tube with a field effect electrode of conducting glass, attached on the surface through a mica separater. (See Fig. 1) The current I across boundary *vs.* applied voltage V is shown in Fig. 1 taking field effect voltage V_F as parameter. I–V curve seems to follow the hyperbolic tangent relation derived by Mueller[1] and show saturation followed by soft breakthrough. The saturation current at room temperature increases remarkably by negative field voltage ($V_F<0$) application which produces p type inversion layer on the both n type Ge surfaces and a kind a channel for hole current across boundary. Positive field voltage, which should form n type layer bridging grain boundary, did not produce remarkable effect except at very high value of V_F.

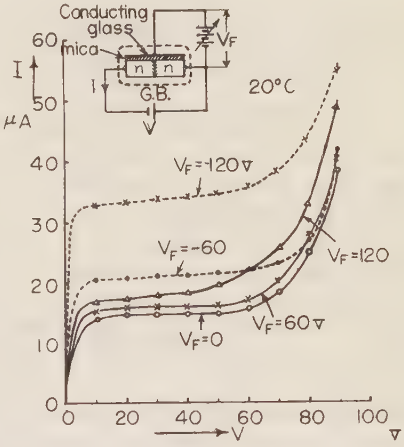

Fig. 1. Current *vs.* voltage across Ge grain boundary at various surface field.

Fig. 2 shows the current I and mean square short circuit noise current $\langle\Delta i^2\rangle$ at 1 KC as functions of surface field voltage V_F at room temperature. One can see that the increase in surface channel current (hole) is accompanied by the increase in $1/f$ noise just as the case of PN junction[2]. Photocurrent response around boundary was obtained by shinning fine beam of chopped light through conducting glass electrode at various field voltage V_F as shown in Fig. 3, which evidently shows the growth of p type channel for $V_F<0$.

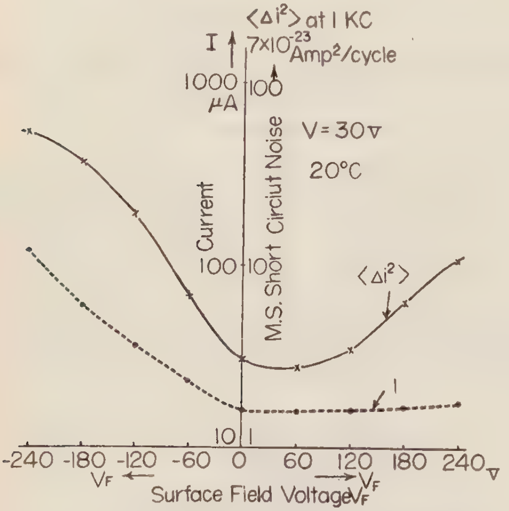

Fig. 2. Current and noise *vs.* surface field voltage.

Without field voltage ($V_F=0$), the I-V curve seems to be little affected by the surface component showing minimum saturation current. (Fig. 2) Noise spectrum, however, shows small $1/f$ component beside larger G-R component at lower frequency. This fact might suggest inherent $1/f$ noise and barrier height fluctuation at the grain boundary.

At lower temperature (−40°C), positive surface field voltage produces remarkable increase in saturation current and noise, on the contrary to the case of room temperature. The mechanism of this phenomena is not clear, but the importance of electron current across boundary in lower temperature[1] seems to be the case. Thanks go to Mr. Shibaike who has carried this experiment.

Semiconducting Properties of $SnSe_2$ and $GeSe_2$*

By Sizuo ASANABE

Fundamental Research Laboratory, Nippon Electric Co. Ltd., Kawasaki-shi, Japan

(Received June 23, 1961)

In connection with the semiconducting properties of SnSe[1),2)] and GeSe[3)], the compounds $SnSe_2$ and $GeSe_2$ were prepared, by melting the stoichiometric amounts of their component materials (Sn, J. M. 4-nines; Ge, about 8-nines; Se, 5-nines) in evacuated quartz tubes. The present note reports some semiconducting properties observed on these compounds.

(i) $SnSe_2$: In Fig. 1 are shown the electrical resistivitiy ρ and Hall coefficient R (negative), measured in the temperature range from 100°K to 800°K using an ordinary d.c. method. The curves A were obtained on the specimen quenched from 430°C and the curves B on the same specimen by repeating the measurements. Both the resistivity and Hall coefficient fall abruptly at about 700°K, being characteristic of ordinary semiconductors. This indicates the onset of intrinsic conduction and therefore, from the resistivity curve in this temperature range the energy gap can be estimated to be about 1.0 eV. The Hall mobility corresponding to the curves A and B in Fig. 1 is in good agreement above 250°K but at lower temperatures it decreases slightly as the measurement is repeated. The temperature dependence of the Hall mobility can be interpreted on the assumption of both acoustical and optical mode scatterings:

$$1/\mu=4.0\times10^{-6}T^{3/2}+8.3\times10^{-2}\{\exp(720/T-1\}^{-1},$$

choosing Debye temperature so that the curve may fit the experimental points. The irreversible changes in ρ and R in Fig. 1 may be ascribed to the similar change in carrier concentrations as observed previously in SnSe[2),4)] and GeSe[3)].

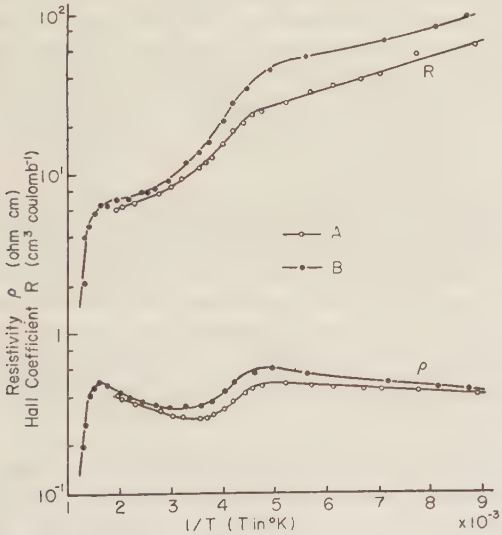

Fig. 1. Resistivity and Hall coefficient, inverse absolute temperature curves for a $SnSe_2$ crystal.

(ii) $GeSe_2$: $GeSe_2$ is a yellow crystal with strong cleavage. The resistivity, being too high to be measured at room temperature, can be measured at high temperatures as shown in Fig. 2. From the slope of the curves obtained on two specimens the energy gap is estimated to be nearly 2.3 eV. On the other hand, the optical absorption of the film evaporated on a quartz plate was measured by using combination of a medium size quartz spectrograph and a "Speckker" diaphragm photometer. The absorption edge at room temperature was found at 5300Å, corresponding to 2.35 eV which was in good agreement with the thermal data.

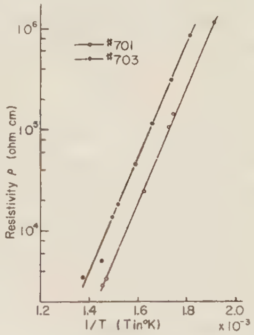

Fig. 2. Resistivity, inverse absolute temperature curves for $GeSe_2$ crystals.

The author should express his sincere thanks to the late Prof. Dr. A. Okazaki for his kind guidance and encouragement and to the members of his laboratory for their interests in the present investigation.

Temperature Dependence of Nuclear Resonance Absorption Line Width in Dy^{161}.

By Poh-Kun TSENG, Naomoto SHIKAZONO,
Hidekuni TAKEKOSHI and Tokio SHOJI

Department of Nuclear Physics, Japan Atomic Energy Research Institute

(Received May 10, 1961)

Ofer et al[1] investigated the spectrum of the recoilles resonance absorption of the 25.7-kev gamma rays in the decay of Tb^{161} using a Dy_2O_3 absorber and Tb^{161} emitter embedded in Gd_2O_3, and found that the spectrum had a triangular shape with a width about an order of 100 times as large as the natural width. They gave an interpretation that both the emission and absorption line would have approximately rectangular shapes produced by the hyper-fine splitting due to the internal paramagnetic field.

We have measured the spectrum varying the temperature of the Dy_2O_3 absorber. The method is the same as the previous one[2]. Tb^{161} was separated from a neutron-irradiated Gd_2O_3 sample by the ion exchange method.

The experiment were done keeping the absorber at the following temperature:

1) liquid nitrogen temperature,
2) room temperature,
3) 100°C,
4) 200°C,

while the source was kept at room temperature.

The absorption spectra are shown in Fig. 1. The width of the spectrum decreases to about one half as the temperature of the absorber rises from the liquid-nitrogen temperature to 200°C, while the depth of the spectrum changes only slightly. The width of the absorption line is shown in Fig. 2 as a function of the temperature of the absorber. The widths of the absorption line in Fig. 2 were obtained by subtracting the widths of the emission line from those of the observed spectra, because the width of the observed spectra are considered to be the sum of those of the emission and absorption line.

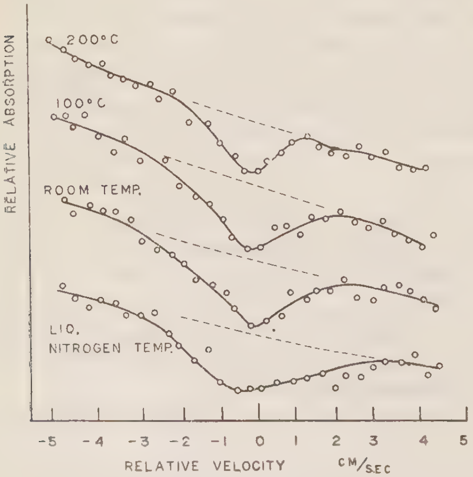

Fig. 1. The temperature dependence of the absorption spectrum as a function of relative velocity between source and absorber.

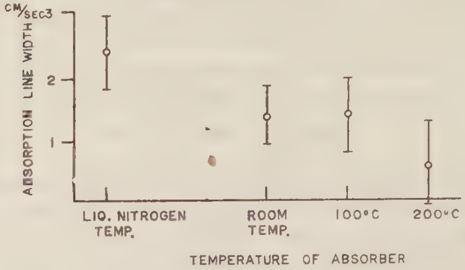

Fig. 2. The absorption line width as a function absorber temperature.

Measurements at the room temperature were made so carefully that hyper-fine structure, if any, might be revealed, but none was observed within the resolution of our experiment, which was less than the natural width of the gamma ray. The reason for the absence of the hyper-fine structure is considered to be that the emission and absorption lines are continuous by nature due to the paramagnetic relaxation.

The fact that the width of the absorption spectrum becomes smaller at higher temperature, while the depth of the spectrum decreases only slightly, will be useful for the measurement of the hyper-fine structure. If Tb^{161} nuclei were embedded in some kind of ferromagnetic material in which internal field at the nuclei would be of the order of 10^6 oe, then, the Zeeman splitting of emission lines would be larger than the width of the absorption line at 200°C which is about one tenth of the width at the room temperature. Under this condition we would be able to observe sixteen lines[3] in the absorption spectrum. The above method would also be applicable to the observation of the hyper-fine structure in other rare-earth nuclei.

We would like to thank T. Momota for his encouragement and H. Amano, H. Nakamura and N. Masaki for preparing the Tb^{161} source.

Cubic Contribution to EPR of Mn^{++} in $MgCl_2$

By Hiroaki MATSUMOTO, Kuniya FUKUDA
Masumi TAKESHIMA and
Yoichi UCHIDA
Department of Physics, Faculty of Science, Kyoto University

(Received June 28, 1961)

Our recent studies on EPR of $MgCl_2$-Mn have revealed that the spin Hamitonian has cubic symmetry term and the values of its parameters given in the previous report[1] need some corrections.

The EPR spectrum of Mn^{++} in $MgCl_2$ single crystal (1.13 mole % of Mn) is shown in Fig. 1 for the static magnetic field parallel to the crystal *c*-axis. These spectral lines are analysed with the spin Hamiltonian:

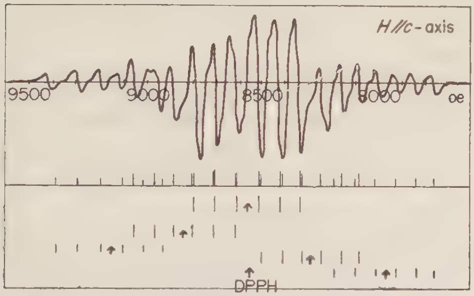

Fig. 1. EPR spectrum of $MgCl_2$-Mn.

$$\mathcal{H}=g\beta \boldsymbol{HS}+\boldsymbol{D}S_z^2+(\boldsymbol{a}/6)(S_\xi^4+S_\eta^4+S_\zeta^4)+\boldsymbol{ASI}\,,$$

where

$$g=2.000\pm0.001\,,\ \boldsymbol{D}=(-135\pm5)\times10^{-4}\,\mathrm{cm}^{-1}\,,\ \boldsymbol{a}=(11\pm5)\times10^{-4}\,\mathrm{cm}^{-1}\ \text{and}\ \boldsymbol{A}=(-82\pm4)\times10^{-4}\,\mathrm{cm}^{-1}\,.$$

The calculated line sites shown in the lower part of Fig. 1 are in good agreement with the observed spectrum.

The optical absorption spectra of $MnCl_2$ single crystals, in which the ligand field on Mn^{++} is the same as that in $MgCl_2$, were analysed by Pappalardo and Stout *et al*[2] and the values of cubic crystalline field parameter *Dq* were obtained as 750 cm^{-1} (Pappalardo) and 830 cm^{-1} (Stout). From these values the parameter $\boldsymbol{a}$ can be evaluated by Watanabe's theory[3] or Powell *et al*'s relation[4], as shown in the following table. The agreement of these values with that derived from the analysis of our spectrum is not so bad. The covalency effect between Mn^{++} and Cl^- as indicated by Pappalardo and Stout (the covalency parameter $\varepsilon=0.03$ or 0.13), if included in the theory, would give better agreement between the experimental value of $\boldsymbol{a}$ and the calculated one. *Dq* can be calculated from the spatial distribution of Cl^- ions and that of 3*d* electrons in Mn^{++} ion[3]. The appropriate value of *Dq* (800 cm^{-1}) can be obtained by using Slater type wave function[5] when screening constant of a 3*d* electron is put to be 0.6 instead of 0.35 for free ion.

The axial field parameter of Mn^{++} is calculated from the above Slater type wave function and electrostatic potential of neighbouring ions as follows[3]:

$$\Delta=13.7\times10^3\,\mathrm{cm}^{-1}\,.$$

From this Δ value and the experimental value of $\boldsymbol{D}$, M′ of Watanabe's theory[3] is evaluated to be 0.35 cm^{-1}.

$MgCl_2$ with 4.93 mole % of manganese showed a broad EPR line as shown in Fig. 2. This broad line cannot be explained by dipole broadening of *hf* lines in Fig. 1 with the assumption of uniform distribution of Mn^{++} ions in $MgCl_2$. This may suggest that manganese ions are not uniformly distributed in annealed $MgCl_2$ single crystals with higher concentration.

Table I. Calculated values of $\boldsymbol{a}$ from optical data of *Dq*.

Dq	$\boldsymbol{a}$ ($10^{-4}\,cm^{-1}$)

An Evidence for the Existence of a Diffusion Layer in the Melting Process of Semiconductors

By Shoji TAUCHI

Central Research Laboratory, Hitachi, Ltd., Kokubunji, Tokyo

(Received July 6, 1961)

Formerly Burton *et al*[1] introduced the concept of the diffusion layer for the growth of the crystals in order to interprete the dependency of the segregation coefficient on the growth conditions. We found, in the course of the molten diffused process of Ge and Si[2], that a diffusion layer also exists in the melting process of a crystal. In this process, after a small portion of the collector crystal is melted slowly and uniformly until it reaches the state in which both melting and growing phenomena completely stop; while maintaining this state for a required period the base and emitter impurities diffuse from the melt into the crystal thus forming a very thin and uniform base layer.

If we assume that the density of impurities in the melt directly under the crystal is equal to that corresponding to the initial doping to the melt, calculated conditions for the formation of base layer are not statisfied experimentally. In order to account for this discrepancy we propose the following model. In the process of melting the crystal a thin layer is formed in the melt which contains neither the base nor the emitter impurities directly under the crystal. The base and emitter impurities diffuse across this layer and then into the crystal. Denoting the *effective width* of the diffusion layer as δ, the net impurity distribution in the base region is given as follows:

$$N_b(x)=N_{b0}\,\mathrm{erfc}\left(\frac{\delta}{2\sqrt{D_M t_m}}+\frac{x}{2\sqrt{D_b t_m}}\right)-N_{e0}\,\mathrm{erfc}\left(\frac{\delta}{2\sqrt{D_M t_m}}+\frac{x}{2\sqrt{D_e t_m}}\right)-N_{c0} \qquad (1)$$

where N_{b0} and N_{e0} respectively denote the density of the base and emitter impurities at the crystal surface in contact with the melt, D_b and D_e the diffusivity of the base and emitter impurities in the crystal, t_m the diffusion time, N_{c0} the collector impurity concentration and D_M the diffusivity of the emitter and base impurities in the melt, assumed to be the same value ($5\times10^{-5}\,\mathrm{cm^2/sec}$) for simplicity.

From equation (1) the relation between the limiting value for N_{b0} (which is defined as N_{b0}^*) and δ becomes

$$\left(\frac{D_b}{D_e}-1\right)\left(\frac{x_m}{2\sqrt{D_b t_m}}\right)^2+\frac{\delta}{\sqrt{D_b t_m}}\left(\sqrt{\frac{D_b}{D_e}}-1\right)\times\left(\frac{x_m}{2\sqrt{D_b t_m}}\right)-\ln\left(\frac{N_{e0}}{N_{b0}}\sqrt{\frac{D_b}{D_e}}\right)=0 \qquad (2)$$

$$N_b(x_m)=0$$

where x_m denotes the distance from the crystal surface to the maximum point of the base impurity concentration. By successive experiments we have determined the limiting value of N_{b0}^* enough to produce a base layer. From this and using the equation (2), we can find the value of $\delta/2\sqrt{D_M t_m}$. This value and the density of impurities as well as N_{b0}^* are given in the Table I. The last column gives the value of δ.

Table I. The width of the diffusion layer.

Material	N_{c0} ($\mathrm{cm^{-3}}$)	N_{e0} ($\mathrm{cm^{-3}}$)	N_{b0} ($\mathrm{cm^{-3}}$)	t_m (sec)	$\frac{\delta}{2\sqrt{D_M t_m}}$	δ (mm)
Si	1.6×10^{16}	2.4×10^{18}	8×10^{16}	15	0.3	0.16
Ge	1.4×10^{16}	8×10^{17}	3.5×10^{16}	15	0.4	0.22

Another evidence for the existence of the diffusion layer is the comparison between the experimental value of the base width[2),3)] and its expected value. For Si *npn* junction if the presence of the diffusion layer is not taken into account the expected values are fairly larger than the observed ones. If it is assumed that $\delta/2\sqrt{D_M t_m}=0.2$, the agreement is quite good as can be seen in the Fig. 1.

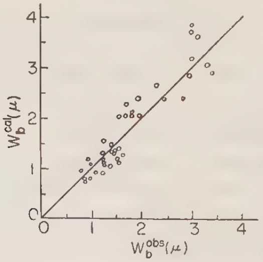

Fig. 1. Comparison of the calculated and observed values of the base width in silicon *npn* junction.

The details will be published in the near future in this Journal.

Appreciation for kind advice and encouragement it given to Mr. M. Tomono, Mr. H. Ueda and Mr. H. Kodera.

The Dynamic Bulk and Shear Viscosities of Polyvinylchloride

By Ryusuke KONO
Department of Applied Physics, Defence Academy, Yokosuka

(Received July 4, 1961)

In recent years an energy-dissipating process associated with volume deformation for various rubbers has been studied by several workers[1]. Following previous work[2] by the author on polystrene and polymethyl methacrylate, the dynamic bulk and shear viscosities of polyvinylchloride were measured in frequencies of 1, 2.25 and 5 Mc/s at temperatures encompassing the transition from glassy to flow state.

Experimental apparatus for the longitudinal and transverse wave measurement was the same as that reported in the previous paper[2].

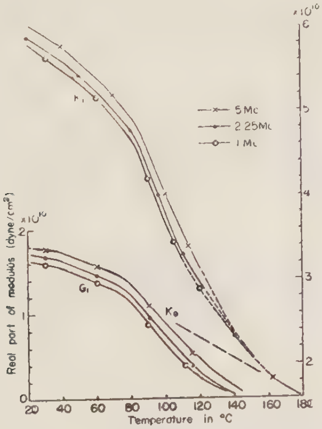

Fig. 1. Real part of the shear and bulk moduli versus temperature.

The real part of the shear modulus G_1 and bulk modulus K_1, the imaginary part of the shear modulus G_2 and longitudinal wave modulus M_2 $(=K_2+4G_2/3)$ are plotted against temperature in Figs. 1 and 2, respectively. The glass transition temperature is 78°C by the measurement of linear thermal expansion. An increase in G_1 and K_1 with increasing frequency is noted even in the glassy region, showing much more remarkable dispersion in the transition region. It was impossible to make any measurements for the shear wave in the region shown by the dotted line because of the high attenuation. The direct determination of the values of K_1 in flow state was impossible, but it can be determined since the values of G_1 in this state were very small in comparison with that of the real part of longitudinal wave modulus M_1 $(=K_1+4G_1/3)$. The dashed line in Fig. 1 represents the bulk modulus in flow state K_0. An extended frequency plot based on the reduced variable technique of Ferry and others[3] (after making a small correction by multiplying the modulus at absolute temperature T by a factor T_0/T) is carried out. The shifted curves of G_1, K_{1p} $(=K_1-K_0)$, G_2 and M_2 for polyvinylchloride at a reference temperature of $T_0=125$°C are shown in Fig. 3. The peak in G_2 occurs almost at the same reduced frequency as that in K_2. The shifting factor a_T versus temperature for shear modulus and bulk modulus are

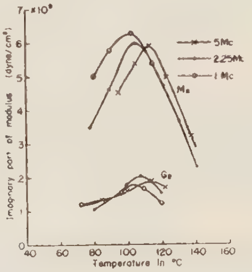

Fig. 2. Imaginary part of the shear and longitudinal wave moduli versus temperature.

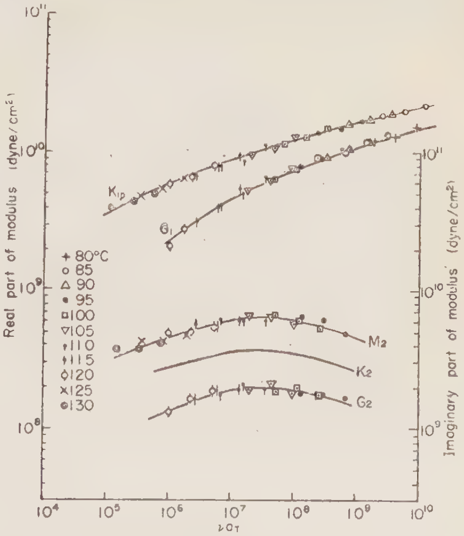

Fig. 3. Real and imaginary parts of the reduced shear and bulk moduli reduced to 125°C.

shown in Fig. 4. Williams-Landel-Ferry's[4] equation fits the experimental data obtained in the temperature range 105°C to 135°C when T_s is chosen as 125°C. If logarithms of the factor a_T for G_1 and K_{1p} are plotted against $1/T$, the plots fall on a single straight line. Thus the apparent activation energy for volume deformations is nearly equal to that for shear deformations. The value of activation energy is 59 Kcal/mol.

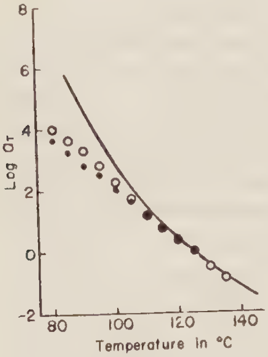

Fig. 4. Shifting factor a_T versus temperature for shear modulus (closed circles) and bulk modulus (open circles) reduced to 125°C. Solid line represents Williams-Landel-Ferry's equation (T_s= 125°C).

It is concluded at once from these results that temperature and frequency dependence, the activation energy, relaxation times for bulk modulus are quite similar to those for shear modulus. Thus the molecular mechanism in the volume and shear deformations should be the same for polyvinylchloride.

Reflection of a Weak Shock Wave in a Perfectly Conducting Gas

By Shigeki MORIOKA

Department of Physics,
Faculty of Science and Engineering,
Ritumeikan University, Kyoto

(Received May 29, 1961)

In this note, discussion is made on the "regular" reflection[1] of a weak plane shock wave propagating in a homogeneous, perfectly conducting gas from a solid wall, in the presence of a uniform magnetic field parallel to the wall. Let us take the system of reference in which the shocks are at rest. Let α be the shock angle, θ the deflection of flow, M the Mach number, A the Alfvén number and p the pressure, and let suffixes 1, 2, 3 denote the various quantities pertaining to the regions bounded by the wall and the shocks as shown in Fig. 1. Then, $x_\nu = \tan(\alpha_\nu - \theta_\nu)/\tan\alpha_\nu$ satisfies the equation

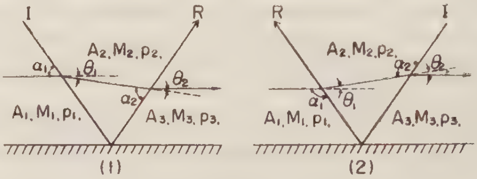

Fig. 1. Regular reflection of plane shock wave. (1) for A_1, $M_1>1$, (2) for A_1, $M_1<1$ and $M_1^2+A_1^2+1>0$.

$$\begin{aligned}&(\gamma+1)(A_\nu^2-1)^2M_\nu^2x_\nu^3\\&+(A_\nu^2-1)\{(\gamma+1)M_\nu^2-2A_\nu^2-(\gamma-1)A_\nu^2M_\nu^2\\&\qquad-(\gamma M_\nu^2+2A_\nu^2)\cot^2\alpha_\nu\}x_\nu^2\\&-\{(2-\gamma)A_\nu^2+(\gamma-1)\}M_\nu^2\cot^2\alpha_\nu x_\nu-M_\nu^2\cot^2\alpha_\nu=0\\&\qquad\qquad(\nu=1,2)\,. \qquad (1)\end{aligned}$$

Assuming that the incident shock is weak and hence so is the reflected shock, we can put

$$\cot^2\alpha_\nu=\lambda_\nu^2(1-\varepsilon_\nu)\,,\quad x_\nu=1-\delta_\nu\,,\quad |\varepsilon_\nu|,\ |\delta_\nu|\ll 1\,, \qquad (2)$$

where

$$\lambda_\nu^2=(A_\nu^2-1)(M_\nu^2-1)/(M_\nu^2+A_\nu^2-1)>0\,.$$

Eq. (1) then becomes

$$\delta_1=F_1\varepsilon_1+G_1\varepsilon_1^2+O(\varepsilon_1^3) \qquad (3)$$

where F_1 and G_1 are functions of A_1^2 and M_1^2 given in (6). On the other hand, A_2, M_2 can be expressed in terms of A_1, M_1, p_1 and δ_1:[2]

$$\begin{aligned}&A_2^2=A_1^2-a_1\delta_1\,,\\&M_2^2=M_1^2-a_1A_1^2\{(\gamma-1)M_1^2+2\}\delta_1\,, \qquad (4)\\&p_2=p_1(1+\gamma a_1A_1^{-2}\delta_1)\,,\end{aligned}$$

where $a_1=A_1^2-1$. Then from Eqs. (1), (2) and (4), λ_2^2 and δ_2 can be expressed as

$$\begin{aligned}\lambda_2^2&=\lambda_1^2(1-R\delta_1)+O(\varepsilon^2)\,,\\ \delta_2&=(F_1+F_2\delta_1)\varepsilon_2+G_1\varepsilon_2^2+O(\varepsilon^3)\,,\end{aligned}\tag{5}$$

where R and F_2 are functions of A_1^2 and M_1^2:

$$\begin{aligned}R&=\frac{M_1^4+\{(\gamma-1)a_1-1\}M_1^2+2a_1}{(M_1^2-1)(M_1^2+a_1)}\,,\\ F_1&=\frac{2(M_1^2-1)(M_1^2+a_1)}{M_1^2\{3(M_1^2-1)+(\gamma+1)a_1\}}\,,\\ F_2&=\frac{2a_1 f}{A_1^2M_1^4\{3(M_1^2-1)+(\gamma+1)a_1\}^2}\,,\\ G_1&=\frac{2(M_1^2-1)^2(M_1^2+a_1)g}{A_1^2M_1^4\{3(M_1^2-1)+(\gamma+1)a_1\}^3}\,,\\ f&=-(2-\gamma)\{(2-\gamma)a_1+1\}M_1^6\\ &\quad+\{3(5-3\gamma)a_1+(5-\gamma)\}M_1^4\\ &\quad-\{(\gamma^2-1)a_1^2+3(6-\gamma)a_1+3\}M_1^2\\ &\quad-2a_1\{(\gamma+1)a_1-3\}\,,\\ g&=-\{(2-\gamma)a_1+1\}M_1^4\\ &\quad+\{(\gamma-1)(\gamma-2)a_1^2+(7-4\gamma)a_1+1\}M_1^2\\ &\quad-2a_1\{(2-\gamma)a_1+4\}\,.\end{aligned}\tag{6}$$

Using Eqs. (2) to (5), the condition for the regular reflection, i.e. $\tan\theta_1=\tan\theta_2$, yields

$$G'\varepsilon_2^2+(F_1+R'\varepsilon_1)\varepsilon_2-(F_1\varepsilon_1+G'\varepsilon_1^2)=0 \tag{7}$$

where

$$G'=G_1+(\cos^2\alpha_1-\tfrac{1}{2})F_1+\sin^2\alpha_1 F_1^2$$

and

$$R'=F_1F_2+(\cos^2\alpha_1-\tfrac{1}{2})RF_1^2\,,$$

and terms of $O(\varepsilon^3)$ have been neglected. Thus, the regular reflection is possible in the range of ε_1 satisfying $D\equiv(F_1+R'\varepsilon_1)^2+4G'(F_1\varepsilon_1+G'\varepsilon_1^2)\geqq 0$, and hence the value of ε_1 corresponding to $D=0$ (say ε_{1e}) gives the limiting shock angle α_e by use of Eq. (2). The values of ε_{1e} as a function of A_1^2, M_1^2 are shown in Fig. 2. The effect of the magnetic field on the limiting curve for the occurrence of regular reflection is shown in Fig. 3. For $M_1>1$ and $1\gg A_1-1>0$ only regular reflection can take place, since the possible value of α_1, such that $90°\geqq\alpha_1\geqq\cot^{-1}\lambda_1$, is contained in the vicinity of $\cot^{-1}\lambda_1$, where it has been found that regular reflection occurs; in fact $\alpha_e\doteqdot 90°$ in this case.

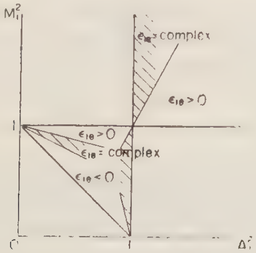

Fig. 2. Values of ε_{1e} as function of A_1^2, M_1^2.

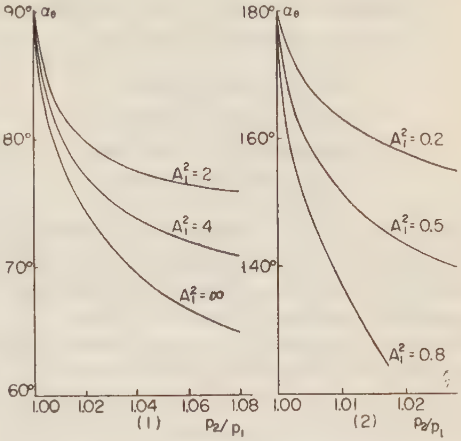

Fig. 3. Effect of magnetic field on limiting curve, above which regular reflection is theoretically impossible. (1) for A_1, $M_1>1$, (2) for A_1, $M_1<1$ and $M_1^2+A_1^2+1>0$.

In general, the presence of the magnetic field tends to enlarge the range of the shock angle in which regular reflection can occur.

Some Extra Lines in Paramagnetic Resonance Spectrum of Heavily Cr^{3+} Doped $K_3Co(CN)_6$

By Takeshi MITSUMA
Electrotechnical Laboratory,
Nagatacho, Tokyo, Japan

(Received June 8, 1961)

Baker, et al[1] have observed the magnetic resonance spectrum of undiluted $K_3Cr(CN)_6$ and suggested the existence of rather strong isotropic exchange interaction between Cr^{3+} ions.

We have observed the paramagnetic resonance spectrum of Cr^{3+}-doped $K_3Co(CN)_6$ with Cr^{3+} concentration of 10% and 15% by weight with an aim of studying nature of exchange interaction in strong covalent bonding crystal.

Measurements have been made at 4.2°K and room temperature using 9.4 Gc/s frequency. The samples are rotated in the *bc*-plane.

In addition to three normal Cr^{3+} lines a number of extra lines are observed. A major part of typical resonance spectrum of $K_3(Cr_{0.10}Co_{0.90})(CN)_6$ is shown in Fig. 1. This curve is obtained at 4.2 °K and in the direction of static magnetic field H_0 forming an angle of 20° with the *c*-axis. Angular variation of the resonance fields of stronger lines are shown in Fig. 2. Lines 'a', 'b' and 'c' are allowed lines and 'd', 'e' and 'f' are forbidden lines of Cr^{3+} ions respectively. This assignment is proceeded using the following spin-Hamiltonian in *bc*-plane,

$$\mathscr{H}=g\beta H_0S_z+(1/2)(3E\cos2\varphi-D)(S_z^2-5/4)$$
$$+(D+E\cos2\varphi)(S_+^2+S_-^2)+i(1/4)E\sin2\varphi$$
$$\times[(S_zS_++S_+S_z)-(S_zS_-+S_-S_z)]\,, \quad (1)$$

where φ is the angle between *b*-axis and H_0.

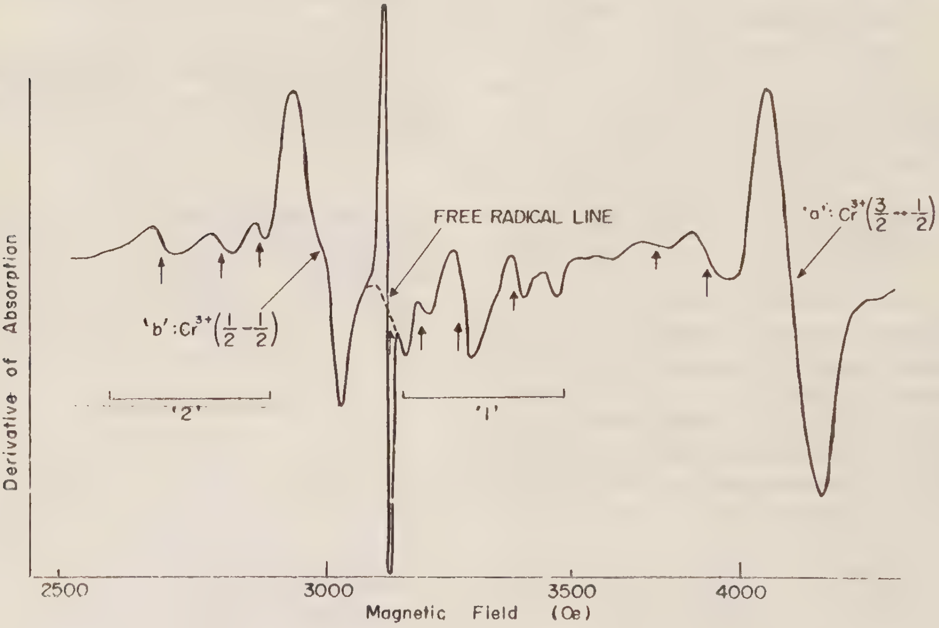

Fig. 1

On the other hand, the group '1', '2' and '3', '4' are the extra lines. Besides these, there are some lines in the neighborhood of lines 'a' and 'c'. The angular dependence of these lines is not so clear.

At room temperature, some of these extra lines are obscure.

The origin of these extra lines is not clear at the moment. But the following experimental evidences are interesting. These lines are not observed in the more diluted salt, $K_3(Cr_{0.01}Co_{0.99})(CN)_6$. Since their angular variation is rather similar and spectrochemical analysis does not show the presence of any other ions in this salts, it seems reasonable to assume that the observed extra lines are produced by Cr^{3+} ions themselves. Considering these facts, our experimental result may be interpreted by the effect of polytypism reported by J. O. Artman, et al[2]. The presence of line '4' may, however, indicate the presence of some other origins, for example, exchange interaction of Cr ions like the case of Cr^{3+} ions in Ruby[3).]** In our case, more careful investigation of the temperature variation of individual lines will be required in order to identify the origin of the extra lines as caused by exchange interaction of Cr ions.

Electrical Properties of TlSe

By Ryuichi Mori* and Kimio Hashimoto

Department of Physics, Faculty of Science
Kyusyu University, Hukuoka

(Received May 25, 1961)

The electrical resistivity ρ and the Hall coefficient R of TlSe single crystals were measured in the temperature range between about 100° and 450°K. The temperature dependences of ρ and R are shown in Figs. 1 and 2, respectively. These values were

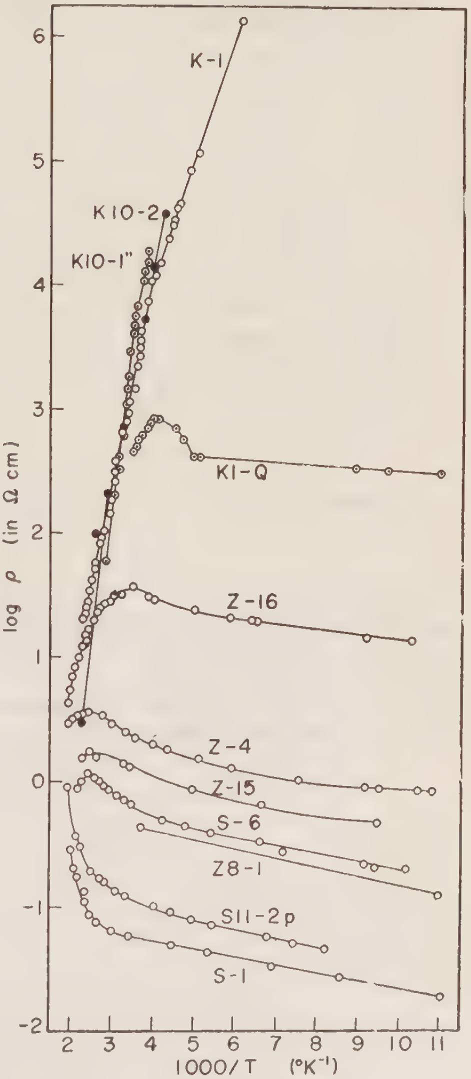

Fig. 1. Resistivity of TlSe as a function of temperature. The symbols denote the samples growing with normal freezing (S), zone-melting (Z) and pulling (K) techniques. The sample K1-Q is the specimen quenched after the measurement of the sample K-1.

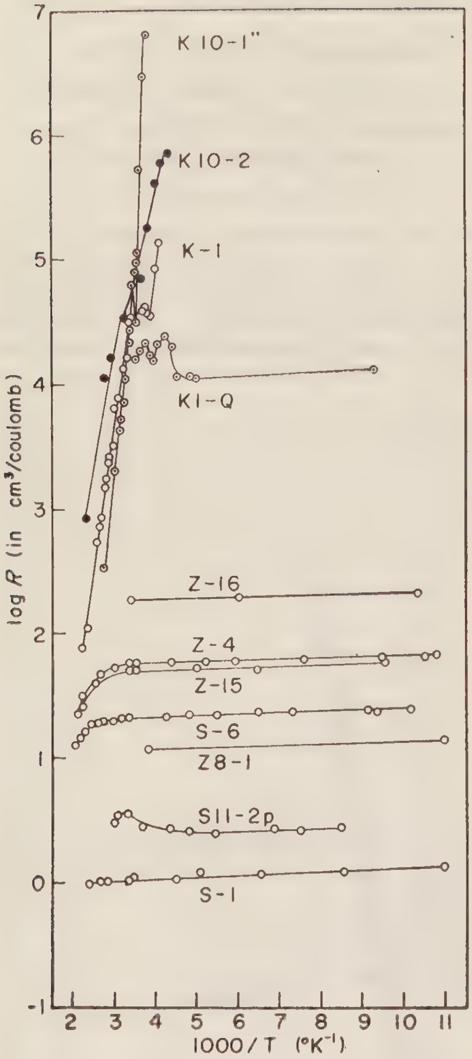

Fig. 2. Hall coefficient of TlSe as a function of temperature.

obtained from the d.c. measurements on the parallelepiped specimens; two of the long side surfaces were the cleavage surfaces.

The Hall coefficients of all the specimens investigated are positive. Although the temperature variations of ρ and R show the characteristics of typical semiconductors, the anomalous humps of R are observed on the some specimens at about 250°K. These humps seem to become marked by heat treatment as the anomalous Hall coefficient on SnSe[1].

Mooser *et al*[2] reported that the intrinsic activation energy of TlSe was 0.57 eV and also Akhundov *et al*[3] reported that it was 0.56 eV. These values were obtained from the temperature dependence of the resistivity. From the present investigations, however, at least two activation energies of about 0.6 and 1.3 eV are obtained. The values of the activation enegies reported earlier might be those of acceptor levels.

Angular Distributions of Photo-protons from Li, Al, S, Ni, and Cu

By Masayoshi MASUDA

Department of Physics, Faculty of Science, University of Osaka

(Received June 26, 1961)

Thin foils of lithium, sulfur, aluminum, nickel and copper have been irradiated with the X-ray beam from a betatron at Osaka University, and angular distribution of photo-protons were obtained by means of a ZnS scintillation detector.

The angular distribution of photo-protons thus obtained can be classified into two broad types, one isotropic and the other forward asymmetric. Aluminum and nickel (21 MeV) belong to the former type; while lithium, sulfur, nickel (18 MeV) and copper fall under the latter type, which is represented by the theoretical form, $a+b\sin^2\theta(1+c\cos\theta)^2$.

As an exceptional case, copper has shown an abnormal angular distribution having a maximum in the forward direction and also a rise up in the backward direction. The functional form which fits best to this distribution has been calculated by a Bendix computor and compared with the recent theory of photo-nuclear reactions.

§ 1. Introduction

It is well known that the process of photo-proton emission is divided into two categories, one is the evaporation process which exhibits an isotropic angular distribution of photo-protons, and the other is the direct process which gives the 90° symmetric and forward asymmetric angular distribution explained by Courant[1] as well as by Levinger[2].

A number of experiments of measuring the angular distribution of (γ, p) have been carried out to study the direct process, and the validity of this model has been confirmed in the energy region of 50–200 MeV.

On the other hand, in the energy region of 20–25 MeV, measurements have shown various types of angular distribution depending on the nuclei. An attempt[3],[4] to ascertain the direct process, which is generally mixed in various processes in this energy region, has been performed with heavier elements as target nuclei, in view of the possibility that the high Coulomb barrier will greatly reduce the number of evaporated protons and the direct process may account for almost all of the emitted protons. But even among these elements, Ce has shown an isotropic distribution.

The aim of this work is to collect as much experimental information as possible about the angular distribution of photo-protons with the special target assembly treated in this paper.

This work has come to a success due to the use of a technique[5] developed recently with regard to the decay properties of the scintillator. By using the decay properties, the discrimination of photo-protons from the strong γ-ray background has been achieved.

§ 2. Experimental Procedure

The experimental arrangement is shown in Fig. 1. The X-ray beam from the betatron was doubly collimated with lead walls. The first collimator has a precise taper angle to the X-ray beam.

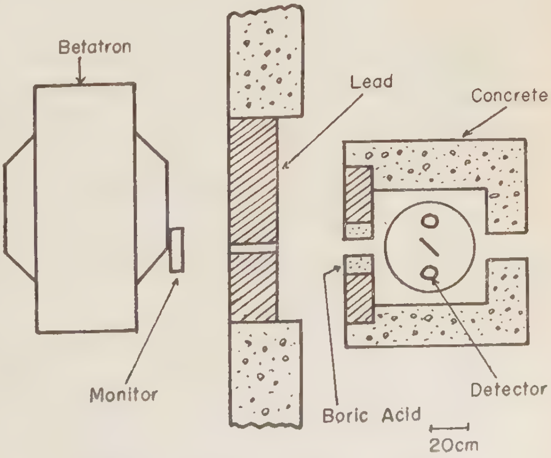

Fig. 1. Experimental arrangement.

As a misalignment of this collimator is one of the most definitive factors which influence the experimental results, the setting has been performed carefully. The optical and the photographic means assuring the coincidence of the center of X-rays with that of the target have been carried out. The detector consists of a Du-Mont 6292 photomultiplier tube and a ZnS scintillator backed by a semi-spherical light reflector. The scintillator has been made by depositing ZnS powder on a glass plate, 1 cm×2 cm in size. The detector and a target foil have been set on a rotating disk, which rotates as a unit about the inciden, X-ray beam.

Angles are set with an accuracy of better than 1 degree.

Measurements have been made simultaneously with two identical counters fixed at 180 degrees with respect to each other, the overall covering region being 30 to 330 degrees. It has been impossible to obtain the intervals from 150 to 210 degrees and from 330 to 30 degrees, because in these regions the X-ray beam strikes the detector assembly.

The typical discrimination curve of photo-protons from a nickel target is shown in Fig. 2. The steeply rising portion of this curve shows the effect of the pile-up of electrons or photons scattered strongly into forward direction due to the Compton effect. The relatively flat portion of this curve is due to the protons from the reaction of Ni (γ, p).

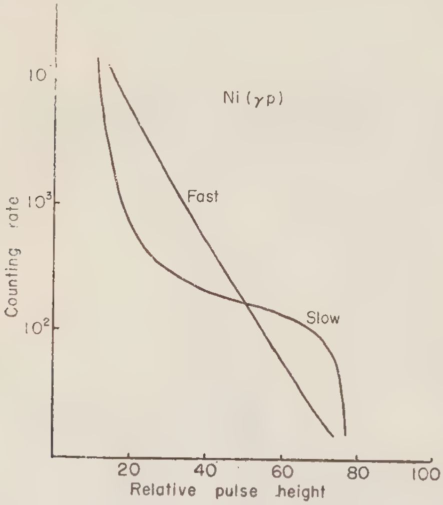

Fig. 2. Amplitude discrimination of proton from Ni(γ, p).

The powdered ZnS phosphors are opaque to own radiation in the thickness which corresponds roughly to the range of one MeV proton. For protons with energies from 1 to 10 MeV, which are mainly studied in this experiment, the light yield from ZnS is approximately independent of the energy. Fig. 2 does not give the energy distribution of photo-protons from Ni, but shows the discrimination curve of protons against the pile-up photons. The thickness of ZnS layer is 10–20 mg/cm². This has been selected for the finest discrimination of protons against the pile-up photons. The targets are foils of natural isotopic composition and their thicknesses are shown in Table I.

The most important thing in the measurement of the angular distribution of photo-protons is to know the energy of the detected protons. Even on the surface of the target the energy distribution of the photo-protons should be strongly deformed from its original form, because the target is sufficiently thick (5–10 MeV range) for the proton energy. Hence only the protons having higher energies are capable of escaping from the inside to the surface of the target. In addition, the air and the aluminum foil which is used as the window of the detector correspond to an energy loss of about 2 MeV when protons pass through these materials. A rough calculation has been carried out on Cu(γ, p) reaction. The result from Byerly and Stephens[6] has been used for the original energy distribution of photo-protons from copper. The target thickness and the proton transmission in various materials must deform this distribution. This is shown in Fig. 3 as "to be detected". This means that the photo-protons which are to be detected by the ZnS scintillator after transmission must have this energy

Table I. Thicknesses of target nuclei.

Target nucleus	Lithium	Aluminum	Sulfur	Nickel	Copper
Thickness in mg/cm²	133	135	160	178	178

distribution. The result of comparison of this experimental energy distribution with the theoretical one for the direct process, which has been calculated from Courant's formula, is shown in Fig. 3 as "direct process". The formula used is:

$$y(e) \approx (Z^2/4A^{4/3})aF(e)\int(N_\gamma(E)/E^3)\,dE \qquad (1)$$

where $y(e)$ is the number of protons of energy e per mole per roentgen ejected by a beam of photons with energy distribution $N(E)$, with maximum energy $E_{\max}$ and $E_{\min}=B_p+e$ (B_p is the proton binding energy); a is Avogadro's number and $F(e)$ is the Coulomb barrier penetration cross section. The photon energy distribution has been taken from the table calculated by using Schiff's formula[7].

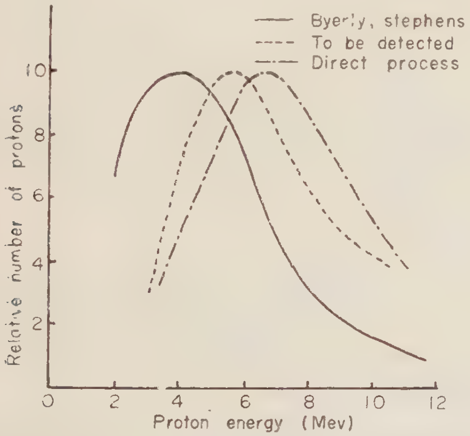

Fig. 3. Proton energy distribution from Cu(γ, p) reaction. The solid line is the result reported by Byerly and Stephens[6]. The dotted line is the energy distribution of detected protons under the present experimental condition. The broken line shows the calculated direct process.

The Coulomb barrier penetrability has been taken from Weisskopf's table[8] using $r_0=1.5\times10^{-13}$ cm. The value of B_p has been taken from the data of Byerly and Stephens ($B_p=6.1$ MeV). The copper foils of natural isotopic composition have been used for the target, but the yield of photo-protons from Cu^{63} and Cu^{65} is 1.07×10^6 p/mole/r and 0.37×10^6 p/mole/r respectively. Besides, the binding energy for Cu^{65} is 7.4 MeV, which is heigher than that for Cu^{63}. Therefore the calculation has been carried out only for Cu^{63}. The result shown in Fig. 3 as "to be detected" agrees roughly with the theoretical prediction for the direct process.

§ 3. Results and Discussion

The angular distributions from the various elements are shown in Figs. 4, 5, 6, 7 and 8.

When the nucleon absorbs the incident photon by electric dipole, the angular distribution has the form, $a+b\sin^2\theta$. The ratio of b/a is given by Courant's formula:

for the $l\to l+1$ transition:

$$b/a=(l+2)/2l \qquad (2)$$

for the $l\to l-1$ transition:

$$b/a=(l-1)/2(l+1)\,, \qquad (3)$$

where l is the orbital angular momentum of the ejected proton before photon absorption. If the electric quadrupole absorption is mixed in the electric dipole, the interference between the two modes gives an angular distribution of the form,

$$a+b\sin^2\theta(1+c\cos\theta)^2\,. \qquad (4)$$

To fit the present experimental data to this equation, the least square fit has been made and the constants have been determined except for the particular case of copper, which will be discussed in detail later. The determined constants are summarized in Table II.

Lithium

The rolled metallic lithium foil, sealed from the air in a polyethylene sack with a nitrogen gas to avoid oxidation of the surface, has been irradiated in a scattering chamber shown in Fig. 1. Even with this treatment the metallic lithium has been oxidized in about

Table II. Results of angular distribution of photo-protons.

Element	Angular distribution	b/a
Lithium	$1+0.25\sin^2\theta(1+0.90\cos\theta)^2$	0.25 ± 0.08
Aluminum	isotropic	
Sulfur	$1+0.57\sin^2\theta(1+0.23\cos\theta)^2$	0.57 ± 0.01
Nickel (21 MeV)	isotropic	
Nickel (18 MeV)	$1+6.0\sin^2\theta(1+0.87\cos\theta)^2$	6.0 ± 0.5

two days, during which period the measurement has been finished.

Some excitation curves of photo-proton reactions with lithium have been reported previously. One can find some curious facts in these results. Different detecting systems have given different results for the excitation function of the photo-proton reaction. For instance, there exists a sharp peak in the cross section curve reported by Titterton and Brinkley[9] but not in that reported by Tucker[10]. In the case reported by Rubin and Walker[11] two sharp peaks exist in the cross section curve, one at 15 MeV and the other at 20 MeV. This arouses interest in studying the angular distribution of photo-protons from lithium in the energy region from 15 to 22 MeV.

Bremsstrahlung of 21 MeV max. energy has been used for excitation of lithium in the present work. The measured angular distribution of photo-protons has a large forward asymmetry as shown in Fig. 4.

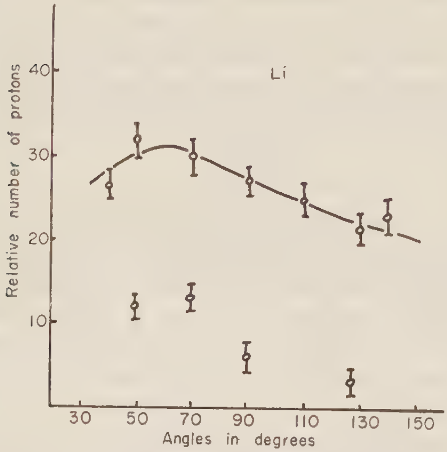

Fig. 4. Angular distribution of photo-protons from lithium for maximum excitation energy of 21 MeV. The smooth curve drawn by the least square has the form,

$$1+0.25\sin^2\theta(1+0.90\cos\theta)^2 .$$

The white dots quoted from the result of Whitehead[12], for excitation with 96 MeV are shown for comparison.

Further interest lies in the angular distribution when lithium is excited by lower energy, 15-18 MeV, where another peak exists in a cross section curve. Unfortunately, the counting rate of protons has been too small to measure the angular distribution of photo-protons with 18 MeV excitation.

There is a report[12] on the angular distribution of photo-protons with bremsstrahlung of 96 MeV, the result of which is similar to that of the present work. Thus it may be concluded that for both excitation energies the same mechanism of photon absorption, that is the direct process, is responsible.

Aluminum

A thin foil of metalic aluminum having a thickness listed in Table I has been irradiated for 100-200 minutes for each measured angle with bremsstrahlung of 21 MeV max., the resultant angular distribution being shown in Fig. 5. This is interpreted to be isotropic.

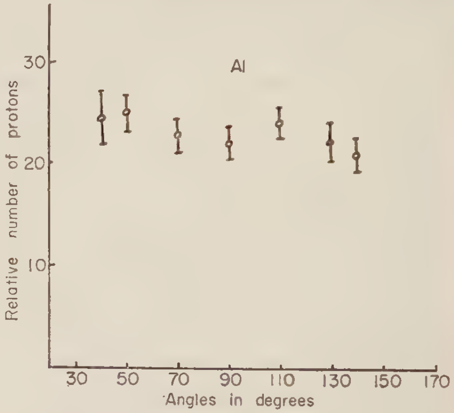

Fig. 5. Angular distribution of photo-protons from aluminum.

According to Ferrero[13], the excitation function for photo-protons of aluminum indicates that the evaporation process is predominant in the energy region of 12-20 MeV, but the direct process begins to contribute above 18 MeV excitation. Thus the excitation by 21 MeV bremsstrahlung will result mainly in the isotropic angular distribution.

Sulfur

Powdered sulfur has been melted so as to form a thin foil between two plane glass plates and has been cooled down in the room temperature, and the foil has been irradiated just after this treatment to avoid curling. The thickness of the foil is shown in Table I.

The angular distribution of photo-protons from sulfur is shown in Fig. 6. A symmetry almost at 90° has been obtained, except for a minor part of forward asymmetry. The expression obtained from the least square fit for this measurement is

$$1+0.57\sin^2\theta(1+0.23\cos\theta)^2\,.$$

The part with 90° symmetry can be interpreted by the direct process proposed by Courant. The value obtained of b/a is 0.57 in the present measurement.

Nickel

As the yield of photo-protons from nickel has been very large, measurement has also been carried out with bremsstrahlung of 18 MeV besides 21 MeV. The results are shown in Fig. 7. The counting rate of photo-protons with 18 MeV excitation has been found to be about 1–2 counts per minute, which is one tenth of the counting rate with 21 MeV excitation. The total count corresponding to one point in the figure is 100–200. The different behaviors of the two curves may be understood as follows. The detecting efficiency of high energy protons relative to that of low energy ones will be higher for 18 MeV excitation than for 21 MeV excitation, because of the effect of energy loss both in the target and in the air of emerging protons and also of the effect of Coulomb barrier supression. This will result in an enhanced forward asymmetry for the case of lower excitation. The larger isotropic part obtaided with a slightly higher excitation, however, can not be considered to be of much value from this point of view. This isotropic distribution agrees nearly with the result reported by Mann and Halpern[14], who used the same instrumental arrangement as that in the present experiment.

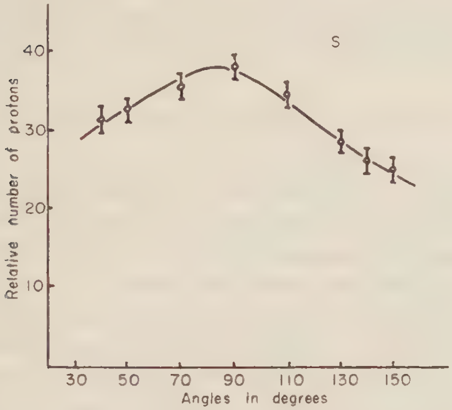

Fig. 6. Angular distribution of photo-protons from sulfur. The experimenta dots fit the expression, $1+0.57\sin^2\theta(1+0.23\cos\theta)^2$.

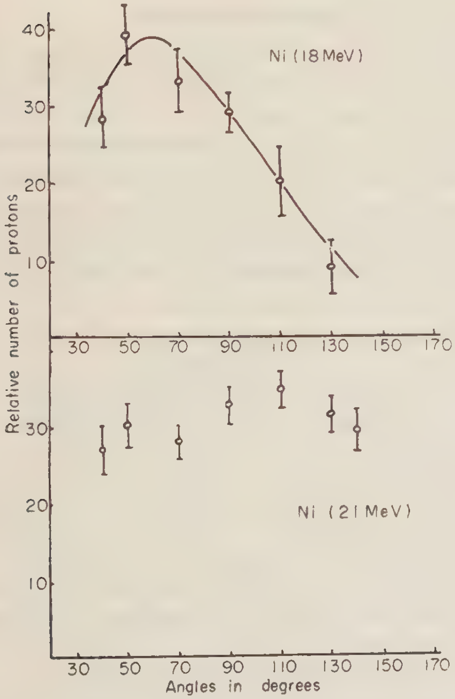

Fig. 7. Angular distribution of photo-protons from nickel. The results of the least square to fit the experimental plots with 18 MeV bremsstrahlung are described with the form,

$$1+6.0\sin^2\theta(1+0.87\cos\theta)^2\,.$$

Copper

A thin foil having a natural isotopic composition has been irradiated with 21 MeV bremsstrahlung, and the irradiation has been repeated 140 times for each angle for a total of 600 minutes in order to eliminate un-

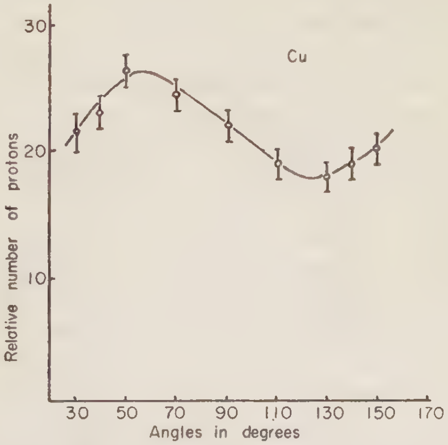

Fig. 8. Angular distribution of photo-protons from copper. The coefficients obtained by the least square fit are listed in Table III, assuming that the form is $\sum_{l=0}^{4} C_l P_l(\cos\theta)$.

certainty of the measurement in the backward direction, which offers a theoretical interest as will be discussed later.

The result is shown in Fig. 8, which indicates an abnormal result. There is a maximum at 50 degrees and a minimum at 130 degrees. The former effect has been found out not only in the present work but also in many references and has been well explained by theory; but the latter effect has never been reported definitely in the case of photonuclear reaction. A similar result has been reported by Spicer[16] for the angular distribution of photo-protons from argon 40. In this reference, higher energy protons showed an angular distribution having a minimum at 130 degrees, which is very similar to the present result. But the author of this reference has stated that this minimum should not be taken seriously since the statistics of the measurement at angles greater than 120 degrees were very poor. In the present measurement, an obvious minimum exists at 130 degrees.

This result has been analyzed by making the least square fit assuming that the form of the angular distribution is:

$$d\sigma/d\Omega=\sum C_l P_l(\cos\theta) \qquad (5)$$

and

$$d\sigma/d\Omega=\sum a_i \cos^i\theta \qquad (6)$$

where θ is the angle between the X-ray beam and the proton detector, $P_l(\cos\theta)$ the Legendre polynomials, and a_i and C_l the coefficients of the two functions.

Table III. Angular distribution coefficients for copper.

Legendre polynomials		Power series	
C_0	21.0494	a_0	21.112
C_1	3.0044	a_1	5.8524
C_2	−1.6930	a_2	8.2572
C_3	−6.0504	a_3	28.449
C_4	−1.0342	a_4	−16.445
		a_5	−55.612

The coefficients have been calculated with the Bendix G-15-D computor and listed in Table III. A good fit is shown in Fig. 8.

The result has been compared with the new theory which is based on the "two-stage mechanism" developed by Sawicki[17]. This mechanism is essentially a two-stage process: the γ-ray interacts with the surface oscillations of the nucleons; a proton bound to the rest of the nucleus interacts with the oscillating core and is emitted.

The copper nucleus has the last proton in a p-state, and according to the theory photoprotons form such a nucleus have an angular distribution showing a minimum in the backward direction, the form of which is given by

$$a+b\sin^2\theta+A\cos\theta(C_1+C_2\cos^2\theta-3C_3\sin^2\theta) \qquad (7)$$

where the term $a+b\sin^2\theta$ refers to the Courant theory and the rest are the interaction terms. Our experimental result is qualitatively in agreement with this theory.

The present result may be compared with those of other works: a forward asymmetry was reported by Mann, Halpern and Rothmann[14] with 25 MeV bremsstrahlung, and for excitation with higher energies, the isotropic angular distribution was reported by Dawson[15] who used 70 MeV bremsstrahlung.

Acknowledgement

The author is indebted to Professor T. Asada for the encouragement given to him throughout the course of the present work. Gratitude is also due to Messrs. M. Okumura, J. Okuma and K. Sasaki for their assistance in the operation of the betatron. Finally, the author wishes to thank Dr. K. Okamoto for his helpful discussion on the result of this work.

Photoprotons from Silicon and Phosphorus

By Katsufusa SHODA, Shoichi SHIINA*, Keisuke KOBAYASHI**, Ken ABE and Motoharu KIMURA

Department of Physics, Tohoku University, Sendai, Japan

(Received March 31, 1961)

Photoprotons from Si and P produced by a 24-MeV betatron have been observed in nuclear emulsions. Fine structures are observed in the energy spectrum of Si, showing a fairly similar shape to the excitation curve of Al (p, γ) reaction. The appearance of these structures is expected by resonating group model and probably by the channel coupling theory as well. The distances of the proton peaks in the spectrum are nearly equal to those expected by these theories. The type of spectrum of Si is different from that of P, and such difference seems to appear between even and odd Z neighbouring nuclei.

The angular distributions for P have large maxima around 90°, but those for Si have not so large maxima and minima. This suggests that the shell structure may have some effects on the photonuclear reactions.

§ 1. Introduction

In the energy region of the giant resonance of photonuclear reactions, the nucleus is highly excited and a large number of levels of the compound nucleus contributes to the transition. In the earliest stage of study of photonuclear reactions, however, the giant resonance was regarded as a broad resonance of the electric dipole interaction of photons with the nucleus[1),2)]. Katz et al.[3)] found first the fine structures of (γ, n) cross sections in their measurement of C^{12}, and O^{16}. Many fine structures have been observed in light nuclei afterward.

Wilkinson[4)] put forward the theory of single particle excitation in photonuclear reactions. According to his theory, fine structures will appear corresponding to single particle transitions. His theory seems to agree with several experiments.

Recently some fluctuations of cross sections or gross structures were also observed in (p, p'), (p, α), (n, n') and some other reactions in the intermediate energy region (10～30 MeV). These fluctuations do not seem to be explained so well by the usual model, and the fine structures of photonuclear reactions mentioned above may have some relations to these fluctuations. Shaw[5)] and Izumo et al.[6)] have calculated the effect of local heating of the nucleus using a resonating group model. On the other hand, Tamura et al.[7)] are trying to explain this phenomenon using the idea of channel coupling. These calculations expect some structures in the cross section curves and also in the energy spectrum of emitted particles for all reactions in the intermediate energy region.

The earlier experiments for the proton energy distributions of (γ, p) reactions of almost all elements in the giant resonance region were plotted with about 1 MeV interval which might be too large to find the fine structure. These roughly plotted proton spectra are in agreement with the predictions of the statistical theory for light and middle weight nuclei. The angular distribution shows a large difference from nucleus to nucleus. The photoproton spectra in several nuclei such as C^{12}, N^{15}, and O^{16} etc. show some fine structures, and the angular distributions have different shapes for different proton energies. De Sabbata[8] has reviewed these experiments and summarized the results.

We have investigated the energy and angular distributions of the photoprotons from Si^{28} and P^{31} with good statistics. Si^{28} and P^{31} are neighboring nuclei for the proton number, and the last shell has six $1d_{5/2}$ protons and one $2s_{1/2}$ proton, respectively. The results for Si^{28} and P^{31} (γ, p), therefore, may help us to understand the effect of shell structure to the reaction mechanism.

Si^{28} (γ, p) was investigated by Emma et al.[9], but the data were given only for the angular distributions. Čujec-Dobovišek[10] have also investigated the Si^{28} (γ, p), P^{31} (γ, p) and S^{32} (γ, p) by 32 MeV bremsstrahlung. According to her results a peak is found at about 8 MeV in the energy spectra for Si and S. This peak corresponds to $1d_{5/2} \rightarrow 1f_{7/2}$ transition at $E_\gamma \sim 20$ MeV through the mechanism stated by Wilkinson. The relatively high fractional yield of high energy protons is in good agreement with the theory. The angular distributions of her results involve a rather significant forward asymmetry, being interpreted to show an intereference between $E1$ and $E2$ absorption.

Our experiment has been done by 24 MeV bremsstrahlung. The reactions will be regarded as simpler at this energy than at 32 MeV.

§ 2. Experimental Procedure and Apparatus

Photoprotons emitted from Si and P irradiated by 24 MeV bremsstrahlung from Tohoku University betatron were detected by Ilford G-special emulsions, which were 600 μ thick and $\frac{1}{2}'' \times 2\frac{1}{2}''$ in size. Two plates and sample were placed on the holder mounted in a evacuated chamber which was combined with the collimator defining the beam area to 0.5 cm × 1.0 cm at the target. (Fig. 1).

The distance between the plates and the targets was about 2 cm and the maximum glancing angle of the plate was about 30°. Such a large glancing angle increases photoproton detection efficiency and reduces the ratio of the neutron-recoil protons to the photoprotons in the emulsion. The background was evaluated by the tracks entering the emulsions from wrong directions, and was lower than 2 percent. The background by the (n, p) reaction at the targets was estimated by the stray neutron number. It was proved to be negligible. In spite of the large glancing angle, the proton energy resolution is determined only by the uncertainty of proton energy absorption arised from target thickness.

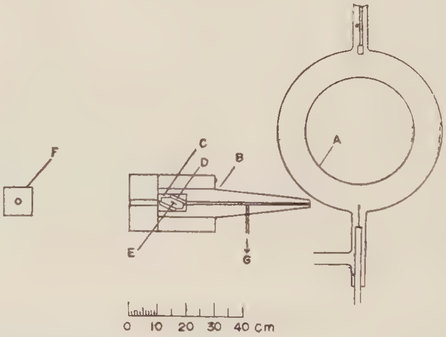

Fig. 1. Experimental arrangement showing A-betatron doughnut, B-lead stacked collimator and reaction chamber, C-plate and target holder, D-nuclear plates, E-target, F-monitor, G-vacuum pump.

The targets were the red phosphorus (19.4 mg/cm²) deposited on the Au-foil, and the natural silicon powder (9.38 mg/cm²) bound on the Au-foil by the cellulose acetate (0.2 mg/cm²). The size of its grain was about several micron in diameter. The thickness of Au foils was 0.19 mg/cm² for both targets. The background from the Au foil and the binder was estimated to be negligible.

The energy of the bremsstrahlung from the betatron was calibrated by the threshould energies of the Cu^{63} (γ, n) (10.8 MeV), Fe^{54} (γ, n) (13.8 MeV) and C^{12} (γ, n) (18.7 MeV) reactions and the drift of the energy was about ±0.05 per cent. The intensity was measured by a Victoreen thimble embedded at the center of a 10 cm cube of Lucite behined the plate chamber and was calibrated to the intensity without the collimator. The uncertainty of the dose values was about 20 per cent.

The plates were processed by dry temperature development with amidol developer. The best condition for hot stage was ninety minutes at 18.5°C for reducing fogs and increasing transparency of the emulsion. The photo-proton tracks were scanned with TIYODA binocular microscopes at a magnification of 600×. The scanned area was 2 mm×40 mm for Si and 3 mm×40 mm for P, and a longer side was parallel to the targets. For each measured proton track, the range, the angle to the beam direction and the corretion for the energy loss due to the target thickness were calculated. Barka's Table[11] was used for the proton range-energy relation. For the energy loss correction, the energy loss due to the effective half target thickness was added to each measured proton energy. The solid angle subtended by the scanned area for each proton direction was calculated geometrically at each point on the target and averaged on the beam area within the range of 10° around the several standard directions. The angular distributions were obtained using this solid angle.

The Table I indicates the exposure data.

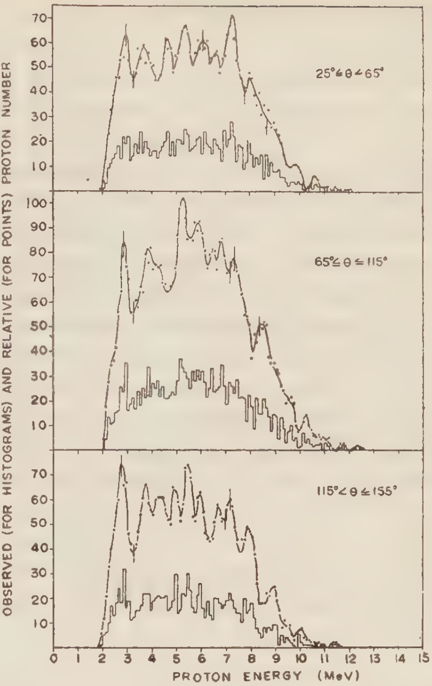

Fig. 2. Energy distributions of protons from Si^{28} for three directional groups. The smoothed results are shown by the points.

Table I. Exposure Data

Element	Si	P
(γ, p) threshold (MeV)	11.59	7.30
(γ, np) threshold (MeV)	24.65	17.91
Betatron energy (MeV)	24	24
Target thickness (mg/cm^2)	9.38	19.4
Roentgens at sample	5000	
Emulsion type	Ilford G-special 600 μ	
Area scanned (cm^2)	1.6	2.4
Total proton number $25° \leq \theta \leq 155°$	4366	3833

Resolution for energy loss by half target thickness

§ 3. Experimental Results

Silicon

The measured energy distributions are shown in Fig. 2 for the three directional ranges, and in Fig. 3 for the total protons. The energy distributions were plotted with 0.1 MeV interval which was much smaller than the resolution, hence, they were smoothed out by the method of Ferreira and Valoshek[12] and the smoothed results are shown in the same figures. These spectra exibit many peaks.

The theoretical energy distributions were calculated using the statistical theory of nuclear reactions. One would not expect the statistical theory to be applicable to such light nuclei as Si^{29} and P^{31}. However, the proton spectra for Mg^{25} (γ, p)[13], Al^{27} (γ, p)[14),15),16], P^{31} (γ, p)[10], A^{40} (γ, p)[17] and other reactions indicated that the statistical theory could reproduce the general features of the observed spectra. Hence we compared the experimental spectra with those of the statistical theory. Both spectra were normalized to fit to experimental points as shown in Fig. 3.

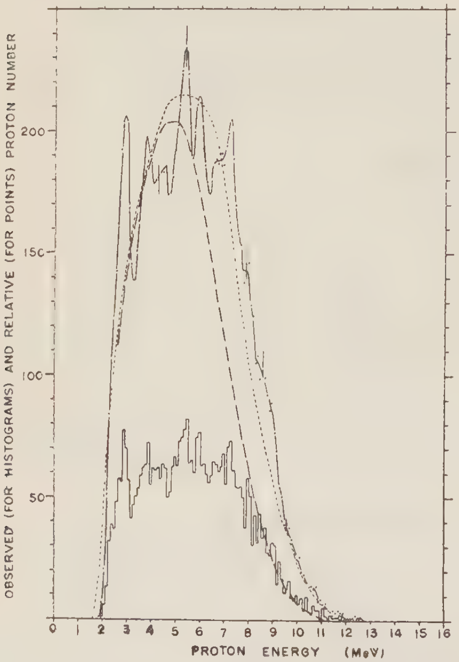

Fig. 3. Energy distribution of total observed protons and calculated distributions by the statistical theory from Si^{28}.

Full line: Observed spectrum smoothed out by the method of Ferreira and Valoshek.

Broken line: Calculated spectrum using $\omega = C \exp[2\sqrt{0.45\,E}]$ MeV^{-1}

Dotted line: Calculated spectrum using $\omega = C \exp[E/2.8]$ MeV^{-1}

Each curve is normalized to best fit to experimental points.

The proton energy distribution based on the statistical theory is given by

$$I(\varepsilon_p) = \varepsilon_p \cdot \sigma_c(\varepsilon_p) \int_{B_p+\varepsilon_p}^{E_{\gamma\,\max}} \times \frac{\sigma_{\gamma n}(E_\gamma) N(E_\gamma, E_{\gamma\,\max}) \omega(E_\gamma - B_p - \varepsilon_p)}{\int_0^{\varepsilon_\gamma - B_n} \varepsilon_n \sigma_c(\varepsilon_n) \omega(E_\gamma - B_n - \varepsilon_n) d\varepsilon_n} dE_\gamma \tag{1}$$

where ε_p and ε_n are the proton and the neutron energy, $\sigma_c(\varepsilon_p)$ and $\sigma_c(\varepsilon_n)$ are the capture cross sections by the residual nuclei for protons of energy ε_p and for neutrons of energy ε_n, which were used by Blatt-Weisskopf's calculations[18]. $\omega(E_\gamma - B_p - \varepsilon_p)$ and $\omega(E_\gamma - B_n - \varepsilon_n)$ are the level densities of residual nuclei after protons and neutrons were emitted, B_p, B_n being the binding energy. The experimental result of Katz et al.[19] was used for $\sigma_{\gamma n}(E_\gamma)$. $N(E_\gamma, E_{\gamma\,\max})$ is the photon spectrum, for which the Schiff spectrum[20] was used. The level density may be represented by using the Blatt-Weisskopf's table[18],

$$\omega = C \exp[2\sqrt{0.45\,E}] \text{ MeV}^{-1}. \tag{2}$$

On the other hand, according to Endt et al.,[21]

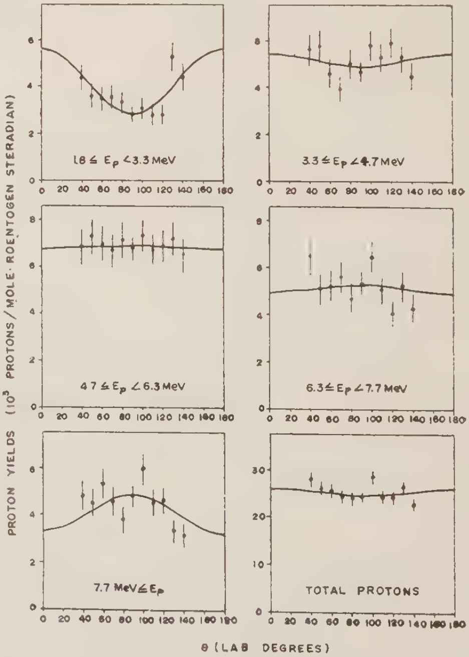

Fig. 4. Angular distributions of protons from Si^{28}. Full lines are obtained by least squares.

the following is deduced from the known levels of Al^{27}:

$$\omega = C \exp[E/2.8] \text{ MeV}^{-1}. \qquad (3)$$

The latter is in good agreement with that obtained from $Al^{27}(p, p')$ reaction which is shown as follows[22]:

$$\omega \propto \exp[E/2.7].$$

The energy spectra were compared for these two level densities.

Table II. Angular distributions calculated by least squares for $a+b \sin^2 \theta$.

Element	Proton energy (MeV)	Augular distributions
Si^{28}	1.8–3.3	$1-(0.50\pm0.39)\sin^2\theta$
	3.3–4.7	$1-(0.09\pm0.44)\sin^2\theta$
	4.7–6.3	$1+(0.01\pm0.40)\sin^2\theta$
	6.3–7.7	$1+(0.06\pm0.49)\sin^2\theta$
	larger than 7.7	$1+(0.48\pm0.73)\sin^2\theta$
	Total	$1-(0.05\pm0.20)\sin^2\theta$
P^{31}	2.7–4.5	$1+(0.85\pm0.42)\sin^2\theta$
	4.5–6.0	$1+(0.35\pm0.34)\sin^2\theta$
	6.0–8.5	$1+(1.31\pm0.59)\sin^2\theta$
	larger than 8.5	$(-0.08\pm0.18)-\sin^2\theta$
	Total	$1+(1.10\pm0.27)\sin^2\theta$

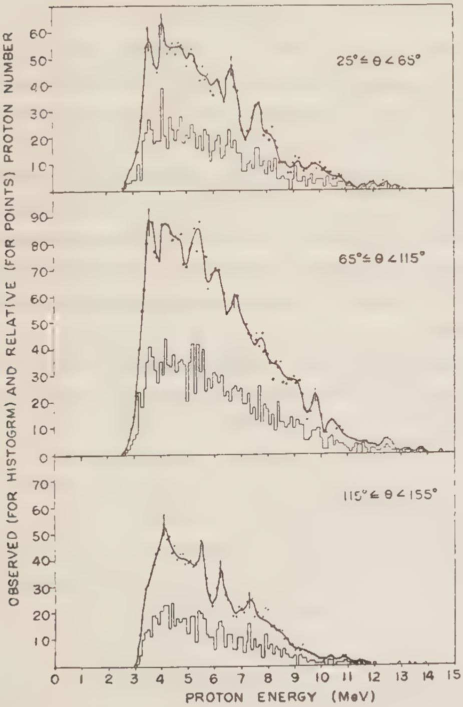

Fig. 5. Energy distributions of protons from P^{31} (γ, p) for three directional groups. The smoothed results are shown by the points.

The angular distributions corrected for the solid angle and devided into several proton energy regions are shown in Fig. 4. In all cases, the observed distributions were fitted with curves of the form $a+b\sin^2\theta$ assuming the symmetric angular distribution. a and b were determined by the least square fit and the calculated distributions are also shown in Fig. 4 and in Table II.

The yield of photoprotons corrected for the angular distribution was 2.9×10^5 protons per roentgen.

Phosphorus

The measured energy distributions are

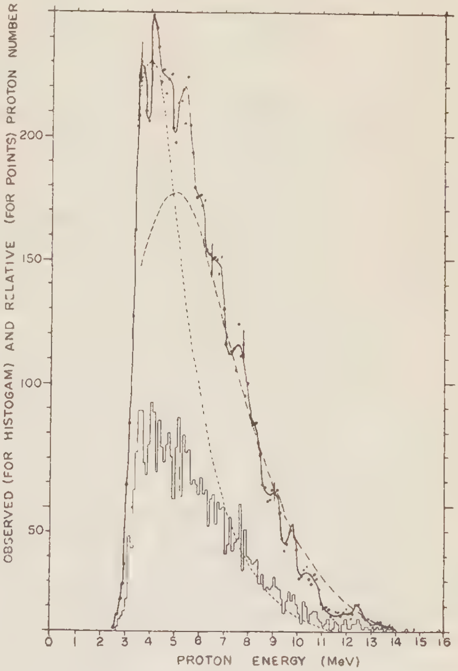

Fig. 6. Energy distribution of total observed protons and calculated distributions by the statistical theory from P^{31}.

Full line: Observed spectrum smoothed out by the method of Ferreira and Valoshek.

Broken line: Calculated spectrum using

$$\omega = C \exp[2\sqrt{0.52\,E}] \text{ MeV}^{-1}$$

Dotted line: Calculated spectrum using

$$\omega = C \exp[2\sqrt{2.42\,E}] \text{ MeV}^{-1}.$$

Each curve is normalized to best fit to experimental points.

shown in Fig. 5 and Fig. 6 in the same treatment as for Si. The proton energy resolution is worse than that for Si, but the spectra seem to exhibit some peaks. Photoprotons from the (γ, np) reactions are not included in Si^{28} results, but in the case of P^{31} they may affect the spectra and angular distributions for the proton energy region lower than 6 MeV.

The theoretical curves based on the statistical theory as in Si are also shown in Fig. 6. Two types of the level density of the residual nucleus were assumed as follows:

$$\omega = C \exp\,[2\sqrt{0.52\,E}]\ \mathrm{MeV}^{-1} \qquad (4)$$

$$\omega = C \exp\,[2\sqrt{2.42\,E}]\ \mathrm{MeV}^{-1} \qquad (5)$$

In Eq. (4) the parameter 0.52 corresponds to Blatt-Weisskopf's table for $A=30$[18]. Montalbetti et al.'s data[23] were used for $\sigma_{\gamma n}(E_\gamma)$ which appear in Eq. (1).

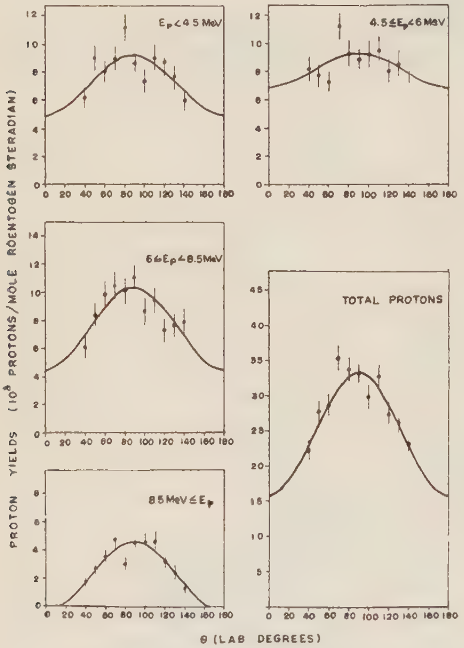

Fig. 7. Angular distributions of protons from P^{31}. Full lines are obtained by least squares.

The angular distributions are shown in Fig. 7. They are all nearly 90° symmetric. The best fitted curves of the form $a + b \sin^2\theta$ were obtained by the least square fit and are also shown in Fig. 7 and in Table II.

The yield of photoprotons corrected for the angular distributions was 3.2×10^5 protons per mole per roentgen according to the result using other plate.

§ 4. Discussion

The yields are compared with the statistical theory. Both calculated and observed values are shown in Table III. The experimental yield for Si^{28} is smaller than the theoretical calculations. In the case of P^{31}, the residual nucleus for (γ, p) is even-even and that for (γ, n) is odd-odd. In general the level density of the former is smaller than the latter. We calculated the yields for two values of the ratio of level density parameter C of even-even nuclei to that of odd-odd nuclei. The ratio is denoted as α. If we assume the following relation[24]

$$4C\,(\text{even-even}) = 2C\,(\text{even-odd}) = C(\text{odd-odd}),$$

α is equal to 1/4 for P^{31} target. The calculated yields using $\alpha = 1/4$ and level density (5) are in good agreement with observed values.

It is difficult to discuss exactly about the energy spectra and the angular distributions for the photoprotons, because bremsstrahlung has a continuous photon energy spectrum. Proton distributions do not uniquely correspond to specific transitions among the nuclear states.

According to the statistical theory, the photoproton spectra calculated by using con-

Table III. Photoproton yields

Element	Observed yield (protons/mol/r)	Calculated yield		α
		Level density	Yield (protons/mol/r)

			3.2×10^5	$\frac{1}{4}$

Table IV. Collection of data. The shapes of proton energy distributions are denoted by *A* and *B* for the nearly same type of proton spectra smoothed out from Si^{28} and P^{31} results respectively.

Element	Z	E_{max} (MeV)	Highest excitation (MeV)	Type of proton energy distribution	Best fitted level density	Yield (protons/mol/r)	ref.
Mg^{25}	12	24	11.93	A	deduced from known $N_a{}^{24}$ levels	1.74×10^5	13
Al^{27}	13	20.8	12.55	$\sim B$	only $\omega=$const. was calculated		14
		25	16.75	B	$C\exp[2\sqrt{0.50\,E}]$	about 0.3 times of Cu^{63} (γ, n)	15
		31	22.75	B			16
Si^{28}	14	32	20.41	$\sim A$		3.7×10^5	10
		24	12.41	A	$C\exp[E/2.8]$	2.9×10^5	present data
P^{31}	15	32	24.70	B	$C\exp]2\sqrt{0.53\,E}]$	4.3×10^5	10
		24	16.70	B	$C\exp[2\sqrt{0.52\,E}]$	3.2×10^5	present data
S^{32}	16	32	23.14	$\sim A$		4.8×10^5	10
A^{40}	18	22.5	10.47	$(\sim B)$	$\exp(E)$	6.6×10^5	17

tinuous cross sections for Si^{28} (γ, n) and for P^{31} (γ, n) are in fairly good agreement with the observed ones except fine structures (Fig. 3 and Fig. 6). The best fit level densities are the following: $\omega\propto\exp[E/2.8]$ for Al^{27} and Si^{27} in the case of Si^{28} target, and $\omega\propto\exp[2\sqrt{0.52\,E}]$ for Si^{30} and P^{30} in the case of P^{31} target.

The observed energy spectrum for A^{40} (γ, p)[17] is in good agreement with the calculated spectrum using the level density $\omega(E)\propto\exp(E)$ and the Coulomb barrier height of 2.5 MeV which is lower than other calculations and expected to arise from a fuzzy nuclear surface. Such lowering of the Coulomb barrier height may be expected to make better agreement for the case of Si^{28} and P^{31}. The large neutron excess would be effective for a fuzzy surface, which may dominate for A^{40} than for P^{31} and Si^{28}.

Table IV contains the photoproton energy distributions for neighbouring nuclei. The proton energy spectra of odd Z and of even Z nuclei seem to have their own definite shapes different from each other. The intensity of photoprotons has broad maximum ranging over several MeV for even Z nuclei as seen in Si^{28}, the type of which we denoted as "*A*" in Table IV. On the other hand, the photoprotons emitted from odd Z nuclei have rather sharp maximum as seen in P^{31}, the type of which we denoted as "*B*" in the Table. It may be expected that the level densities of residual nuclei are different between (γ, p) reactions of odd Z and even Z nuclei. The threshold energies of (γ, p) for the odd Z nuclei are a few MeV lower than those for the even Z nuclei. Now we consider that some amount of energy concentrate on a proton in the nucleus to be emitted after absorption of photon, and that the excitations by the gamma rays of the same energy are equal in both the even Z and the odd Z nuclei. Then, the excitation of residual nuclei after proton emission with the same energy is a few MeV higher for the even Z nuclei than for the odd Z nuclei, and this difference may cause the different proton energy spectra. The spin and parity are different between the ground states of the even and the odd nuclei, then the condition of these compound nuclei and their residual nuclei are also different in the reaction. Under these condition, the different excitation of particles in the nucleus may cause the different particle emission modes or different selection rules of transitions. It is desirable to compare the proton spectra from various elements at the same excitation energy above the threshold.

It is interesting that we have another experiments showing similar features to that described above for difference between proton energy spectra. Allan[25,26] observed two types of proton energy spectrum in (n, p) reaction. For example, the proton energy distributions for Fe^{54} and Fe^{56} are very different. Although this difference is independent of Z, it is similar to that between $Si^{28}(\gamma, p)$ and $P^{31}(\gamma, p)$. As the proton energy distributions of (n, p) reaction are not known so much, we shall not discuss further this points.

For such light nuclei as O^{16}, which have large level spacings, fine structures in the cross section and the energy spectrum have been observed in both (γ, p) and (γ, n) reactions. Now, in the present experiment, several peaks are found in the energy distributions of photoprotons from both Si^{28} and P^{31}, although the one of the latter might be somewhat obscured because of its poor resolutions. Čujec-Dobovišek[10] calculated the energies of protons emitted through the direct process according to the Wilkinson model[4]. She obtained the strongest $1d_{5/2} \to 2p_{3/2}$ direct transition at $E_p = 8.5$ MeV in the case of $Si^{28}(\gamma, p)$. Although one finds some trace of a peak at $E_p = 8.5$ MeV in the present result, it is not definite. Further, in smaller energy region, there exist many peaks which do not always agree with the Wilkinson theory. It should be pointed out here, however, that the energies of transitions assumed in the Wilkinson model are strongly criticized[27] and new theories[28)-30] are proposed to explain this problem. Therefore the agreement of the proton energy may be expected, but it is not definite.

The cross section measurement of $Al^{27}(p, \gamma)$ reaction[31),32),33] in which the transition to the first excited state of Si^{28} is stronger than that to the ground state shows many fluctuations by proton bombarding energies. Let us assume now that all protons from $Si^{28}(\gamma, p)$ come from the transitions to the ground state of Al^{27} (hereafter abbreviated to ground state protons), and that the cross section of $Al^{27}(p, \gamma_0)$ (gamma transition to the ground state of Si^{28}) is negligible compared with that of $Al^{27}(p, \gamma_1)$ (gamma transition to the first excited state (1.78 MeV) of Si^{28}). We can then calculate the cross sections of $Si^{28}(\gamma, p)$ from the photoproton energy spectrum by dividing with the photon number and correcting the energy scale for the recoil of the residual nucleus. On the other hand, we can also calculate the same cross section from the $Al^{27}(p, \gamma)$ data using the detailed balance theorem, assuming that the excitation energy of the compound nucleus Si^{28} is given by $E_{ex} = \frac{27}{28}E_p + 9.81$ MeV, (9.81 MeV is the Q value of γ_1).

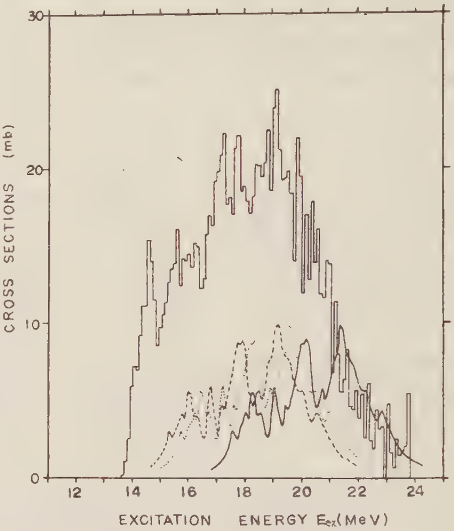

Fig. 8. Comparison of experiments for $Si^{28}(\gamma, p)$ Al^{27} and for $Al^{27}(p, \gamma)$ Si^{28}. The histogram shows $Si^{28}(\gamma, p)$ Al^{27} cross section assuming all proton transitions are to Al^{27} ground state. Heavy curve is $Si^{28}(\gamma, p)$ Al^{27} cross section calculated by detailed balancing from $Al^{27}(p, \gamma)$ Si^{28} cross section using the same Q value as that of γ_0. Dotted curve is the cross section using the Q value of γ_1. Broaken curve is obtained by shifting the dotted curve 0.5 MeV lower to best fit the histogram.

Fig. 8 shows the comparison of these two cross sections. We may find some parallelism between the two cross sections. We see, however, the energy discrepancy of about 0.5 MeV. If the Q value in the cross section from $Al^{27}(p, \gamma)$ is given by that value corresponding to γ_0, this cross section is further shifted to the higher energy side.

Of course there are many points which should be examined more carefully. These two experiments, $Si^{28}(\gamma, p)$ and $Al^{27}(p, \gamma)$, are not the exact inverse processes, because a fairly large number of the photoprotons are not the ground state protons, and also because the shape of the cross section of $Al^{27}(p, \gamma_0)$ may be different from that of (p, γ_1) that we plotted in Fig. 8. In fact the experiment at Chalk River finds the difference between both reactions (p, γ_0) and (p, γ_1)[31]. However if we infer the shape of Al (p, γ_0) from the sentence of ref 31, still the discrepancy in energy between Si^{28} (γ, p) and Al^{27} (p, γ_0) seems to exist. Therefore, although the experimental accuracy and also the assumptions used in deducing the cross sections must be checked more carefully, the existence of this discrepancy will not be excluded. If this is true, it may be an interesting problem from theoretical viewpoint.

According to Izumo's calculation[6], some resonating groups with about seven nucleons in the nucleus play a role in the intermediate energy nuclear reactions, and the gross levels may be found with larger distances than natural nuclear level distances in the same excitation. The distance of peaks in the photo-proton spectra from Si^{28} are about 600 KeV, which is in good agreement with our result. It should be noted, however, that these gross structures can be explained also by the channel coupling theory[7].

The angular distributions corresponding to each proton energy group show nearly the

Table V. Computed angular distributions for photoprotons, assuming the compound process.

$$A+\gamma \rightarrow A^* \longrightarrow B+p$$
$$J_A+l_\gamma \rightarrow J_C \longrightarrow J_B+l_p$$

J_B is the final channel spin.

(a): Si^{28} (γ, p) $J_A=0^+$

Transition	J_c	l_p	J_B	J of residual state	Angular distribution

		2	2	$3/2^-$, $5/2^-$	$1-1/2\sin^2\theta$
		3	2	$3/2^+$, $5/2^+$	$1+\sin^2\theta$
		2	3	$5/2^-$, $7/2^-$	$1+1/4\sin^2\theta$
$M1$	1^+	1	0	$1/2^-$	$\sin^2\theta$
		1	1	$1/2^-$	$1-1/2\sin^2\theta$
$E2$	2^+	1	1	$1/2^-$	$1-1/2\sin^2\theta$
		3	1	$1/2^-$	$1+2\sin^2\theta-5/2\sin^4\theta$

(b): P^{31} (γ, p) $J_A=1/2^+$

Transition	J_c	l_p	J_B	J of residual state	Angular distribution
$E1$	$1/2^-$	1	1/2	0^+	constant
	$3/2^-$	1	1/2	0^+	$1+3/2\sin^2\theta$
$M1$	$1/2^+$	0	1/2	0^+	constant
	$3/2^+$	2	1/2	0^+	$1+3/2\sin^2\theta$
$E2$	$3/2^+$	2	1/2	0^+	$1-1/2\sin^2\theta$
	$5/2^+$	2	1/2	0^+	$1+2\sin^2\theta-5/2\sin^4\theta$

same distributions in each nucleus. The angular distributions expected from the transitions between single levels and a compound nucleus of definite J_c formed in the reaction are shown in Table V. Some of the cases are in good agreement with each experimental angular distribution.

Other angular distributions are expected by the $l \rightarrow l \pm 1$ transitions of the direct photoelectric effect models led by Courant[34] and Wilkinson[4].

According to Courant's calculation, the distributions of the photoprotons are

$$N(\theta)=l+\frac{1}{2}(l+2)\sin^2\theta$$

for the $l \rightarrow l+1$ transition,

$$N(\theta)=l+\frac{1}{2}(l-1)\sin^2\theta$$

for the $l \rightarrow l-1$ transition.

l is the orbital angular momentum carried by the emitted proton while it was within the nucleus. The Wilkinson model predicts that only the $l \rightarrow l+1$ transitions are important. The experimental angular distributions for Si^{28} are almost isotropic within the experimental error except for $E_p \gtrsim 7.7$ MeV. The angular distribution of photoprotons greater than 7.7 MeV can be attributed to the d state transition, but the isotropic parts cannot be predicted in this model. One of the angular distributions observed for P^{31} (γ, p) agrees with that from s state transition of the direct model and others agree with p or d state transitions.

Si^{28} and P^{31} are neighbouring nuclei, but the angular distributions are different from each other. This suggests that the shell structure may have some effects on these photoreactions.

A Linear Electron Accelerator as the Injector of 1 BeV Synchrotron

By Tetsuji NISHIKAWA*, Jiro TANAKA, Akira MIYAHARA
and Hiroo KUMAGAI

Institute for Nuclear Study, University of Tokyo, Tokyo, Japan

(Received April 8, 1961)

The design study and the general aspect of a linear electron accelerator is described. Since this linear accelerator is used for the injector of the strong focusing synchrotron under construction, the spread of the output energy is desired to be as small as possible. For this purpose the cause of the energy spread has been reexamined and divided into two kinds; one is the different phase motions of the electrons injected at the various phase angles and the other is the variations of the microwave power, frequency, and other parameters. By the careful design, especially on the buncher, and by the use of the prebuncher and the stable power system, the output energy spread of about three percents has been obtained at the energy of 6.5 MeV.

§ 1. Introduction

This is the first paper of the series on the linear electron accelerator which has been constructed as the injector for 1 BeV electron synchrotron in the Institute for Nuclear Study. This work began in the spring of 1956. The design study was performed in 1957[1]. Then, we started to the experimental tests for the pumped klystron amplifier, pulse transformer, test cavities, electroforming of the accelerator tube, etc. These preliminary studies were finished in 1959[2], and we spent about one year or more for the overall construction of the accelerator. The accelerator began to operate successfully in the beginning of this year.

Usually, a pulse transformer or a d. c. generator type accelerator such as Van de Graaff generator is used as the injector for an electron synchrotron. While, if we use a linear accelerator, we shall get more intense beam than the previous ones. The peak current of a linear accelerator will reach up to some hundred milliamperes. In general, however, the energy spread of the output beam of a linear accelerator is unfavourably large. Especially, if the output energy is low, the energy spread of ready-made linear accelerators are larger than 10 percent. On the other hand, the tolerable energy spread of the electron beam which can be trapped into synchrotron orbit is less than 3%, so that the use of a linear accelerator becomes inefficient[3]. We reexamined the cause of the energy spread of the linear accelerator and carefully designed and constructed the accelerator as the injector for the synchrotron so as to have a good energy spectrum and stability. The spread of a few percent is aimed at the energy of 6 MeV and the beam current of 100–200 mA. Although the synchrotron has not yet been completed, the linear accelerator is operating very well and the performance is close to the designed values.

---

§ 2. General Performance

The general performance of the linear accelerator is shown in Table I. The output energy of 6 MeV is sufficiently high in order to use the fixed frequency RF acceleration for the synchrotron, since the velocity of the electron reaches to 0.997c at this energy. For higher energy, we had a little difficulty to get the microwave power tube available in Japan, especially to keep its maintenance cost cheap. Also this energy is the most favourable to the injection problem from the linac to the synchrotron.

Table I.

Beam energy	6 MeV
Beam current	100 mA (peak)
Pulse repetition rate	21.5 pps
Beam pulse width	2μ second
Beam energy spread	$<5\%$
Beam diameter	<10 mm
Beam divergence	$\sim 10^{-3}$ radian
Total length on the machine	<5 m.

The repetition cycle of 21.5 c/s is that of the synchrotron magnet power supply. The pulse width of more than 1 μsec is enough to the injection time which is required from the synchrotron operation. The microwave frequency, 2759 Mc, was chosen arbitrarily, though some lower frequencies seemed to be more favourable. The block diagram is shown in Fig. 1. We shall discuss details of this diagram in the later section. The type of the accelerator is the $\pi/2$-mode travelling wave type such as that of the Mark III accelerator of Stanford[4], while the shunt impedance is somewhat lower. The microwave power is obtained from a pumped klystron amplifier with a maximum peak power of 5 MW. The total length of the accelerator is about 3 m.

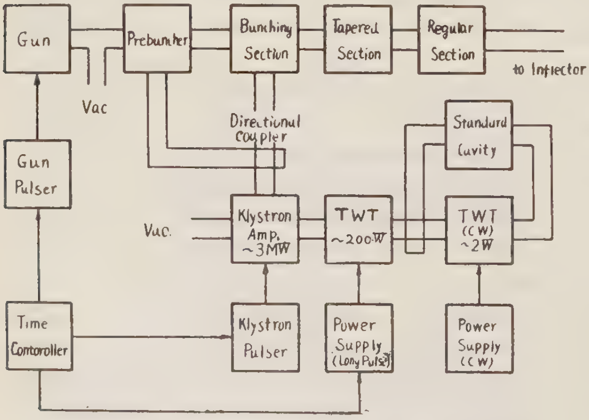

Fig. 1. Block diagram of the linear accelerator.

§ 3. Discussions on the Energy Spectrum

Two types of the causes for the energy spread are considered. The first is the fluctuations such as the instabilities of microwave frequencies and powers, or the thermal change of dimensions of the accelerator cavities. The second is the phase oscillation of electron beam which gives different average electric field during the transit through the accelerator for each electron injected in different phases. The second cause is more serious if we want to bunch the electron beam within a small phase angle in the earlier part of the accelerator so called the bunching section.

The energy spread of the output of the bunching section of Stanford Mark III accelerator was reported to be 2 MeV at the center value of about 5 MeV. For the low energy linac, the second effect becomes more important than the first one. So we shall discuss the second type of energy spread, at first.

a. *Energy spread due to different phase motions*

The electron on the phase angle, $\Delta(z)$, with respect to the point on the travelling wave $\pi/2$ ahead of the point of maximum acceleration, has the output energy, V, which is given by

$$V=\int_0^{z_0} eE(z)\sin\Delta(z)dz\,, \qquad (1)$$

where $E(z)$ is the maximum field strength, and z is the length along the accelerator axis. As is shown in Fig. 1, we shall divide the accelerator tube into three sections, that is, the regular section, the tapered section, and the bunching section. In the regular section we can use an accelerator tube, in which the phase velocity of the wave is matched with the light velocity, since the electron energy is sufficiently high in this section. The dimensions of each cavity in this section are same for all. Before being injected into this section, the electron beam is bunched so as to have a small phase spread, $\pm\delta\Delta$. Thus, if we write the center value of the phase angle of the electron bunch as Δ, we can assume that Δ is constant and $\delta\Delta$ is small enough in this section. The energy spread, δV, caused by the phase spread in this section will be written as,

$$\frac{\delta V_r}{V_r} \approx \frac{\sin\Delta_r - \sin(\Delta_r \pm \delta\Delta_r)}{\sin\Delta_r}, \qquad (2)$$

where the suffix r means the value of regular section. V_r is the energy gained by the electron in this section. Equation (2) has a minimum value when $\Delta_r = \pm(\pi/2)$: $\Delta_r = -(\pi/2)$ corresponds to the maximum acceleration. Near this position, we have

$$\frac{\delta V_r}{V_r} \approx (\delta\Delta_r)^2 . \qquad (3)$$

As is shown later, V_r is about 2 MeV, and we must take $\delta\Delta_r \approx 10°(\approx 1/6\,\mathrm{rad})$ in order to get the spread of total output energy less than 1%. This condition on the phase shift seems to be very serious, but is found to be necessary if we consider the accumulating effects discussed later.

Then, we shall consider the effects of the energy and phase spread in the input of the regular section to the output energy spread. To study these effects, we shall use the Hamiltonian which is given by Slater[5] for the description of the electron motion in a linear accelerator. The Hamiltonian function expressed by the axes moving with the velocity v_w of the travelling wave is given by

$$H/m_0c^2 = \frac{1-\beta_e\beta_w}{\sqrt{1-\beta_e^2}} - \frac{\alpha\beta_w}{2\pi}\cos\Delta , \qquad (4)$$

where the non-dimensional parameters, β_e, β_w and α are v_e/c, v_w/c and $eE\lambda_0/m_0c^2$, respectively.

Since this Hamiltonian function does not involve the time explicitly, it remains constant during the motion of an electron. If we write the value of the input and the output using the suffix 1 and 2, respectively, we have a relation

$$\sqrt{\frac{1-\beta_{e,r2}}{1+\beta_{e,r2}}} - \frac{\alpha_{r2}}{2\pi}\cos\Delta_{r2} = \sqrt{\frac{1-\beta_{e,r1}}{1+\beta_{e,r1}}} - \frac{\alpha_{r1}}{2\pi}\cos\Delta_{r1} , \qquad (5)$$

in the regular section, for which $\beta_w = 1$.

We can also safely assume that $\beta_{e,r1} \approx \beta_{e,r2} \approx 1$, in the regular section and that $\delta\Delta_{r1}$, $\delta\Delta_{r2} \ll 1$ where $\delta\Delta_{r1} = \Delta_{r1} + (\pi/2)$, i.e. $\delta\Delta_{r1}$ is the deviation of phase angle from $-\pi/2$. Then equation (5) becomes

$$\frac{1}{\gamma_{r1}} - \frac{1}{\gamma_{r2}} = \frac{1}{\pi}(\alpha_{r1}\delta\Delta_{r1} - \alpha_{r2}\delta\Delta_{r2}) , \qquad (6)$$

where $\gamma = 1/(\sqrt{1-\beta_e^2})$ is the nondimensional parameter corresponding to the total energy of the electron. Since the velocity of the electron is slightly smaller than the light velocity, $\delta\Delta_{r2}$ is smaller than $\delta\Delta_{r1}$ due to the phase slip.

If we write $\alpha_{r1} = \alpha_{r2} + \delta\alpha_r$ $(\delta\alpha_r > 0)$ taking into account the attenuation of the guide, we have

$$\frac{1}{\gamma_{r1}} - \frac{1}{\gamma_{r2}} = \frac{1}{\pi}[\alpha_{r1}(\delta\Delta_{r1} - \delta\Delta_{r2}) + \delta\alpha_r\delta\Delta_{r2}] , \qquad (6')$$

from equation (6). Using equation (3), the phase slip, $(\delta\Delta_{r1} - \delta\Delta_{r2})$ must be less than $2\delta\Delta_r$ and also $|\delta\Delta_{r2}| \leq \delta\Delta_r (\delta\Delta_{r2} \leq 0)$, so that we can obtain

$$\frac{1}{\gamma_{r1}} - \frac{1}{\gamma_{r2}} \lesssim \frac{1}{\pi}(\alpha_{r1} + \alpha_{r2})\delta\Delta_r . \qquad (7)$$

In our case, $\alpha_{r1} + \alpha_{r2} \approx 1$, $\delta\Delta_r = 1/6\,\mathrm{rad}$, and $\gamma_{r2} = 13$. Thus we have $\gamma_{r1} \gtrsim 8$, i.e. the injection energy into the regular section must be higher than 3.5 MeV to obtain a good energy spectrum. We had set it as 4 MeV.

In order to be bunched within a small phase spread, the electron injected in various phases must oscillate in several complete cycles in the low energy side of the accelerator. Ponce de Leon[6] discussed the bunching action in detail in the design study for the Stanford Mark IV accelerator. We also used the similar formula for the parameters α_b, Δ_b in the bunching section, like as

$$\alpha_b = 0.4 + 0.3\sin\frac{\pi}{2}\left(\frac{\xi - 4}{4}\right), \qquad (8a)$$

$$\Delta_b = -\frac{\pi}{6}\left[1 + \sin\frac{\pi}{2}\left(\frac{\xi - 4}{4}\right)\right], \qquad (8b)$$

where ξ is the distance from the input of the accelerator measured by the free space wave length, λ_0. Since electrons experience the considerably large defocusing force from the electro-magnetic wave in the bunching section and also the defocusing force is different for phase angles, it is somewhat difficult to focus the electron beam by a proper longitudinal magnetic field. This gives the upper limit for the length of bunching section, so that we take $0 \leq \xi \leq 8$. At the output of the bunching section, the energy of electrons will reach to about 1 MeV, and the phase to the microwave will be bunched within ±1/6 rad. After this section, electrons enter into the tapered section where $\alpha_t=0.7$ (const.) and $\varDelta_t=-\pi/3$ (const.). The dimensions of cavities in this section are tapered so as to match the wave velocity with the electron velocity. These values of α_t and $\varDelta_t$ can also be matched with the values of the regular section by a little phase shift at the output of the tapered section. The so-called buncher of our accelerator includes these two sections, the bunching section and the tapered section.

As discussed above, the Hamiltonian of an electron remains constant during the phase motion, unless there were non-adiabatic change in parameters. Thus, the area of a closed orbit in the phase space, which is written by an electron, remains also constant during its phase motion around the phase stable position. If we take the amplitude of phase and energy oscillation of an electron as $\delta\gamma$ and $\delta\varDelta$ as is given above, we have

$$\delta\gamma\delta\varDelta=\text{constant} \tag{9}$$

through the accelerator guide. At the input of the bunching section, we took the phase stable position $\varDelta_{b1}=0$ so as to give the desirable condition for the bunching action as was shown in equation (8b). Then, from equation (4), we can find the formula for $\delta\gamma_{b1}$ to be

$$\delta\gamma_{b1}\approx\frac{2\beta_{w,b1}}{\sqrt{1-\beta_{w,b1}^2}}\left[\frac{\alpha_{b1}\beta_{w,b1}}{\pi\sqrt{1-\beta_{w,b1}^2}}(1-\cos\delta\varDelta_{b1})\right]^{1/2}, \tag{10}$$

on the assumption that the electrons injected into the accelerator have the phase spread $\delta\varDelta_{b1}$ and just the energy matched with the wave velocity. $\delta\gamma_{b1}$ corresponds to the amplitude of the energy oscillation when the injected electron at $\delta\varDelta_{b1}$ started the phase oscillation. Taking $\alpha_{b1}=0.1$ corresponding to equation (8a) and $\beta_{w,b1}=\frac{1}{2}$ corresponding to the injection energy of 80 kV, $\delta\gamma_{b1}$ is given by

$$\delta\gamma_{b1}\approx0.15[1-\cos\delta\varDelta_{b1}]^{1/2}\,. \tag{10$'$}$$

Since there is no appreciable phase bunching action both in the tapered and regular sections, $\delta\gamma\cdot\delta\varDelta$ is less than $0.2\times(1/6)\approx0.03$, corresponding to the output energy spread of 100 keV. Thus, at the input of the bunching section the electrons only injected within the phase angle of $\pm\pi/6$ will satisfy the conditions for the output energy spread.

This is serious and is the reason that we use a prebuncher before the injection of the bunching section.

In the prebuncher, which is an ordinary velocity modulator of an electron beam, the electron beam suffers a non-adiabatic change of parameters, and can be bunched into a small angle without considerable changes in energy. A design study on the prebuncher was made[1], and it was found that about 2/3 of electrons injected having the uniform distributions for the phase angle can be bunched into the phase spread within $\pm\pi/6$. The energy change due to the phase prebunching is small enough, and found to be less than ±15 kV, so that the area is constant at the

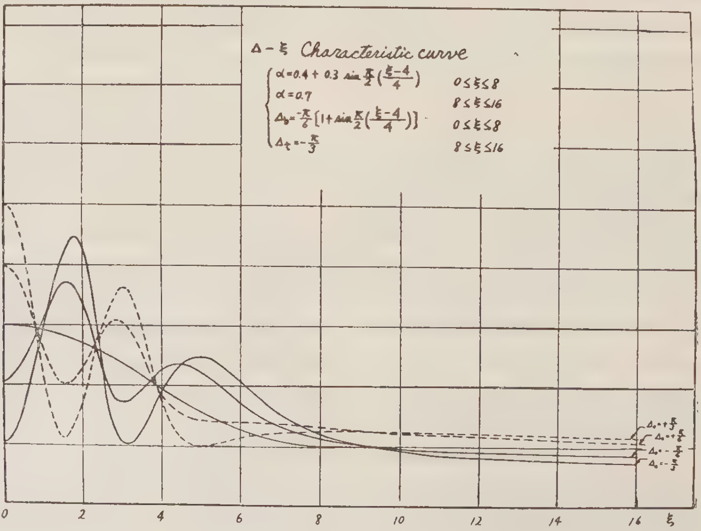

Fig. 2. $\varDelta-\xi$ characteristic curve for the buncher.

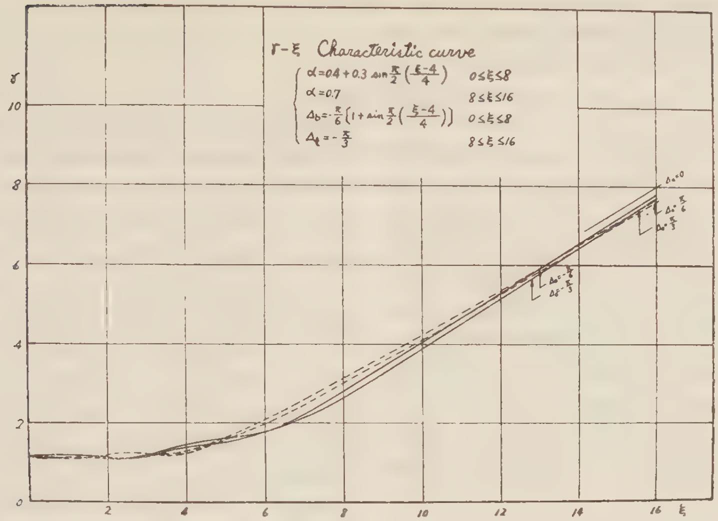

Fig. 3. $\gamma-\xi$ characteristic curve for the buncher.

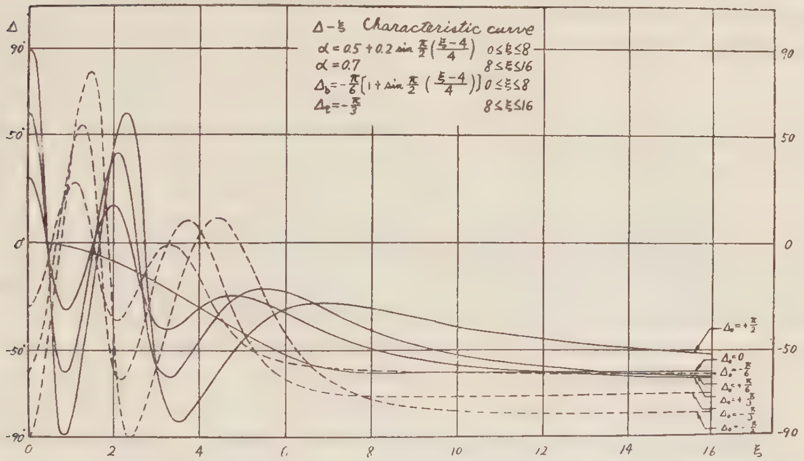

Fig. 4. $\Delta-\xi$ curve when the parameters were changed from the designed values.

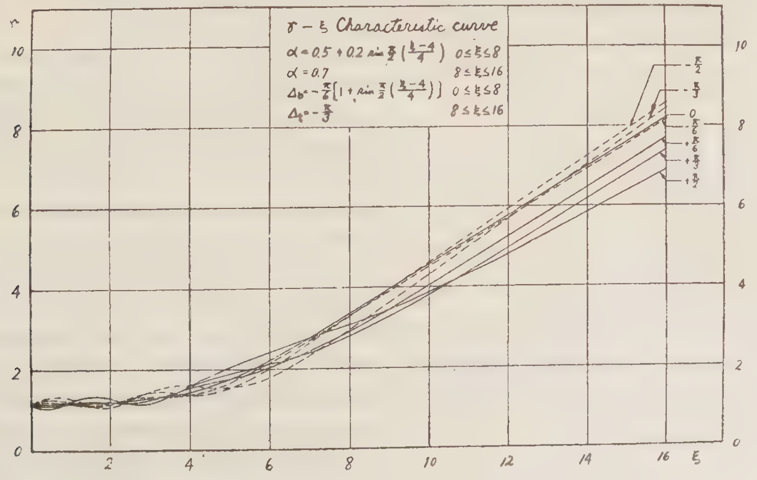

Fig. 5. $\gamma-\xi$ curve when the parameters were changed from the designed values.

output of the phase prebuncher, $\delta\gamma_{p2}\cdot\delta\Delta_{p2}$, is less than 0.03. The required power to the prebuncher is only 5–10 kW, which is fed from a directional coupler attached to the main waveguide.

We had checked the above considerations in the buncher including the tapered section using a digital computor of Yurin-Calculation Service Center, and the results are shown in Fig. 2 and Fig. 3. The calculated results show good characteristics of the bunching and tapered sections. This graph shows that, actually, the electrons having the phase spread of about 120°, which is twice the value discussed by the adiabatic theorem, may be used. Some modifications on parameters would destroy such good characteristics as shown in Figs 4 and 5.

b. *Energy spread due to variation of the microwave power and frequency*

The phase angle Δ, when $v_e \approx c$, can be written as

$$\Delta=\omega\left(t-\frac{z}{v_p}\right)\approx 2\pi\frac{z}{\lambda_0}\left(\frac{1}{\beta_e}-\frac{1}{\beta_w}\right)$$
$$=2\pi z\left(\frac{1}{\lambda_0\beta_e}-\frac{1}{\lambda_g}\right), \tag{11}$$

where λ_g is the wavelength in the accelerator guide. Thus the phase shift, $\delta\Delta_f$, due to the variation of wavelength, $\delta\lambda_0$, is given to be

$$\delta\Delta_f=2\pi z\left(\frac{\delta\lambda_g}{\lambda_g{}^2}-\frac{1}{\beta_w}\frac{\delta\lambda_0}{\lambda_0{}^2}\right)$$
$$=\frac{2\pi z}{\lambda_0}\left(\frac{c}{v_g}-\frac{1}{\beta_w}\right)\frac{\delta\lambda_0}{\lambda_0}. \tag{12}$$

In this expression, v_g is the group velocity along the accelerator guide and is equal to $d(1/\lambda_0)/d(1/\lambda_g)$. In our case, c/v_g is order of 10^2, whereas β_w is 0.5–1, so that $\delta\Delta_f$ can be approximated as,

$$\delta\Delta_f\approx\frac{2\pi z}{\lambda_0}\frac{c}{v_g}\frac{\delta\lambda_0}{\lambda_0}. \tag{13}$$

This equation becomes

$$\delta\Delta_f=Uz\frac{\delta f}{f}, \tag{14}$$

if the variation of $\delta\lambda_0/\lambda_0$ is replaced by the frequency variation $\delta f/f$, and $c/v_g\cdot 2\pi/\lambda_0$ by U. Using this formula we can calculate the energy spread in the regular and the tapered section; the results are

$$\left(\frac{\delta V_r}{V_r}\right)\approx\frac{1}{6}L_r{}^2U^2\left(\frac{\delta f}{f}\right)^2, \tag{14a}$$

and

$$\left(\frac{\delta V_t}{V_t}\right)\approx\frac{L_t}{2\sqrt{3}}U\left(\frac{\delta f}{f}\right), \tag{14b}$$

where L_r and L_t are the length of the regular section and the tapered section, respectively. In the above calculation, we assumed that the group velocity is constant through the guide and that the attenuation of the power is sufficeintly small. Taking $L_r=L_t=1$ m, $V_t=3$ MeV, δV_r, $\delta V_t=100$ keV and $V_g=0.017\,c$, we find that the frequency instability must be less than 1.5×10^{-4} in the regular section and 3×10^{-5} in the tapered section. In the bunching section. In the bunching section, the instability will not give any serious effect on the energy variation because of the phase stability. Thus the frequency allowance is the most serious in the tapered section and the fluctuation should be within ±50 kc.

Such frequency stability is achieved by the power system shown in Fig. 1. The main oscillator is the TWT feed back oscillator having the standard cavity made from invar. About two watts continuous output power is obtained from this oscillator, and amplified up to about two hundred watts by a pulsed travelling wave tube amplifier. Then the TWT amplifier is used as the driver of the pumped klystron amplifier, the peak power of which is about 3 MW.

This klystron amplifier is designed with an improvement on the vacuum pump and will be discussed in the second paper[7].

The change in the microwave power also affects the output energy of the electron beam. Since the field strength is proportional to the root of the power flow, it is necessary that the power level should be kept within the instabilities of 4% to keep the energy instabilities less than 2%. Since the klystron amplifier is used at nearly saturated driving power, the output power change is mainly caused by voltage variation of the pulsed power supply. The linear droop of beam voltage during the pulse is responsible to the energy spread as discussed by Stanford Mark III linac group[4]. The energy spread is given by $(5x/4)(t_p-t_F)$ percent from this effect, taking the linear droop x percent per μsec, the filling time t_F, and the duration of electron pulse t_p. Corresponding to the parameters $t_p=2$ μsec and $t_F=0.6$ μsec, the droop must be held $x=1$ percent/μsec in order to limit the spread to 2 percents or less. Also if we wish to keep the value of the maximum energy within the instability of 3 percents, variation in beam voltage between pulses must be less than 2.5 percents. We have established such stable pulsed power supply by some technical refinements on the usual line type pulser and the pulse transformer as discussed in the second article[7].

c. *Other effects*

The temperature variation will cause the change of resonant frequencies of the accelerator cavities which corresponds to the phase shift of electrons to the wave. This effect can be treated as well as the effect due to the frequency variations. By a reasonable estimation, we can find that the change of temperature by about 1°C will cause the output energy shift of about 2%. This effect, however, will not so much affect the energy spread, unless there were some short time fluctuations. Our accelerator has a temperature control system, which controls the temperature change in the accelerator guide within ±1°C, though we do not use it at the present stage.

Dimensional errors in accelerator cavities also cause the phase shift, and will destroy the designed characteristics of the accelerator guide. The phase shift due to dimensional errors, $\delta\Delta_m$, in an accelerator cavity is given by

$$\delta\Delta_m = \frac{\pi}{2}\beta_w \frac{c}{v_g}\left(\frac{\delta f_0}{f_0}\right), \tag{15}$$

where δf_0 is the error in the resonant frequency, f_0, of that cavity. If we take random dimensional errors in cavities, the overall phase shift of electrons will be given by $\sqrt{N}\delta\Delta_m$ after the transit through N cavities. It is desirable that the shift is less than 1/6 rad which is the value discussed in Sec. 3a. Since the total number of cavities is about 100, $\delta\Delta_m$ must be less than 1.5×10^{-2} rad. From equation (15), we can obtain the tolerance of the resonant frequency, $\delta f_0 \leq 200$ kc, for $v_g/c \approx 0.017$. In practice, the cavities were made so accurate that the corresponding errors in their resonant frequencies are less than ±100 kc as shown in the third paper[8].

Finally, the transverse beam spread may cause the spread in the output energy of electrons. Since the diameter of beam can be held as small as 1 cm by a longitudinal magnetic field, and since the wave-length is sufficiently large as 10 cm, this effect, which depends on the value of

$$J_0\left(j\frac{\sqrt{1-\beta_w^2}}{\beta_w}\frac{r}{\lambda_0}\right),$$

is negligibly small, except near the entrance of the bunching section.

§ 4. Determination of Cavity Dimensions

The principle to determine cavity dimensions in a travelling wave linear accelerator is as follows:

1) First, we settle the frequency of microwave which will be used.

2) Then, the distribution of the phase velocity of the wave along the accelerator guide is assumed.

3) Dimensions of cavities can be determined from the frequency and the phase velocity, if the wave mode of the guide is decided.

4) We can also estimate the attenuation constant along the guide, which determines the microwave power loss.

5) If the available microwave power and the desired beam intensity are fixed, we can calculate the field strength along the guide.

6) Immediately, the velocity change of electrons is determined from the field strength.

7) The velocity of electrons must be in accord with the phase velocity of the wave everywhere in the accelerator.

Actually, the calculations are made by means of successive approximations. In our design study, several methods published previously by the Stanford and A.E.R.E. groups[9] have been used to determine the field distribution and the phase velocity along the guide. The effect of beam loading is treated as well

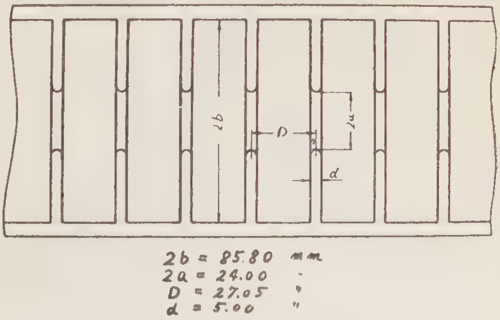

Fig. 6. Dimensions of the regular section.

as the methods worked by Saxon and by Neal[10]), with a little modification to the tapered section. The cavity dimensions in the regular section are shown in Fig. 6. Some curves which give the calculated values of the dimensions of cavities of the buncher varying with the normalized length, ξ, are shown in Fig. 7.

In order to calculate cavity dimensions, we used a modified method of Slater's four-terminal network theory[11]) on the periodically loaded waveguide. Our formula used is for $\pi/2$-mode,

$$\frac{\chi}{2}=\cot k(D-d)\,, \tag{16}$$

where

$$\frac{\chi}{2}=\frac{3}{2}\,\frac{\pi b^4}{a^3}\,k\left\{\frac{J_1(2.405)}{2.405}\right\}=0.1098\,\frac{b^4}{a^3}k\,, \tag{17a}$$

and

$$k^2=\frac{\omega^2}{c^2}-\left(\frac{2.405}{b}\right)^2. \tag{17b}$$

χ is the normalized susceptance of the disk loading in the cylindrical waveguide, and cal-

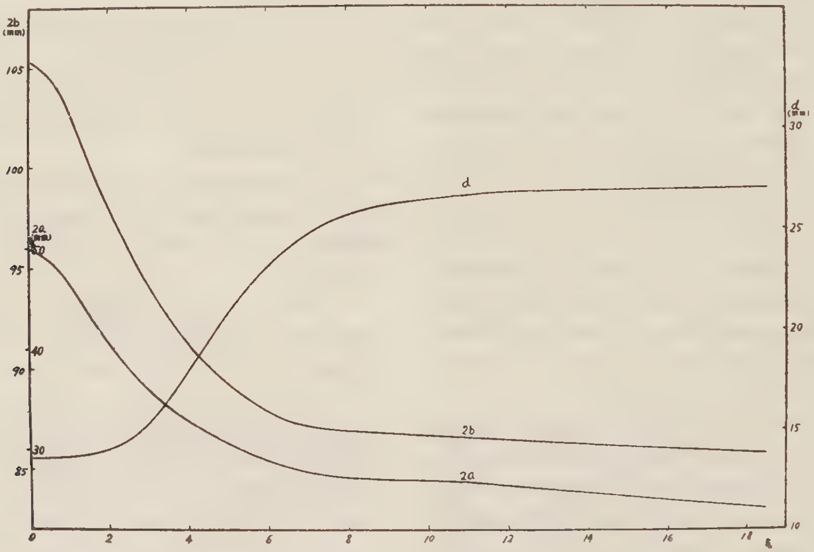

Fig. 7. Dimensions of the buncher.

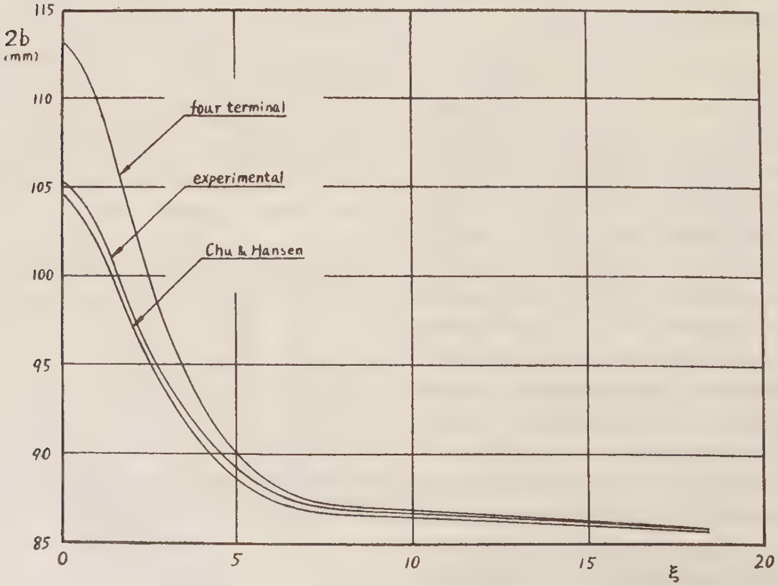

Fig. 8. Comparison between the calculated and experimental values of $2b$.

culated by a quasi-static field method. This formula is simpler than the others and has good accuracy which is enough to give the values of dimensions of the test cavities, by which the accurate dimensions are determined experimentally. The comparison between the calculated values and the experimental ones of $2b$ for the given values of $2a$, D, d and β_w, are shown in Fig. 8. This is obtained from a careful experiment of test cavities reported in a separate article[12]. The error in resonant frequency is less than one megacycle in the regular and tapered sections, while it becomes considerably large as several ten megacycles in the first cavity of the bunching section, in which the disk hole is too large and the disk spacing is too small for the approximation used. Actually, the resonant frequency considerably depends on the shape of the cross section of the disk, and was corrected to that of the standard one using a perturbing theorem.

It is the distinctive feature of this method that the equation (16) is convenient to estimate the changes of resonant frequency, δf_0, due to some dimensional changes. Such esti-

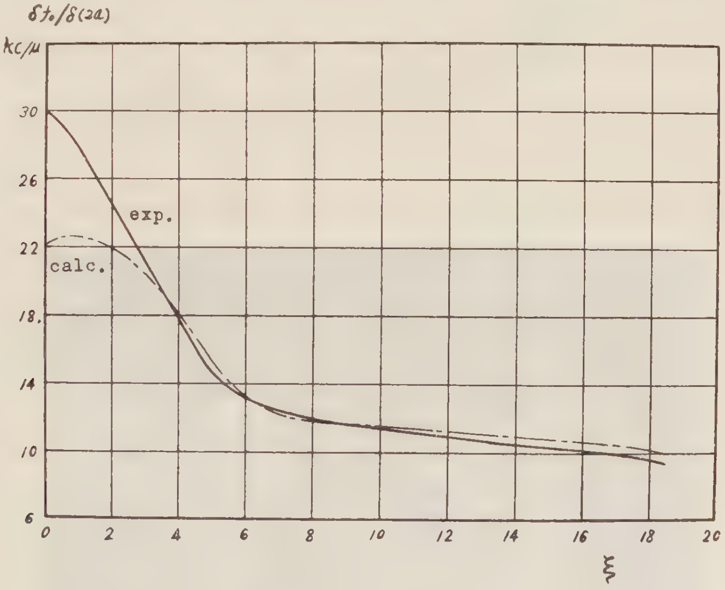

Fig. 9. Comparison between the calculated and experimental values of $\delta f_0/\delta(2a)$.

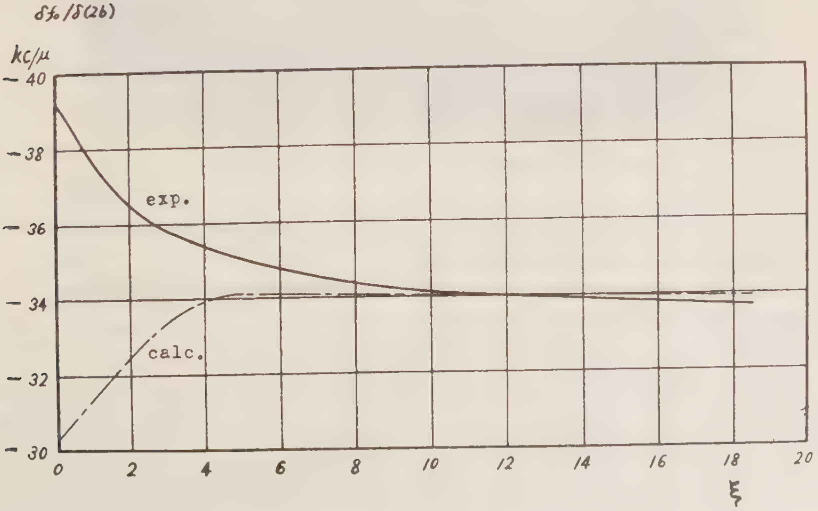

Fig. 10. Comparison between the calculated and experimental values of $\delta f_0/\delta(2b)$.

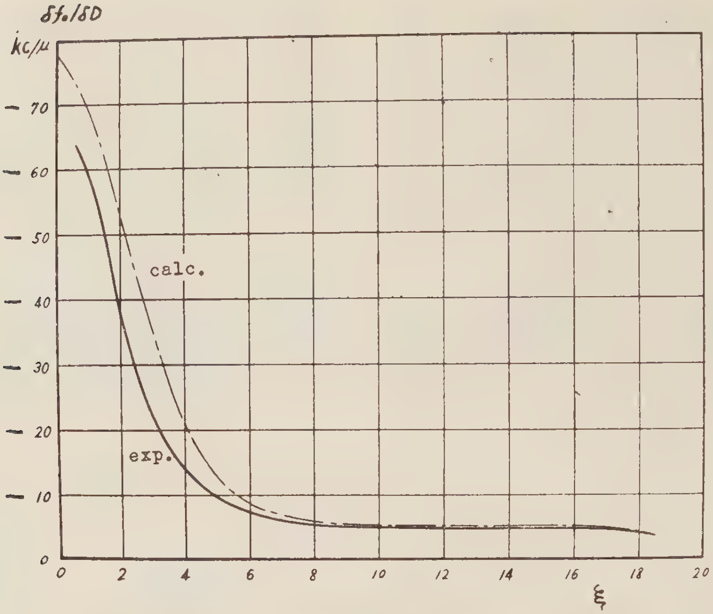

Fig. 11. Comparison between the calculated and experimental values of $\delta f_0/\delta D$.

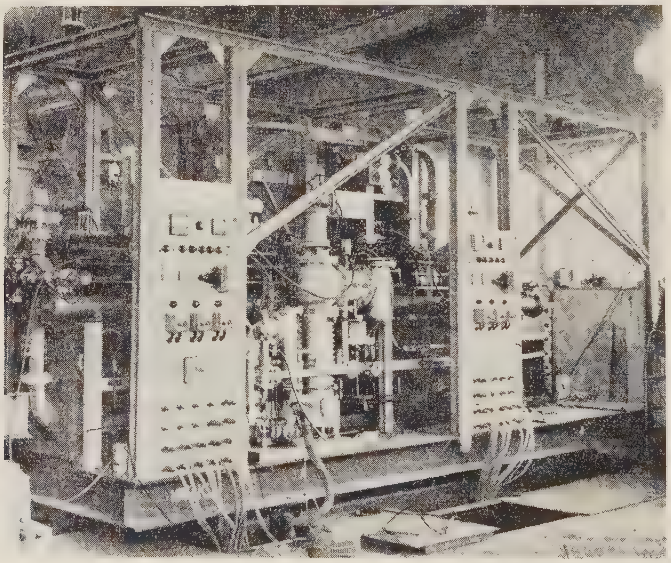

Fig. 12. Photograph of the linear accelerator.

mations are useful for the determination of the accurate dimensions by the experiment of test cavities, and also for the discussion on the effect of the phase shift due to the temperature variations and machining errors, discussed in Sec. 3c. Figs. 9, 10 and 11 give the comparison between the calculated values (dotted lines) and the experimental ones (real lines). The agreement is fairly good, although the calculated curve of $\delta f_0/\delta(2b)$ differs from the experimental results in the neighbourhood of the entrance of the buncher.

§ 5. Results and Discussions

The picture of the linear accelerator is given in Fig. 12.

The accelerator was constructed carefully so as to accord with the designed features, and found to operate meeting with the expectation. The energy spectrum was obtained by a spectrometer using an analyzing magnet. An observed spectrum is shown in Fig. 13, which shows the total spread of about three percents at 6.5 MeV. When we did not use the prebuncher, the spread increased to about 5 percents. It was found that the shape of the spectrum depends on the microwave power and the beam loading, the cause of which seemed to be due to the improper field distributions to match the electron velocity with the wave velocity. This effect would probably become important in the tapered section. The detailed characteristics are now being studied.

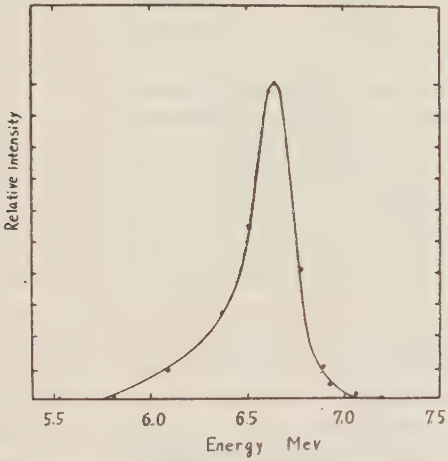

Fig. 13. An observed energy spectrum.

The details of the practical construction will be reported in the following articles.

Acknowledgement

The authors wish to express their hearty thanks to the synchrotron group of the Institute for Nuclear Study of the University of Tokyo for their useful discussions. The contribution of Dr. Y. Kobayashi and Mr. R. Yamada in measuring the characteristic performance of the accelerator is also appreciated.

" Gamma Rays from the Proton Bombardment of Sulphur and the O$^+$ Second Excited State of ^{32}S "

By Yasuo HIRAO

Department of Physics and the Laboratory of Nuclear Studies,
Faculty of Science, Osaka University, Osaka

(Received April 19, 1961)

The analysis of gamma rays from natural sulphur, separated sulphur-32 and sulphur-34 bombarded by protons up to 5.7 MeV was carried out.

Excitation function of the 2.24 MeV gamma ray due to the transition (1st-ground state of ^{32}S) was measured. Resonances were found at Ep=4.77, 5.10, 5.35 and 5.60 MeV, which correspond to the excitation energies of 6.93, 7.24, 7.48 and 7.71 MeV of ^{33}Cl, respectively.

Gamma rays were observed with a single and three crystal spectrometers. In addition, using gamma-gamma cascade coincidence and sum coincidence methods, energies and decay scheme were determined as follows:

^{32}S: 0.92 MeV (5th-2nd), 1.20 (6th-2nd), 1.54 (2nd-1st), 2.23 (3rd-1st), 2.24 (1st-ground) and ~4.3 (3rd or 4th-ground).

^{34}S: 0.97 (7td-3rd), 1.17 (2nd-1st), 2.13 (1st-ground), 3.30 (2nd-ground), 3.91 (3rd-ground) and 4.11 (5th-ground).

The 3.78 MeV gamma ray due to the transition (2nd-ground of ^{32}S) was not found.

The angular correlation between the cascade gamma rays of 1.54 and 2.24 MeV shows good agreement with the transition of O$^+$(E2)2$^+$(E2)$^+$. Then the 2nd state of ^{32}S at 3.78 MeV has a spin of O$^+$. This assignment agrees with the calculation of the j-j coupling shell model.

With a three crystal spectrometer, nuclear pair from the 2nd state of ^{32}S at 3.78 MeV was searched. The intensity of the nuclear pair was about 2% or less of the 1.54 MeV gamma ray.

The configurations of this O$^+$ second state and the ground state of ^{31}P are also discussed.

§ 1. Introduction

The analyses of gamma ray spectra from excited states of various nuclei have brought valuable informations on the properties of nuclei. So far detailed investigations have been carried out for the gamma ray transitions from various nuclear excited states following the decays of radioactive nuclides and from excited states formed by proton or neutron capture. As compared with the amount of these investigations, gamma rays from the excited states formed by inelastic scattering have been studied only for a few elements in spite of many advantages such as; that the method can be applied to most of the nuclei, that the cross section is relatively large, and that it is especially suitable for studying low-lying states. For the last four years we have investigated the gamma rays due to inelastic scattering of protons up to 5.7 MeV[1] and of 10 and 14 MeV[2] for several elements. In this paper also, the analysis of gamma rays from natural sulphur, separated sulphur-32 and sulphur-34 bombarded by protons up to 5.7 MeV will be reported.

^{32}S:

Natural abundances of sulphur isotopes are 95.018, 0.750, and 4.215% for ^{32}S, ^{33}S, and ^{34}S, respectively. Several investigators have reported the measurements on the excitation energies of the low-lying states of ^{32}S. By a magnetic analysis of ^{35}Cl$(p, \alpha)^{32}$S reaction[3], levels were found at 2.237±0.008, 3.780±0.008, and 4.287±0.008 MeV, 4.465±0.10, and 4.698±0.10 MeV.

From the measurement of neutron angular distributions in ^{31}P$(d, n)^{32}$S reaction[4], 1_p's were assigned as 0 for the transitions to the ground and the 2nd states, and as 1 for the transition to the 1st state. Since the ground state of ^{31}P have been known to have a spin of 1/2 and even parity, the value of $1_p=0$ for the transition to the ground state of ^{32}S indicates that it has even parity and a spin of 0 or 1. This is in agreement with the fact that the spin of all even-even nuclei is 0.

In the case of the transition to the 1st state, the value of $l_p=2$ indicates that it has even parity and spin 1, 2, or 3. Considering the results of the reaction ^{32}S(e, e')[5] and the reaction ^{31}P$(p, \gamma)^{32}$S[6], the spin and parity of this state has been assigned to be 2^+. It is consistent with the general tendency for light even-even nuclei that the 1st state possesses the spin and parity of 2^+.

The value of $l_p=0$ for the transition to the 2nd state at 3.78 MeV indicates that this state has even parity and spin 0 or 1. On the other hand, there are several reports that the 3.8 MeV gamma rays were observed in the reactions ^{31}P$(p, \gamma)^{32}$S[7] and ^{32}Cl$(\beta^+)^{32}$S$^*(\gamma)$[8],[9]. The authors of these papers concluded that these gamma rays were due to the direct transition from the second state to the ground state. It follows that the assignment of spin 0 to this state is excluded. Considering these results, it has been hitherto assigned to be 1^+. It is worthy of attention that the 2nd state has a spin of 1 and even parity. Several authors[10],[11] have discussed the configurations of these states and the ground state of ^{31}P on the basis of the shell model. They pointed out the difficulty of any interpretation for the 1^+ state at such low energy as will be discussed in §4. It seems that experimentally these is no doubt that $l_p=0$ is the correct assignment. We suspect, however, that the gamma ray of 3.8 MeV is not due to the transition from the 2nd state, but due to the transition between higher states of ^{32}S. From these reasons it is of interest to find out the branching ratio of the gamma rays from this state to the ground and the 1st states, using the reaction ^{32}S$(p, p'\gamma)$, which leads to only several low-lying excited states. In addition it is also of interest to measure the cascade gamma-gamma angular correlation if these gamma rays could be found.

^{34}S:

By a magnetic analysis of the ^{37}Cl$(p, \alpha)^{34}$S at $E_p=7.0$ MeV, levels were found at 2.127, 3.302, 3.915, 4.073, 4.114, 4.621, 4.685 and 4.876 MeV, all ±0.008 MeV[3].

The spin and parity of the 1st state at 2.127 MeV is found to be 2^+ from the allowed characters of β^- decay of ^{34}P$(J=1^+)$ to the ground and the 1st states of ^{34}S[12] and of β^+ decay of ^{34}Cl$^m(J=3^+)$ to the 1st state of ^{34}S[13].

The spin and parity of the 2nd state of ^{34}S is also found to be 2^+ from gamma-gamma angular correlation[14]. This assignment is consistent with the β^+ decay of ^{34}Cl^m[13].

From the decays of ^{34}P and ^{34}Cl^m, about 4 MeV gamma rays were also observed[15],[16]. If these gamma ray energies are accurately equal, this gamma emitting state of ^{34}S should also have 2^+ for the same reason as in the 1st state of ^{34}S.

§ 2. Experimental Methods

Molecular ion beam of hydrogen accelerated by Osaka University 44 inch cyclotron was used. The energy of the proton was estimated to be 5.7 MeV ±0.1 MeV, and it was degraded at 100 keV intervals by aluminum absorbers in order to measure the excitation curve. The beam defining slit was made of a gold plate with a circular hole one mm in diameter The proton beam current was about one mμa for the gamma-gamma coincidence experiments, and was about ten mμa for the other experiments. The targets were prepared by painting BaSO$_4$ powder onto thick gold plates. Most of the measurements were made with a natural sulphur target, but a few were made

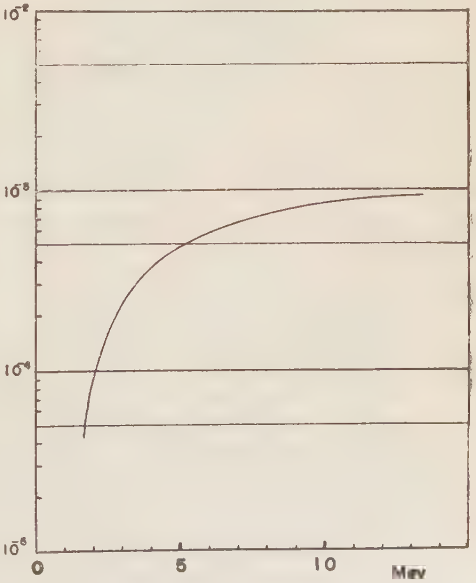

Fig. 1. The energy-efficiency curve of the three crystal pair spectrometer, as shown in Fig. 2, for gamma rays incident to the front surface of the centre crystal.

with separated ^{32}S and ^{34}S. The target of ^{34}S was a thin Pb_2S layer spattered on a thick gold backing.

We used a NaI(Tl) scintillator, 3-inch diameter by 3-inch long, for the measurements of gamma ray spectra and the excitation curve. We also used a three crystal scintillation spectrometer[17]. The energy-efficiency curve of this spectrometer was calculated and is shown in Fig. 1. This spectrometer have a NaI(Tl) scintillator 1½ inch diameter by 4-inch long as a center crystal and two NaI(Tl) scintillators, 3-inch diameter by 3-inch long, as side crystals. For the measurements of gamma-gamma coincidence spectra, sum coincidence spectra, and gamma-gamma angular correlations, two NaI(Tl) scintillators, 3-inch diameter by 3-inch long were used, and sometimes a scintillator, 5-inch diameter by 4-inch long, was used. For the nuclear pair detection, we used another spectrometer, which was a sort of three crystal pair spectrometer, having a well-type plastic scintillator, 1½-inch diameter by 2-inch long, as the centre detecter. All the spectra were analyzed by a 20 channel and a 30 channel pulse height analyzer, having a dead time of about 2.5 μsec. The coincidence method is a so-called "fast-slow" method. The resolving the of fast coincidence is about 5×10^{-8} sec using a diode bridge coincidence circuit[18]. This resolving time was chosen according to the frequency of the cyclotron. The block diagram of the coincidence experiments is shown in Fig. 3.

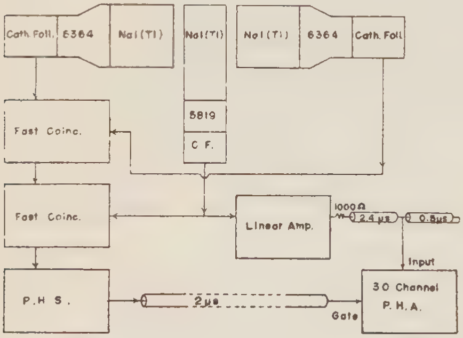

Fig. 2. Block diagram of the three crystal pair spectrometer.

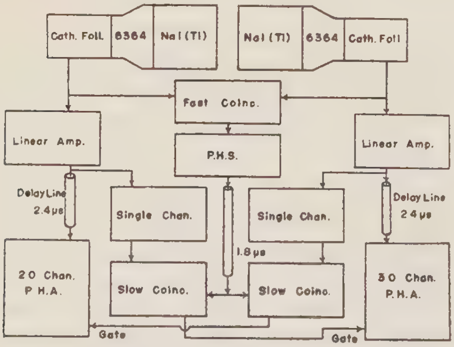

Fig. 3. Blook diagram of the coincidence experiment.

§ 3. Experimental Results

Excitation Function of 2.24 MeV Gamma Ray:

The intensity of the most intense gamma ray of 2.24 MeV, which is almost due to the transition from the 1st to the ground state of ^{32}S, was measured as the function of incident proton energy, using a NaI(Tl) scintillator, 3-inch diameter by 3-inch long. The result is shown in Fig. 4. The Q-value of $^{32}S+p$ reaction is 2.285 MeV. So far several resonances have been found at $E_p=0.59$, 1.90, 2.30, 2.81, 2.90, 2.92, 3.09, 3.19, 3.38 and 3.72 MeV[19]. In the present experiment, resonances have been found at $E_p=4.77$ and 5.10 MeV. These correspond to the excitation energies of 6.93 and 7.24 MeV of ^{33}Cl, respectively. At $E_p=5.35$ and 5.60 MeV also, broad resonances were found, which corresponded to 7.48 and 7.71 MeV of ^{33}Cl, respectively. The result is

Gamma Ray Spectra:

Fig. 5 and Fig. 6 show the gamma ray pulse height distributions from the single NaI(Tl) scintillation spectrometer, 3-inch diameter by 3-inch long, and the three crystal scintillation pair spectrometer, respectively, at right angles to the incident proton direction. Natural sulphur compound was used as a target. These spectra were measured at the incident proton energy of 5.7 MeV. Arrows in Fig. 5 and Fig. 6 indicate the positions of the gamma ray energies expected from the well established level energies. These show good agreements with the peak positions of the spectra. The possible origins and the relative intensities of the gamma rays in Fig. 5 are tabulated in Table II. These values have been corrected by the energy-efficiency curve of Fig. 1. The efficiency at about 1.2 MeV is too low to

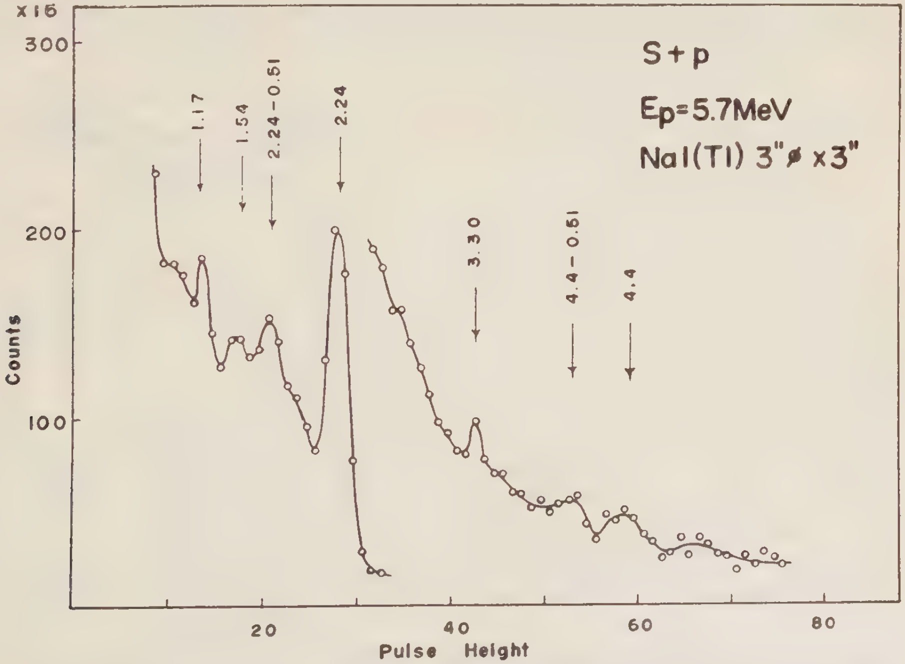

Fig. 5. Gamma ray pulse height distribution from the single NaI(Tl) scintillation spectrometer, 3-inch diameter by 3-inch long, at right angles to the proton beam direction. Target was made with natural sulphur compound, $BaSO_4$, and incident proton energy was 5.7 MeV. Arrows in Figs. 5, 6, etc. indicate the positions of the gamma ray energies expected from the well established level energies.

estimate the relative intensity of the 1.2 MeV gamma ray. As tabulated in Table 2, previously reported gamma rays, 1.17 (2nd-1st of ^{34}S), 2.24 (1st-ground of ^{32}S) and 3.30 MeV (2nd-ground of ^{34}S), were found and 2.13 MeV gamma ray (1st-ground of ^{34}S) was comprised in the peak of the intense 2.24 MeV gamma ray (1st-ground of ^{32}S). The intensity ratio

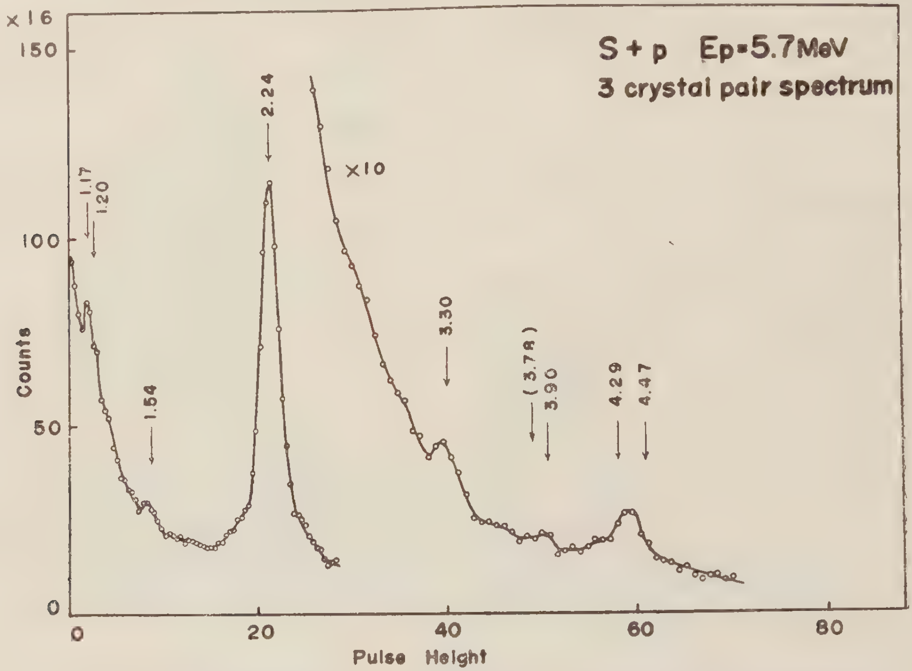

Fig. 6. Three crystal pair spectrum at proton energy of 5.7 MeV and right angles to the proton beam direction. Natural sulphur compound, BaSO$_4$, was used as a target.

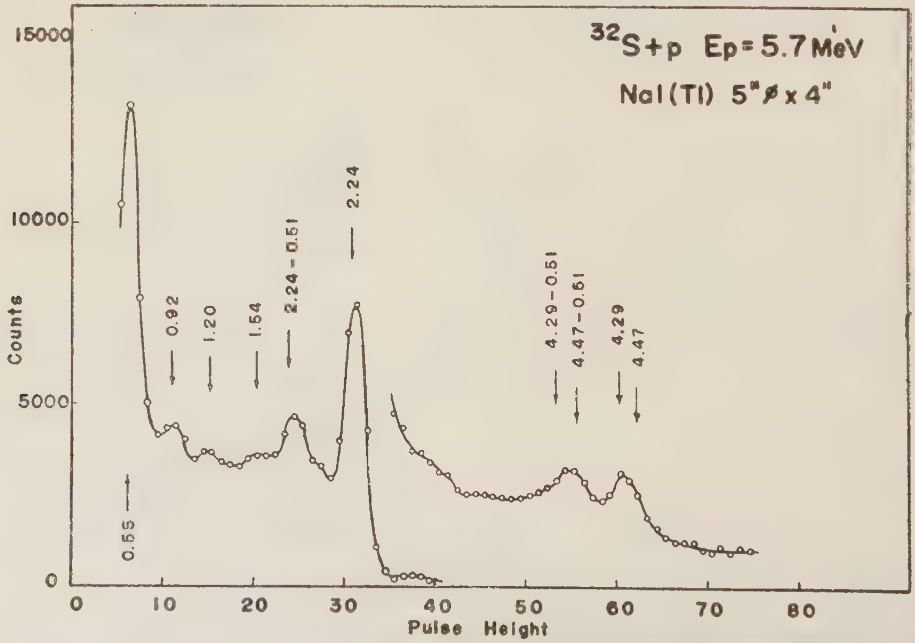

Fig. 7. Gamma ray spectrum from proton bombardment of the target of separated sulphur-32 compound, BaSO$_4$, at incident proton energy of 5.7 MeV, using a NaI(Tl) scintillation spectrometer, 5-inch diameter by 4-inch long.

of the 1.17 Mev to the 3.30 MeV gamma rays was found to be $\gtrsim 40/7$, while the ratio previously reported is 73/27[14]. This discrepancy indicates that the peak at 1.17 MeV may comprise 1.20 MeV gamma ray (6th-2nd of ^{32}S). The gamma ray of 1.54 MeV was newly found and may be due to the transition (2nd-1st of ^{32}S) while the gamma ray of 3.78 MeV (2nd-ground of ^{32}S) was not found, which was reported by other authors[7],[8],[9] as was mentioned in § 1. This fact brings forward once more the problem whether the spin of the 2nd state is 1 or 0. Very weak gamma ray at about 3.9 MeV may be due to the transition (3rd-ground of ^{34}S), although it is scarcely noticeable. The peak at about 4.3 MeV is, perhaps, of the gamma ray transition (3rd-ground of ^{32}S) and (4th-ground of ^{32}S) in part.

Next the gamma ray spectrum from proton bombardment of separated ^{32}S target, at $E_p = 5.7$ MeV, was observed. The result is shown in Fig. 7 and Table III. Observed peaks are well explained with the energies expected from ^{32}S. However, as the abundance of ^{34}S in this separated target as an impurity is not accurately known, the spectrum may comprise the gamma rays from the excited states of ^{34}S in part. An intense peak at 0.55 MeV is due to coulomb excitation of Au target backing. 0.92 MeV gamma ray may be due to the transition (5th-2nd of ^{32}S). The other higher energy peaks are of the same gamma rays as of Figs. 5 and 6. 3.3 MeV gamma ray (2nd-ground of ^{34}S) vanishes, while 1.2 MeV gamma ray still remained. This result supports the above consideration that this gamma ray is due to the transition (6th-2nd of ^{32}S).

Table III. Gamma ray energies, possible origins and relative intensities of the single spectrum from separated sulphur-32 target using a NaI(Tl) scintillator, 5-inch diameter by 4-inch long, at 5.7 MeV of incident proton energy, at right angles to the incident proton direction. Relative intensities were corrected for the efficiencies of the spectrometer.

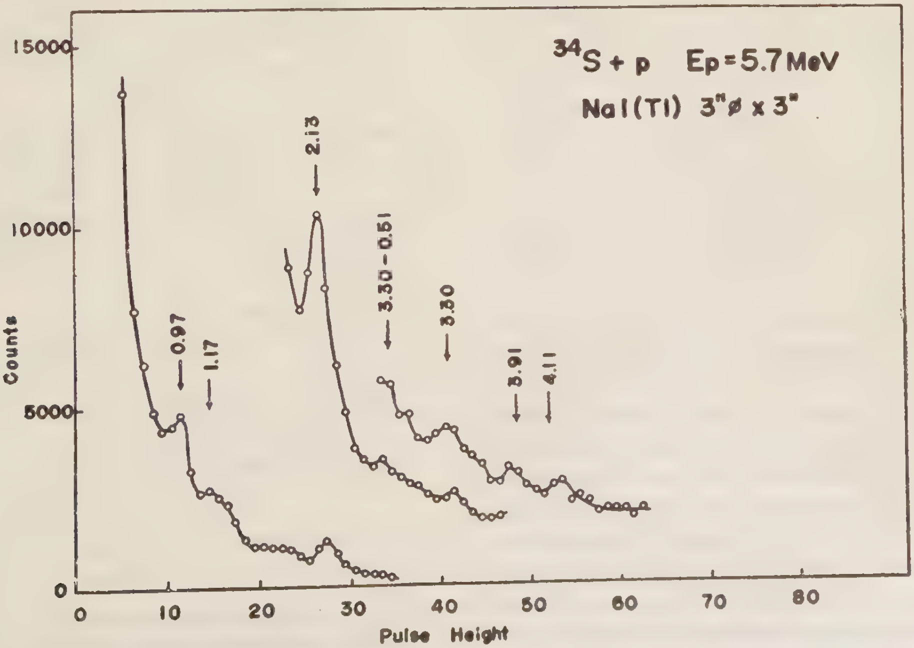

Fig. 8. Gamma ray spectrum from proton bombardment of the target of separated sulphur-34 compound, Pb_2S, at incident proton energy of 5.7 MeV, using a NaI(Tl) scintillation spectrometer, 3-inch diameter by 3-inch long.

Next the gamma ray spectrum from proton bombardment of separated ^{34}S target, at E_p= 5.7 MeV, was observed. The result is shown in Fig. 8 and Table IV. Observed peaks can also be explained with the energies expected from the well established levels of ^{34}S. The peak at about 1 MeV may be due to the transition (7th-3rd of ^{34}S). The peaks at 1.17, 2.13 and 3.30 MeV correspond to the previously reported gamma ray transition (2nd-1st of ^{34}S), (1st-ground of ^{34}S) and (2nd-ground of ^{34}S) respectively. The peaks at 3.9 MeV and at 4.1 MeV are due to the transitions (3rd-ground of ^{34}S) and (5th-ground of ^{34}S), respectively. These gamma rays may be the same as previouly observed in the decays of ^{34}Cl^m(β^+) ^{34}S*(γ) and ^{34}P(β) ^{34}S*(γ). One cannot find gamma ray at about 1.5 MeV, and this fact indicates that the 1.54 MeV gamma ray, described above, is not of ^{34}S, but of ^{32}S.

Table IV. Gamma ray energies, possible origins and relative intensities of the single spectrum from separated sulphur-34 target, using a NaI(Tl) scintillator, 3-inch diameter by 3-inch long, at 5.7 MeV of incident proton energy, at right angles to the incident proton direction. Relative intensities were corrected for the efficiency of the spectrometer.

γ ray energies	Possible origins	Relative intensities

Coincidence Spectra:

Next, we observed the coincidence spectra gated by the 2.24 MeV gamma ray at several bombarding energies, using natural sulphur target as shown in Fig. 9. The energies and the relative intensities of these gamma ray at 5.7 MeV incident proton energy were tabulated in Table V. The incident beam current was chosen to be small so that the accidental coincidence counts would be negligible. In order to establish the decay scheme of these gamma rays, the incident proton energy was degraded with aluminum absorbers wtih 100 keV intervals. As shown in Fig. 8, the intensities of each coincidence gamma rays became smaller with the degradations of proton energy, while the excitation curve of 2.24 MeV gamma ray observed with the single NaI(Tl) scintillator had a peak at 5.1 MeV and then the intensity of the 2.24 MeV gamma ray was rather higher at lower incident proton energies as was shown in Fig. 4. From these facts it is concluded that the 2.2 MeV gamma

Table V. Coincidence gamma rays gated between 2.00–2.35 MeV were listed at proton energy of 5.7 MeV. Natural sulphur target and two NaI(Tl) scintillators, 3-inch diameter by 3-inch long, were used. Relative intensities were corrected for the efficiency of the spectrometer.

γ ray energies	Possible origins	Relative intensities
0.96 MeV	(5th-2nd of ^{32}S) (7th-3rd of ^{34}S)	5
1.19 〃	2nd-1st of ^{34}S (6th-2nd of ^{32}S)	22

2.23 〃	4th-1st of ^{32}S	23

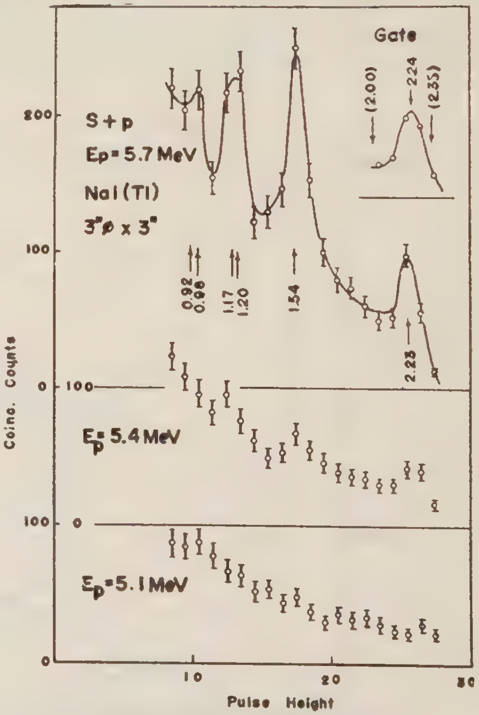

Fig. 9. Coincidence spectra gated by the gamma rays of 2.00–2.35 MeV, using two NaI(Tl) scintillators, 3-inch diameter by 3-inch long, at proton energies of 5.7, 5.4 and 5.1 MeV. Target was a natural sulphur compound, BaSO$_4$.

ray coincident with 2.24 MeV gamma ray is hardly due to accidental coincidence but the true cascade gamma ray of the transition (4th-1st of ^{32}S). These results confirm at the same time that the 1.54 MeV gamma ray is due to the cascade transition (2nd-1st of ^{32}S) and accidental counts are negligible. The gamma ray of about 1.2 MeV is almost due to the transition (2nd-1st of ^{34}S), but a part of it may be due to the transition (6th-2nd of ^{32}S), in comparison with the coincidence spectra of separated ^{32}S target, as will be described later. The gamma ray of about 0.9 MeV energy is perhaps due to the transition (5th-2nd of ^{32}S). All of these coincidence gamma rays are consistent with the single spectra and three crystal pair spectrum as were described already.

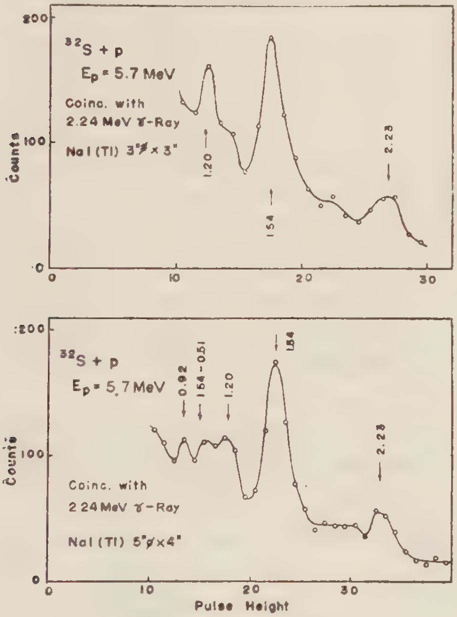

Fig. 10. Coincidence spectra gated by the gamma rays of 2.00-2.35 MeV, using two NaI(Tl) scintillators, 3-inch diameter by 3-inch long and 5-inch diameter by 4-inch long, at proton energy of 5.7 MeV. Target was a separated sulphur-32 compound, $BaSO_4$.

Table VI. Coincidence gamma rays gated between 2.00-2.35 MeV were listed at proton energy of 5.7 MeV. Separated sulphur-32 target and two NaI(Tl) scintillators, 3-inch diameter by 3-inch long and 5-inch diameter by 4-inch long, were used. Relative intensities were corrected for the efficiency of the spectrometer.

Cascade coincidence spectra were also observed using separated ^{32}S target. Results are shown in Fig. 10, and are tabulated in Table VI. These results also show that these coincidence gamma rays are almost due to the cascade transitions of ^{32}S.

Sum Coincidence Spectra:

Next we observed a sum coincidence spectrum(20) of the 2.24 MeV and 1.54 MeV gamma rays, in order to confirm the decay of the second state at 3.78 MeV of ^{32}S. The gate of the sum coincidence was set at 3.78 MeV. Geometrical and circuit arrangement for this experiment are the same as in the cascade coincidence experiment with the exception of interposition of a summing network of two output pulses from two detectors just before the gating single-channel pulse-height analyzer. The result is shown in Fig. 11. This spectrum shows a typical shape of simple cascade decay. In this case, also, the accidental coindence counts were negligible, considering the single counting rate of the 2.24 MeV gamma ray from each detector. In a sum coincidence measurement, one most take care to avoid a false peak caused by any inadequate gate setting, in which case the spectrum is not symmetric about the mean energy of two cascade gamma rays. The result of sum coincidence measurement, as shown in Fig. 11, supports the result of cascade coincidence that the 1.54 MeV gamma ray and the 2.24 MeV gamma ray are emitted in cascade and the former may be due to the transition from the 2nd state at 3.78 MeV to the 1st state at 2.24 MeV of ^{32}S. From the consideration of the detection efficiencies of these experiments, it is concluded that the 2nd state decays in cascade and branching ratio of the direct transition to the cascade transition is less than 5%. The 1^+ assignment for the 2nd state becomes, therefore, not exclusive. Then, in order to determine the spin of this state, we have measured the gamma-gamma angular correlations of the cascade gamma rays from this state. If this state has spin 0, the direct gamma ray transition to the ground state is forbidden.

Gamma-Gamma Angular Correlations:

Gamma-gamma angular correlation measurements can be separated into three parts. First, we measured the angular distributions of the 1.54 MeV gamma ray in coincidence with the 2.24 MeV gamma ray, rotating two detectors with fixed angles to each other around

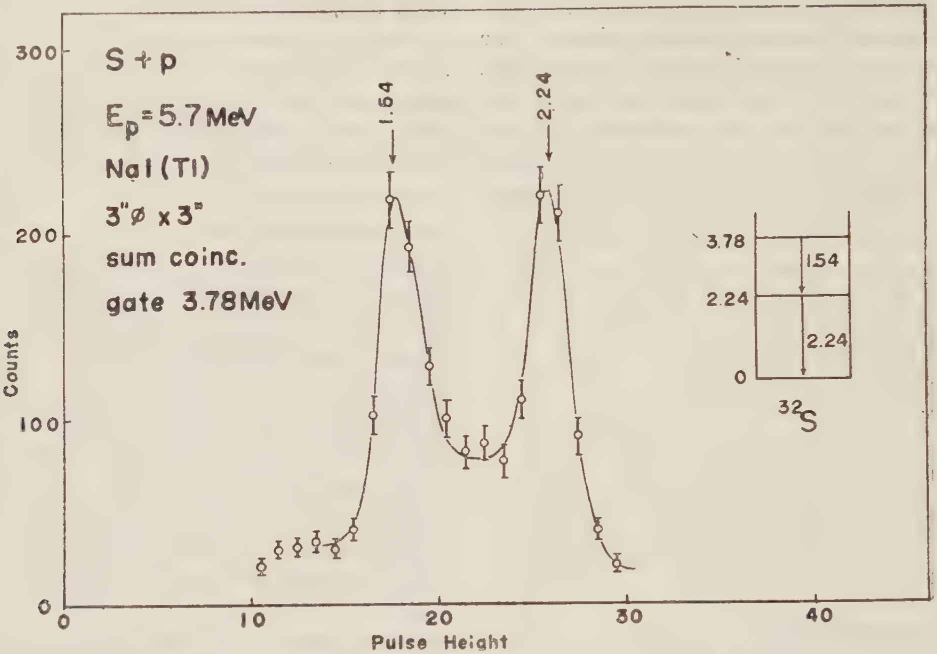

Fig. 11. Sum coincidence spectrum gated at 3.78 MeV, using two NaI(Tl) scintillators, 3-inch diameter by 3-inch long, at proton energy of 5.7 MeV, using natural sulphur compound, $BaSO_4$, as a target.

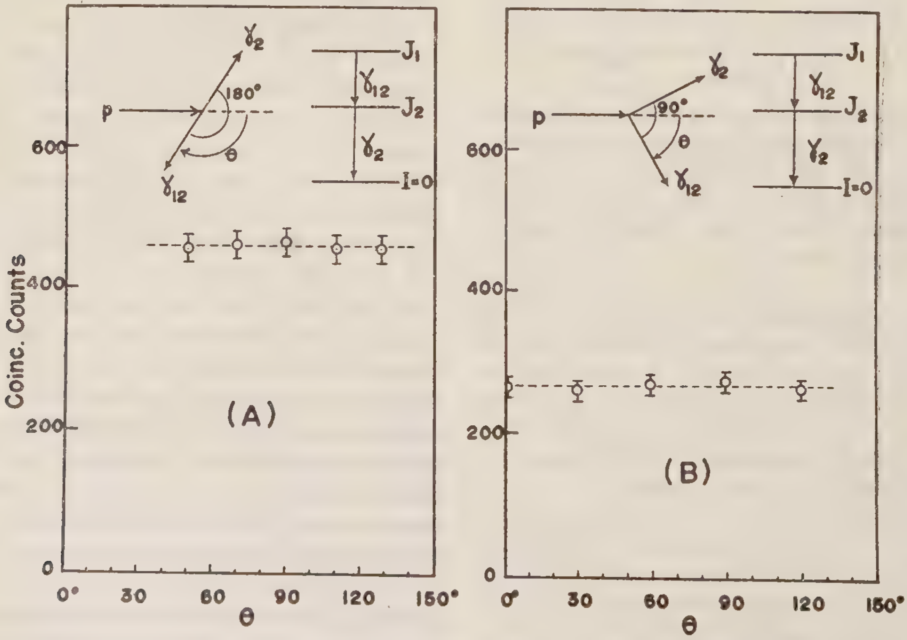

Fig. 12. Angular distribution of the 1.54 MeV gamma ray in coincidence with the 2.24 MeV gamma ray, rotating two detectors, 3-inch diameter by 3-inch long, with fixed angle to each other, about the axis as shown in figure.

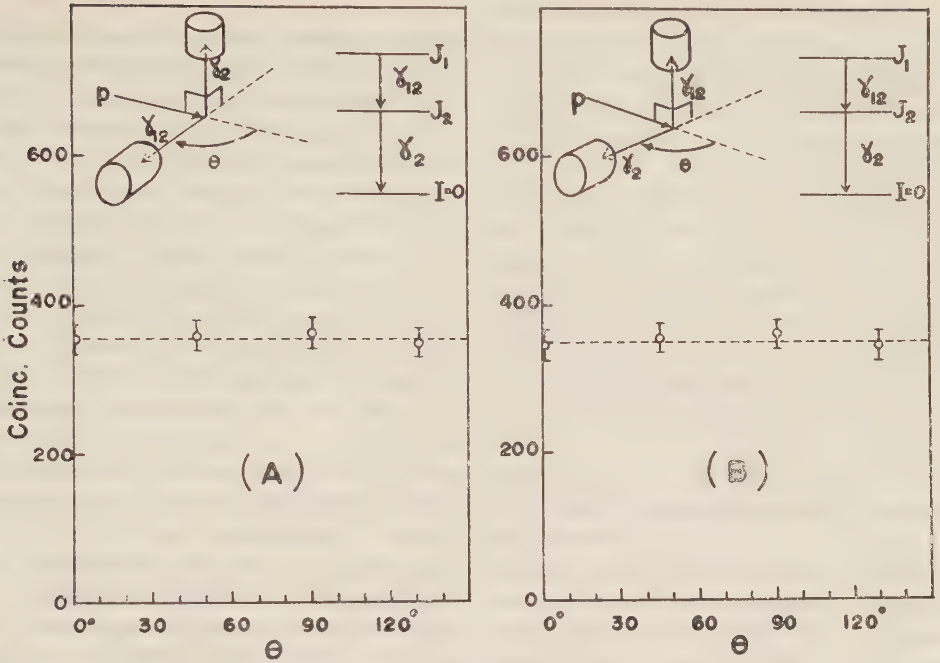

Fig. 13. Angular distributions of the 1.54 MeV and 2.24 MeV gamma rays in coincidence with the 2.24 MeV and 1.54 MeV gamma rays, respectively, using two detectors, 3-inch diameter by 3-inch long, one of which was fixed on the rotating axis and the other was rotated in the plane which includes the proton beam direction, as shown in the figure.

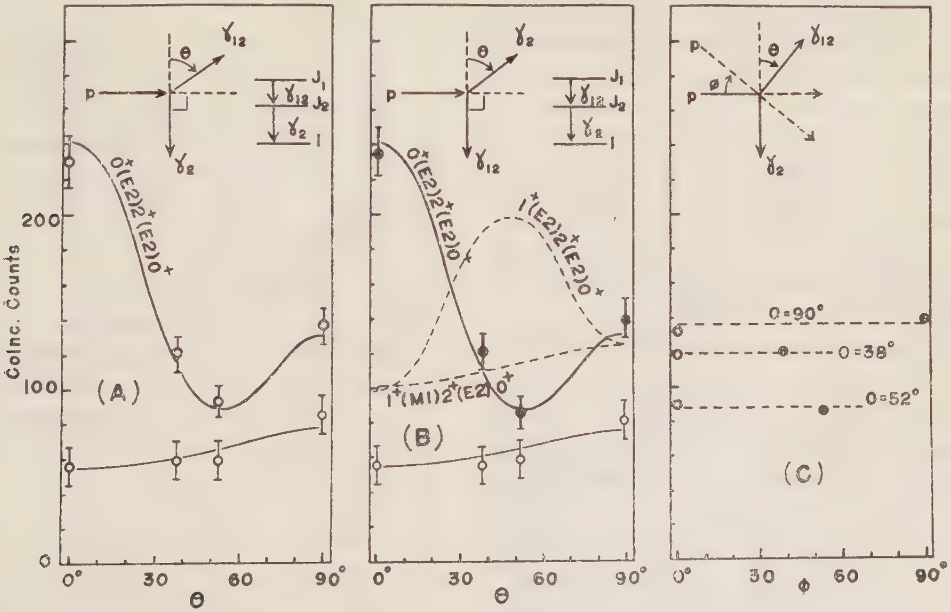

Fig. 14. Angular correlations of the 1.54 MeV and 2.24 MeV gamma rays using two detectors, 3-inch diameter by 3-inch long, one of which was fixed at right angles to the beam direction and the other was rotated about the axis at right angles both to the beam direction and to the direction of the fixed detector, as shown in the figure. Solid and dashed curves represent the calculated angular correlation curves, corrected by the finite solid angles of the detectors. In (A) the 2.24 MeV gamma ray (γ_2) was fixed and in (B) the 1.54 MeV gamma ray (γ_{12}) was fixed. The lower curves show the angular correlations of the 2.23 and 2.24 MeV gamma rays observed in the same way. In (C) the identity of two correlation curves is shown.

the axis through the target position and perpendicular to the plane which includes both the detectors and the incident proton direction. The measured results are shown in Fig. 12. The distributions were found to be isotropic within statistical errors.

Next, one detector was placed on the rotating axis and the other was rotated around the same axis. In this case also, the distribution was found to be isotropic as shown in Fig. 13. These results indicate that the nuclei followed by the gamma emission are not aligned and, therefore, cascade gamma-gamma angular correlation can be treated in the same way as for a radioactive nuclide.

The gamma-gamma angular correlation was measured in the same arrangement as the first case but one detector was fixed at right angles to the incident proton direction and another was rotated around the same axis. In this experiment also, two multichannel pulse height analyzers and two single-channel pulsd height analyzers were used as shown in Fig. 3, in order to gate one another by the 2.24 MeV gamma ray. The results are shown in Fig. 14. These results agree with the theoretical calculation for the transitions $0^+(E2)2^+(E2)0^+$ as shown in Figs. 14(A), (B). The theoretical angular correlation for this transition is as follows:

$$W(\theta)=1+0.357P_2+1.07P_4 .$$

The theoretical curves in Fig. 14 have been corrected for the effect of finite solid angles of the detectors. On the other hand, the theoretical angular correlation for the cascade, $1^+(M1, E2)2^+(E2)0^+$, is as follows:

$$W(\theta)=(1-0.250P_2)+\delta^2(1+0.679P_2-0.762P_4)$$
$$+2\delta(1+0559P_2) ,$$

where δ represents a mixing ratio. The first and the second terms are the correlation functions for the pure cascades $1^+(M1)2^+(E2)0^+$ and $1^+(E2)2^+(E2)0^+$, respectively. The third term is the contribution due to the interference between M1 and E2 transitions. One can not fit the experimental results with $1^+(M1, E2)2^+(E2)0^+$ even if any large mixing ratio is assumed.

It is interesting that two kinds of tripple angular correlations, one of which are gated by γ_2 at fixed detector and the other gated by γ_2 at rotating detector as shown in Figs. 14(A) and (B) respectively, become identical for the case that $I=0$ and $L_{12}=L_2=J_2$, where these symboles are also shown in Figs. 14. This fact makes the analysis of tripple angular correlation simple. For an even-even nucleus, it is the case that γ_{12} is pure E2 transition. In the present case J_1 have been restricted to be 1^+ or 0^+ from the result of the reaction $^{31}P(d, n)^{32}S$ as was previously described. Therefore, as the further analysis, mere consideration of pure E2 transition from 1^+ state for γ_{12} will do, considering the identity of angular distributions in Fig. 14(A) and Fig. 14(B), even if there be not the evidence of isotropic distribution for γ_{12} or there be any accidently cancellation of angular distribution, although the fact is that there are evidences of isotropic distributions, as shown in Fig. 12 and Fig. 13. In such tripple correlation, also, it is found that one can not fit the experimental angular correlations to calculated curve of $1^+(E2)2^+(E2)0^+$. It is, therefore, concluded that the spin and parity of the 2nd state at 3.78 MeV are 0 and even. At the same time, it is confirmed that the 1st state at 2.24 MeV has the spin of 2 and even parity, which has been assigned tentatively.

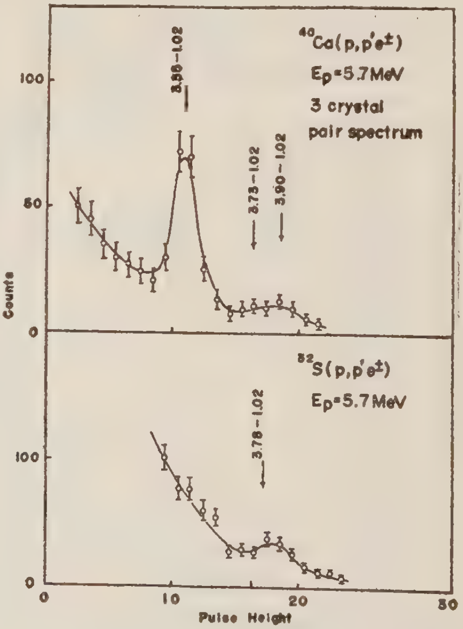

Fig. 15. The spectrum of the nuclear pairs from the 1st state of ^{40}Ca, using three crystal pair spectrometer with a well type plastic scintillator as a centre detector. The lower curve shows the pair spectrum from the proton bombardment of natural sulphur compound, BaSO$_4$, as a target.

Nuclear Pair Detection:

We searched the nuclear pair from the 2nd state to the ground state using a three crystal pair spectrometer as shown in Fig. 2. For a test of the detector, we observed the nuclear pairs from the 1st state of ^{40}Ca using the reaction ^{40}Ca$(p, p'e^{\pm})^{40}$Ca. The result was shown in Fig. 15. Using the same arrangement, we searched the nuclear pairs from the 2nd state of ^{32}S, but no distinct pair peak was found. Considering the detection efficiencies of the spectrometers and the proton beam currents, it was deduced that the intensity of nuclear pairs is about 2% or less of that of the 1.54 MeV gamma ray.

On the other hand, the 1st 0^+ state of ^{40}Ca at 3.35 MeV has a half-life of 1.4×10^{-9} sec, while the estimated half-life using the single particle model is 4.9×10^{-12} sec for E2 transition of 1.54 MeV gamma ray. From these fact it is estimated that the intensity of the nuclear pair from the 2nd 0^+ state of ^{32}S may be about 0.4% of that of 1.54 MeV gamma ray. We think that the efficiency and resolution of the spectrometer is too low to detect such low intensity pairs.

§ 4. **Discussions**

0^+ Second Excited State of ^{32}S:

As mentioned already in § 1, several authors[10),11)] pointed out the difficulty of any theoretical explanation for the 2nd state of ^{32}S that possesses the spin of 1 and even parity. R. Huby and H. C. Newns discussed as follows[10)]. They assumed for this state to be double, one component having 0^+ and the other some reasonable spin and parity, say 2^+ or 4^+, and to lie in energy closer than 20 KeV, which is the accuracy of the energy determination. With these assumptions the stripping reaction ^{31}P$(d,n)^{32}$S could excite both these levels but the transition to the component having 0^+ masked the other. In addition the gamma ray transition to the ground state now no longer makes 0^+ impossible since it can arise from the component having non-zero spin. On the other hand, A. Arima calculated the energy levels, spins and parities of ^{32}S, on the basis of the j-j coupling shell model[11)]. From the results of his calculations the first $T=1$ state appears at 7.18 MeV, the first $J=1$ states appears at 8.00 MeV, and the 0^+ excited state appears at 4.12 MeV. According to his discussions, if it is experimentally sure that there is no low-lying 0^+ state in ^{32}S, the theoretical low-lying 0^+ state in this nuclei shows the inadequacy of the values of the parameters in the calculation.

The assignment of 0^+ for the 2nd state, however, can remove these theoretical difficulties. The configuration of the theoretically calculated state at about 4 MeV may be $(s_{1/2})_0^2(d_{3/2})_0^2(T=0, J=0)$, while the ground state is $(s_{1/2})_0^4$. If these two state are formed by s-wave protons from the ground state of ^{31}P as found in the reaction ^{31}P$(d, n)^{32}$S, it is deduced that the configuration of the ground state of ^{31}P may be mixed with $(s_{1/2})^1_{1/2}(d_{3/2})_0^2$ and $(s_{1/2})^3_{1/2}$. This configuration gives reasonable agreement with the theoretically calculated magnetic moment on the basis of the j-j coupling shell model. If this configuration is pure $(s_{1/2})^3_{1/2}$, the calculated magnetic moment can not explain the experimental valve. This configuration mixing of the ground state of ^{31}P are supported by the angular distribution measurement of protons in the reaction ^{31}P$(d, p)^{32}$P[22)].

Recently, B. D. Kern carried out the search of the 3.8 MeV gamma ray in the reaction ^{32}S$(n, n'\gamma)$ when $^2D(d, n)^3$He neutrons of energies greater than 3.8 MeV but less than 4.32 MeV were used to bombard a sulphur sample[23)]. No 3.8 MeV gamma ray was found with two different geometrical arrangements. This fact confirms our experimental result.

If the 2nd state of ^{32}S has a spin of 0^+, we meet another question why the higher excited states decay scarcely to the 0^+ ground state but to the 0^+ 2nd state. According to the single particle estimations, the intensities of the direct transitions of the states at about 5 MeV to the ground state are not less than 10^2 times of those of the cascade transitions through the 2nd state, even if these are E1 or M1 transitions. Experimentally the intensities of the direct transitions are not more than about a half of those of the cascade transitions. It is considered that some unknown selection rules may exist or these cascade gamma rays may be due to the transitions between higher excited states of ^{32}S than 3.78 MeV.

The 3rd and 4th States of ^{32}S:

The cascade transition from the 3rd state to the 1st state of ^{32}S could not be observed.

If the observed gamma ray of about 4.3 MeV is attributed to the direct transition from the 3rd state to the ground state, the 3rd state may have a spin of 1^- or 2^+.

On the other hand, the 4th state decays through the 1st state by the emissions of the cascade gamma rays of 2.23 and 2.24 MeV. The angular distribution data between these cascade gamma rays, as is shown in Fig. 14, can be tentatively explained with the transition $1^-(E1)2^+(E2)0^+$, although the data are too poor to assign definitely the spin of the 4th state. If the spin of this state is 1, the direct transition to the ground state may also exist comprised in the peak at about 4.3 MeV. Moreover, it is possible that the 3rd state has a larger spin and is scarcely excited by the inelastic scattering process and the gamma ray at about 4.3 MeV is almost due to the transition from the 4th state, although there is a little ambignity of the energy determination. For the spin assignments of these states it is necessary to measure the more accurate energies and intensities for the gamma rays of about 4.3 MeV.

The Excited States of ^{34}S:

The 3.91 and 4.11 MeV gamma rays were found. Considering the results of $^{34}\mathrm{Cl}^m(\beta^+)\,^{34}\mathrm{S}^*(\gamma)$[16], it is deduced that the 3.91 MeV state has a spin of 3^+ and the 4.11 MeV state has a spin of 2^+. The 4.88 MeV state decays with the cascade gamma ray of 0.97 MeV to the 3.91 MeV state. Then the spin of the 4.88 MeV state may be 2 or 3.

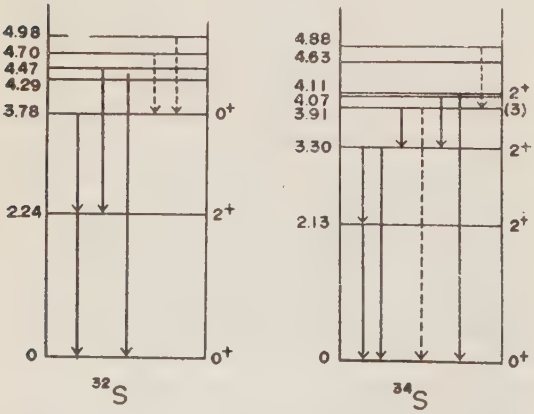

Fig. 16. The level schemes of ^{32}S and ^{34}S. Arrows indicate the gamma ray transitions observed in the present experiment. Only the 0.62 and 0.77 MeV gamma rays were observed not in the present experiment but in the decay of $^{34}\mathrm{Cl}^m$.[16]

Acknowledgments

The author wishes to thank Mr. K. Kaneko and his collaborators for the separation of sulphur isotopes at the Institute for Nuclear Study, University of Tokyo. The author is very grateful to Prof. T. Wakatsuki for his continual guidance, encouragement and discussion throughout the progress of this work. He is also indebted to Mr. I. Miura for many valuable collaborations and discussions.

Reaction $O^{16}(\gamma, p)N^{15}$ by 20.5 MeV Polarized Bremsstrahlung

By Katsufusa Shoda

*Department of Physics, Tohoku University,
Sendai, Japan*

(Received May 6, 1961)

D_2O soaked, H_2O soaked and unsoaked emulsions were irradiated simultaneously at the characteristic angle by the 20.5 MeV polarized bremsstrahlung from a thin Al target in a betatron. The linear polarization of the gamma rays from 4 MeV to 6 MeV was estimated to be 31.7±5.0% by observing the azimuthal angular distribution of photoprotons from deuterons. The H_2O soaked emulsion and unsoaked one were used to study $O^{16}(\gamma, p)$ reaction. The proton energy spectrum shows a structure which agrees with the earlier results except a peak at 1.1 MeV of proton energy. This peak which has never been found corresponds to the well-known resonance in $N^{15}(p, \gamma)O^{16}$ at 1.05 MeV of proton energy. The azimuthal angular distributions of photoprotons caused by several photon energy regions were observed. From these angular distributions it is shown that a resonance at a photon energy of 17.3 MeV is $E1$ transition, and the corresponding level of O^{16} is considered to have $J=1^-$, $T=1$, which is in good agreement with the theoretical calculation in the intermediate coupling.

§1. Introduction

The photoproton emission from O^{16} has been studied recently[1-9], and many proton peaks in the energy spectrum have been observed. In principle these structures of the spectra should not be compared directly with those of the cross section, because the transitions to the excited states of the residual nucleus plays an important role in the case of the proton spectra. In practice, however, Johansson et al.[7] and Milone et al.[9] studied the cross section and the branching ratios to the levels of N^{15} using nuclear emulsions and oxigen gass targets, and found that almost all proton emissions in the region before the giant resonance ($E_\gamma<20$ MeV) accompany mainly ground state transitions. Then the cross section can be obtained from the proton energy spectrum in this low energy region.

Spicer[1] found a large photoproton resonance at $E_\gamma=14.7$ MeV and concluded, by observing the proton angular distribution, that this transition must be $M1$ or $E2$ absorption. Johansson and Forkman[3),7] examined the proton energy spectra and angular distributions using 20.5 MeV and other higher energy bremsstrahlung. They found the several peaks in the cross section. They estimated the types of main transitions using the angular distributions and ratios between photoproton and photoneutron yields. According to their estimation there exists $E1$ or $M1$ absorption at $E_\gamma\approx17$ MeV, $M1$ or $E2$ absorption at $E_\gamma\approx19$ MeV and $E1$ absorptions around 21 MeV and 23.5 MeV.

The reaction $N^{15}(p, \gamma_0)O^{16}$ is considered to be the inverse process of $O^{16}(\gamma, p)N^{15}$ at smaller photon energy than about 20 MeV (suffix 0 denotes the transition to the ground state), because almost all photoproton transitions are the ground state transitions in these energy regions. Schardt et al.[10] observed a large resonance at $E_p=1.05$ MeV which corresponded to the level of O^{16} at 13.09 MeV ($J=1^-$, $T=1$). Wilkinson et al.[11] examined the (p, γ_0) resonance up to $E_p=4$ MeV. Excepting the 1.05 MeV resonance, they found no pronounced resonance. This result is inconsistent with the existence of a large resonance at $E_\gamma=$ 14.7 MeV in Spicer's data. Tanner et al.[12] observed the cross section of (p, γ_0) in the proton energy region between about 4 MeV and 8 MeV. They found the peaks of cross section at 5.6 MeV and 7.4 MeV which were in good agreement with the photoproton results[3),7),9)]. In the giant resonance region Cohen et al.[13] observed the cross section of (p, γ_0) and found that this cross section agreed with the cross section of ground state transition of photoprotons[2),4),7),9)].

Elliott and Flowers[14)] calculated the properties of the odd parity states of O^{16} which might be considered to arise from the configurations $p^{-1}d$ and $p^{-1}2s$. The calculation was performed in the intermediate coupling scheme including the spin-orbit splittings of the p and d shells. According to their calculations five levels of $J=1^-$, $T=1$ appear at 13.1, 17.3, 20.4, 22.6 and 25.2 MeV having the electric dipole widths 0.06, 0.14, 0.02, 12 and 5.8 keV respectively. Some of these energy levels are in fairly good agreement with the photoproton experimental data. The 22.6 and 25.2 MeV levels correspond to the giant resonance.

A large peak of the observed (γ, p) cross section below the giant resonance corresponds to the 17.3 MeV level. According to the results of Johansson et al. the absorption for $M1$. The experimental angular distribution this level is $E1$ or corresponds to the d wave emission or s wave emission of photoproton for $E1$ or $M1$ absorption respectively. Elliott and Flowers' calculation shows that the 17.3 MeV level corresponds to the $p^{-1}d$ state and agrees with the experimental angular distribution if the absorption is $E1$. However, according to the comparison made by Johansson et al. between the cross sections of (γ, n) and (γ, p), the assumption of d wave emission does not seem to be reasonable. On the other hand, Weisskopf[15)] suggests that the photon absorption below the giant resonance may be $M1$ absorption. We see from these discussions that the property of the 17.3 MeV level is not clear. The 13.1 MeV level predicted by Elliott and Flowers' calculation was not found in photodisintegration, but this level has been observed in $N^{15}(p, \gamma_0)O^{16}$ reaction[10),11)].

In general, the multipole order in photodisintegration can be estimated by the polar angular distribution of emitted particles, but the parity of multipole can not be estimated by this distribution only. Agodi[16)] calculated the effect of photon polarization on nuclear photoeffect. The polar angular distribution of the emitted particles in the photoreaction induced by unpolarized photon and the azimuthal angular distribution in a plane orthogonal to the incident polarized photon beam may be expressed as follows respectively,

$$I(\theta)=N_p(a_0+a_2\cos^2\theta) \qquad (1)$$

$$F(\phi)=N_A(1+P\alpha_0\cos 2\phi) \qquad (2)$$

where P is the ratio of the intensity of polarized photons to the total photons and ϕ denotes the emission angle from the direction of the electric vector of photons on the plane orthogonal to the beam. According to his calculation, if a single multipole is responsible for the transition, the relations between Eq. (1) and Eq. (2) are as follows,

$$\alpha_0=(-1)^\sigma\frac{a_2}{a_0} \quad \text{for dipole transition} \qquad (3)$$

$$\alpha_0=(-1)^\sigma\frac{a_2}{5a_0} \quad \text{for quadrupole transition} \qquad (4)$$

where σ is defined as zero for magnetic and 1 for electric multipoles. Owing to these results, the absolute value of the ratio of α_0 to a_2/a_0 exibits a large difference for dipole and quadrupole transitions and the sign of α_0 relative to a_2/a_0 distinguishes the electric multipole transition from the magnetic one when the multipole order is known. The maxima and minima in the azimuthal angular distribution are interchanged in each case.

The linear polarization effect of bremsstrahlung produced by electrons in MeV region has been studied recently[17)-25)]. According to the theoretical calculation the largest polarization appears at the characteristic emission angle, $\Theta=mc^2/E_0$, where m is the electron rest mass and E_0 is the electron total energy. The degree of polarization of the 17 MeV photons in the 20.5 MeV bremsstrahlung is theoretically estimated to be about 10%.

The azimuthal angular distribution of 17 MeV photoproton groups from O^{16} caused by the polarized 20.5 MeV bremsstrahlung may give the more detailed properties of this level if it is combined with the polar angular distribution of the experiment of Johansson et al.[7)]

§ 2. Experimental Procedure and Apparatus

The degree of polarization of bremsstrahlung is strongly dependent on the photon emission angle. The multiple scattering of electrons in the target, the oscillation and the beam cross section of circulating electrons in the betatron doughnut affect the photon emission angle and will reduce the degree of polarization. In order to reduce these effects, a thin Al target (2.5 mg/cm²) of 1 mm×5 mm was used and the beam stopper (Pt 1.5 mm thick) was placed at 15 mm from the stable orbit near the opposite to the target. The expander current was chosen as small as possible, and the cross section and the oscillation amplitude of the electron orbit were measured by autoradiography of induced activity on a thin Cu target. The best position of the target was determined for the same condition as shown in ref. 25.

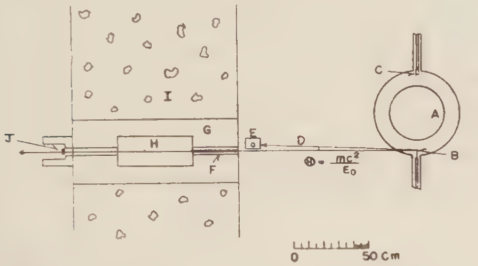

Fig. 1. Experimental arrangement showing **A**-betatron doughnut, **B**-bremsstrahlung target (Al 2.5 mg/cm² thick), **C**-electron gun and beam stopper, **D**-direction of the center of bremsstrahlung, **E**-monitor, **F**-lead collimator, **G**-lead shield, **H**-sweep magnet, **I**-concrete wall, **J**-nuclear plates.

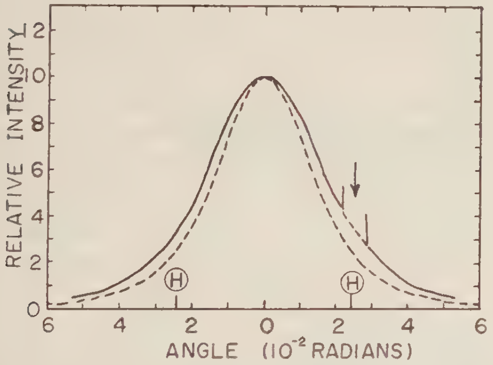

Fig. 2. The angular distribution of the bremsstrahlung. Full line: experimental result. Broaken line: theoretical curve. The direction of the irradiation beam is shown by an arrow.

After these preliminaly experiments, D_2O soaked, H_2O soaked and unsoaked plates mounted on thin watertight bakelite holders were irradiated simultaneously by the 20.5 MeV bremsstrahlung at the characteristic angle as shown in Fig. 1. Each plate was 1″×1″ in size cut from a 1″×3″ Ilford C2 200 μ thick nuclear plate.

The effects of multiple scattering of electrons in the target, the oscillation and the cross section of the incident electron beam were examined by the angular distribution of the bremsstrahlung with Fuji Type 80 X-ray film. The results of photometric observation of the angular distribution of bremsstrahlung and the determination of the angle between the direction of the beam center and that irradiating the plates are shown in Fig. 2. The theoretical curve for a very thin target was calculated by the simple formula[26]

$$F(\theta)=1/[1+(E_0\theta/mc^2)^2]^2 .$$

This was also shown in the same figure. The deviation of the experimental result from the theoretical curve is not so large.

The irradiation dose was measured by a Victoreen chamber embedded in a small cube of Lucite which was calibrated by the chamber at the center of a 10 cm cube of Lucite. The experimental dose value may have large error owing to large back ground. The plates were developed by an amidole developer, pH. of which was adjusted with HCl in order to minimize fogging. Tiyoda binocular microscope was used for the scanning at a multiplication of 60×1.5×10.

The range of protons was determined by measuring the projected length of the tracks on the plane of the emulsion and their depth corrected for the schrinkage factor. The latter was determined by measuring the thick-

ness of emulsion after soaking with a micrometer and measuring the thickness after development by the microscope. For the range-energy relations of D_2O and H_2O soaked emulsions, the table calculated by Krohn and Schrader[27] was used.

The data of exposure are given in Table I.

§ 3. Experimental Results and Discussions

a) *Polarization of 20.5 MeV bremsstrahlung*

The relation between the energy of the photoproton from deuteron (E_p) and the incident photon energy (k) are given by

$$E_p=\frac{k-\varepsilon}{2}+\sqrt{\frac{k-\varepsilon}{4Mc^2}}\,k\cos\theta\,, \qquad (5)$$

where ε is the threshold energy of deuteron photodisintegration, θ is the emission angle of photoprotons, and M is the proton mass. The proton spectra expressed by the photon energy using Eq. (5) and the azimuthal angular distributions for several energy groups are shown in Figs. 3 and 4 for D_2O and H_2O soaked plates. In these figures the number of protons in the H_2O soaked plate is normalized to the same number of oxigen atoms as in the D_2O soaked plate. H_2O soaked plate is used for the back ground subtraction for the deuteron photodisintegration. The glancing angle of the observed protons is between ±45°. Under such condition of observation, the difference

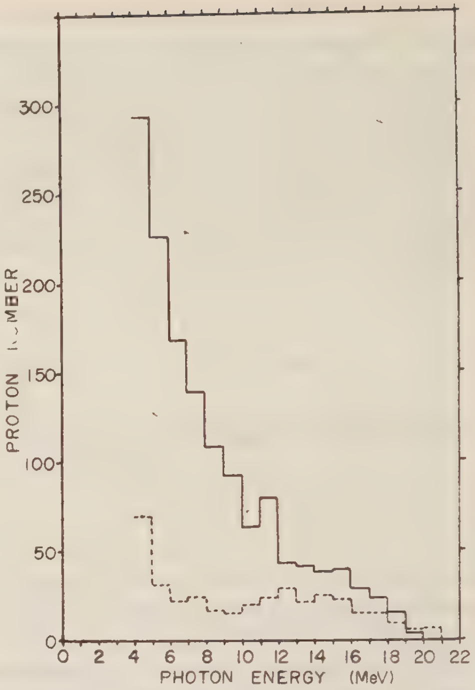

Fig. 3. Energy spectra of photoprotons from D_2O and H_2O soaked plates. The abscissa is calculated photon energy using Eq. (1) assuming that all the photoprotons come from deuteron photodisintegration. The proton number from the H_2O plate is normalized to the same number of oxigen atoms as in the D_2O soaked plate. The full line and the broaken one are the results of D_2O and H_2O soaked plates respectively.

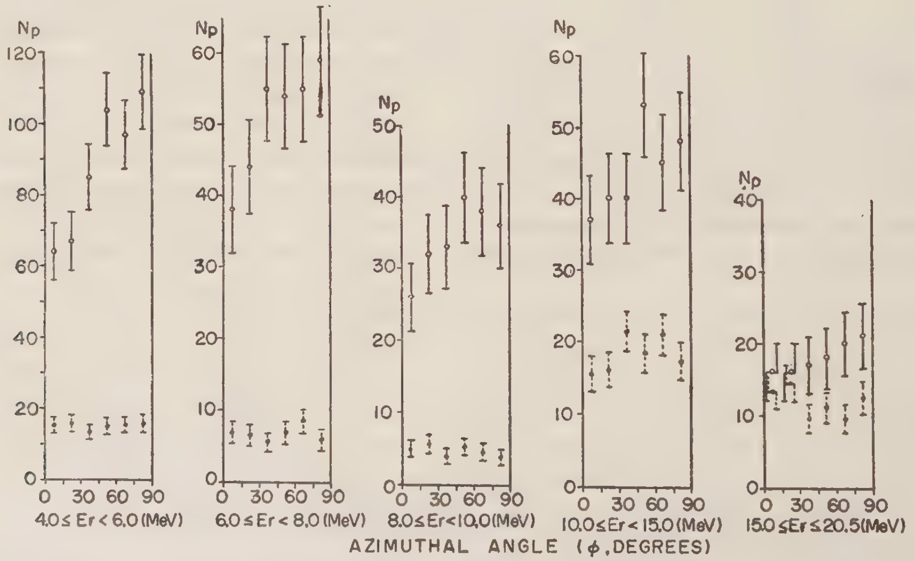

Fig. 4. Azimuthal angular distributions in D_2O and H_2O soaked plates. The proton number from the H_2O plate is normalized to the same number of oxigen atoms as in the D_2O soaked plate. Open and closed circles are the results by D_2O and H_2O soaked plates respectively.

of the thickness of the emulsions affects the effective volume of observation. However, the thickness is not so different between the two emulsions, that the effective volume can be assumed to be equal for the two plates. The best fitted angular distributions of the form $a+b\sin^2\phi$ for the H_2O soaked plate are calculated by the least squares and are subtracted from the observed angular distributions by the D_2O soaked plate. Using the subtracted angular distribution, the best fitted angular distributions of photoprotons from deuteron are calculated as in H_2O soaked plate.

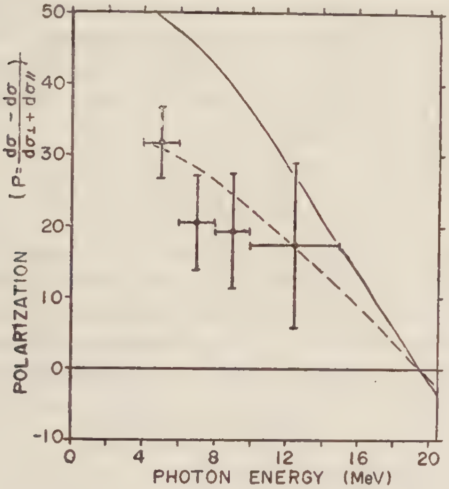

Fig. 5. Energy dependence of polarization % of 20.5 MeV bremsstrahlung. The solid curve is a calculated one using the Gluckstern and Hull's equation. The broaken curve shows a normalized one with the experimental point.

The polarization of the bremsstrahlung is calculated by these angular distributions assuming the $E1$ transition for the deuteron photodisintegration. In Fig. 5, the photon energy dependence of polarization of 20.5 MeV bremsstrahlung is given from the results shown in Fig. 4. The calculated curve by Gluckstern and Hull[18] and also the normalized curve best fitting the experimental points are shown in the figure.

b) *Photoprotons from* O^{16}

The observed photoproton energy spectra for the H_2O soaked and unsoaked plates are shown in Fig. 6. The glancing angle of the observed protons is between ±60° or ±45°.

The photoprotons in the H_2O soaked emulsion involve the back ground protons emitted from nuclei other than O^{16}. In order to obtain the spectrum of photoproton emitted from O^{16}, the back ground protons must be subtracted from the proton spectrum of the H_2O soaked plate.

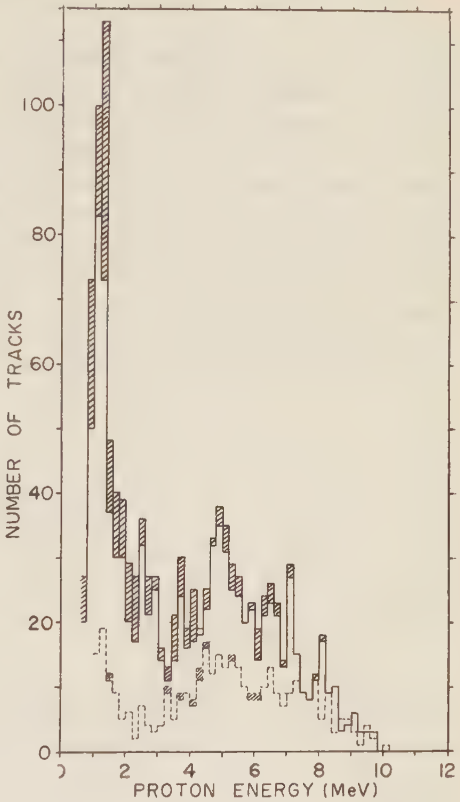

Fig. 6. Observed photoproton energy spectra for the H_2O soaked and unsoaked plates. Full line: for the H_2O soaked plates. Broaken line: for the unsoaked plates. The shaded parts show the protons with the glancing angle between 45° and 60° in plus and minus.

If we denote by N the total proton tracks in the unit area of emulsion for all directions, and denote by n those in ±45° of glancing angle, N is proportional to n

$$N=fn\ .$$

f will be a function related to the thickness of emulsion at exposure, proton energy and polar angular distribution. If the last is denoted by $A(1+B\cos^2\theta)$, f is given by

$$f=\frac{4\left(1+\frac{B}{3}\right)}{\sqrt{2}\left(2+\frac{B}{3}\right)-\frac{R}{D}\left(1+\frac{B}{4}\right)}$$

$$\text{when}\quad \frac{D}{R}\geq\cos 45^\circ\ .$$

$$=\frac{2\left(1+\frac{B}{3}\right)}{\frac{D}{R}\left[1+\frac{B}{6}\left(\frac{D}{R}\right)^2\right]}\,.$$

$$\text{when}\quad \frac{D}{R}\leq\cos 45°\,,$$

where D and R are the thickness of the emulsion and proton range respectively. n and n' are assumed to be decomposed as $n=n_0+n_b$ and $n'=n_0'+n_b'$ for H_2O soaked and unsoaked plates respectively, where oxigen and back ground are denoted by the suffixes 0 and b. Denoting the f function for n_0, n_b, n_0', n_b' by f_0, f_b, f_0', f_b', the following relations are obtained for each plate,

$$f_0N=f_0(n_0+n_b)=f_0n_0+\frac{f_0}{f_b}f_bn_b$$

$$f_0'N'=f_0'(n_0'+n_b')=f_0'n_0'+\frac{f_0'}{f_b'}f_b'n_b'\,.$$

The number of atoms which emitt the back ground protons is equal in the same area of the two emulsions because these two plates are cut out from the one plate, and therefore the total number of back ground protons in each plate is the same i.e. $f_bn_b=f_b'n_b'=N_b$. According to Johansson et al.'s result[7] of angular distributions, B is assumed to be $-7/9$, 0.6 for the region of proton energy 4.4–5.0 MeV, 6.2–7.3 MeV respectively, and 0 for other regions. These of B values are continued smoothly. We assume $B=0$ for the back ground protons. Using these values, f_0/f_b and f_0'/f_b' are calculated. These ratios are nearly equal and can be equated to the mean value F in each proton energy within the error of 1.5%. Considering the relations mentioned above, a method of subtraction is obtained as follows

$$f_0N-FN_b=f_0n_0$$

$$f_0'N'-FN_b=f_0'n_0'\,,$$

where f_0n_0 and $f_0'n_0'$ show the total proton number from oxigen in the two plates. Actually, the observed two proton spectra Fig. 6 were normalized to the same area, multiplied by f_0 and f_0' and subtracted the same

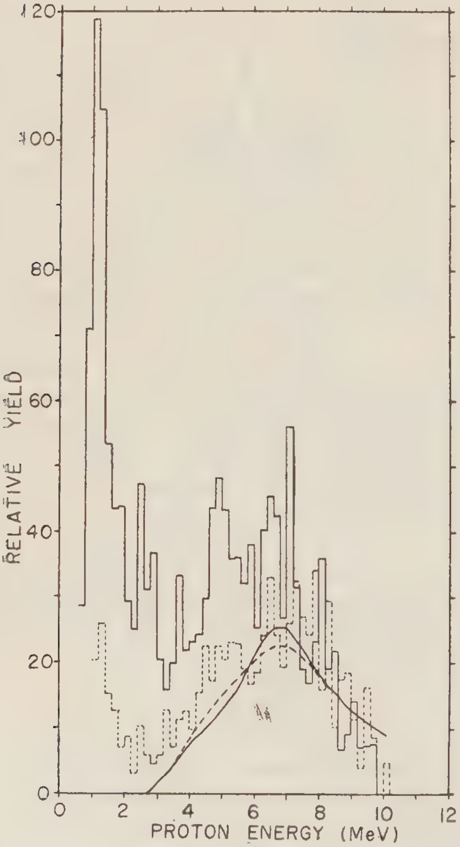

Fig. 7. The proton energy spectra corrected for the emulsion thickness and the back ground spectrum to be subtracted. Full line hystogram: for the H_2O soaked plate; broaken line hystogram: for the unsoaked plate; full curve: spectra of back ground to be subtracted (FN_b); broaken curve: spectra of back ground (N_b).

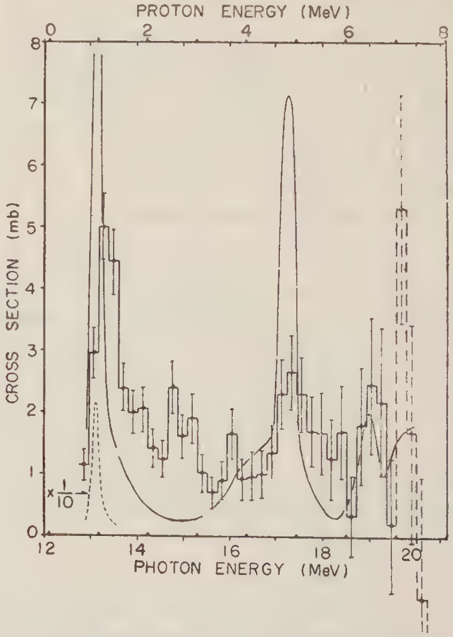

Fig. 8. Cross section of $O^{16}(\gamma, p)N^{15}$ assuming that all proton transitions are those to the ground state of N^{15}. The hystogram is the present result and the curves are the calculated cross sections from the experimental (p, γ_0) cross section using the detailed balance theorem.

spectra (FN_b) to give the same shape of subtracted results. In Fig. 7, f_0N, $f_0'N'$, FN_b, and N_b are shown. After subtraction, f_0n_0 is considered to be the photoproton spectrum from O^{16}.

The cross section of $O^{16}(\gamma, p)$ was then obtained and the results are shown in Fig. 8. The energy on the abscissa is given by $E_\gamma = 12.11 + (17/16)E_p$. The proton spectrum and the cross section are in fairly good agreement with the results of Johansson et al. except the region lower than 14 MeV of photon energy. In this energy region, almost all transitions are those to the ground state of N^{15}, and the (γ, p) cross section can be calculated by the experimental (p, γ_0) cross section using the detailed balance theorem. The cross section obtained by such a calculation is also shown in Fig. 8. The agreement in the shape between the two cross sections is good. The absolute values of the present experimental cross section are smaller than the calculated one. In the present experiment, however, the energy resolution is lower than the others and the error in the value of dose is probably large.

The peak at 14.8 MeV of photon energy has never been observed in $N^{15}(p, \gamma_0)O^{16}$. Spicer[1] found a strong peak at 14.7 MeV in (γ, p) reaction. In the results of Johansson et al.[7] a small peak was found corresponding to this energy in the photoproton spectrum caused by 20.5 MeV bremsstrahlung. In both of the present case and that of Johansson et al. a peak may be expected by the transition from resonances at about 20 MeV to the excited level at 5.3 MeV in N^{15}. This may be included in the peak at 14.8 MeV. The examination using the lower energy bremsstrahlung would be desirable for more complete study.

The azimuthal angular distributions of protons with the glancing angle smaller than 60° are shown in Fig. 9 for both H_2O soaked and unsoaked plates. The errors in the figure are only the statistical ones. The angular distributions after subtraction of the back ground fit the form $A + B\sin^2\phi$ using the least squares. The results are shown in Table II together with other values.

The theoretical azimuthal angular distri-

* Obtained by ref. 7.

† Present data of polarization.

The polar and azimuthal angular distributions are represented as follows:

$$I(\theta) = N_p(a_0 + a_2\cos^2\theta)\,, \qquad F(\phi) = N_A(1 + P\alpha_0\cos 2\phi)\,.$$

butions were calculated using Eqs. (1)-(4). In these calculations the results of the polar angular distributions obtained by Johansson et al.[7] and the polarization degrees obtained in the present experiment were used. For the proton group of $0.8 \leq E_p < 2$ MeV, the polar angular distribution has not been observed in $O^{16}(\gamma, p)N^{15}$, but it was estimated by the angular distribution of radiation in $N^{15}(p, \gamma_0)O^{16}$ reaction[10],[11],[28] which was measured to be isotropic within about 10%. This (p, γ_0) result was used in the present calculation. The angular distributions are nearly isotropic and are of no use to determine the parity of multipolarity except for the region of $4.4 \leq E_p \leq 5.6$ MeV. For the proton group $4.4 \leq E_p \leq 5.6$ MeV which corresponded to the transition induced by photon around 17.5 MeV, the asymmetry of the azimuthal angular distribution was observed though the experimental error was large. The sign of the assymetry shows that the transition is $E1$ as shown in Table II when $E1$ or $M1$ transition is possible[7].

According to Elliott and Flowers' calculation, the levels having $J=1^-$, $T=1$ below 20.5 MeV which correspond to the peaks of $E1$ transition are expected at 13.1 and 17.3 MeV. These energies are in good agreement with the present result. For the 13.1 MeV level the present result can not determine the multipolarity of transition, but the experimental result of angular distribution of gamma rays in $N^{15}(p, \gamma_0)O^{16}$ [10],[11],[28] shows that it is a strong $E1$ transition[10],[11],[28],[29]. Wilkinson et al.[11] suggested that this state of O^{16} was well described as $p^{-1}2s$ and probably contained less than 3% in intensity of $p^{-1}d$. These facts are in good agreement with Elliott and Flowers' result. For the 17.3 MeV level, the present result suggests it is caused by $E1$ transition, and therefore the polar angular distribution of the results of Johansson et al. shows that the proton emission from the 17.3 MeV level of O^{16} is d-wave[7], so that the configuration of this level is mainly $p^{-1}d$ which is in good agreement with Elliott and Flowers' result. Thus Elliott and Flowers' calculation gives a good interpretation of the $E1$ transition in photodisintegration of O^{16}.

The author would like to thank Prof. M. Kimura for his interest and encouragement in the course of the present work, and also Dr. K. Okamoto for his discussions. He is indebted to Mr. R. Togei for his useful help in the earlier stage of the experiment. Thanks are also due to Miss Y. Nagahama for scanning many plates.

(Received May 8, 1961)

Angular distributions for the $N^{14}(d, p)N^{15}$ ground state reaction were studied at the deuteron energies of 15.2 and 13.8 MeV, and were compared with the angular distributions for the $C^{12}(\alpha, p)N^{15}$ ground state reaction at such alpha-particle energies that the compound nucleus 0^{16} would be produced at the same excitation energies as would be produced by the bombardment of N^{14} with deuteron of the above energies. Similar comparisons between the two reactions were made by using the available experimental results including our previous results. It is seen that the $N^{14}(d, p)N^{15}$ ground state reaction proceeds mainly via the stripping process at deuteron energies above 8 MeV showing no appreciable change of the angular distribution with deuteron energy, though the angular distribution for the $C^{12}(\alpha, p)N^{15}$ ground state reaction shows critical energy dependence in the corresponding energy range.

§ 1. Introduction

Previously, some of the authors[1)] reported the angular distributions for the $N^{14}(d, p)N^{15}$ ground state reaction at the deuteron energies of 16.2 and 16.7 MeV. The results are compared with the deuteron stripping theory and it is also pointed out that these angular distributions are quite similar to those for the $C^{12}(\alpha, p)N^{15}$ ground state reaction[2)] at such bombarding alpha-particle energies that the compound nucleus 0^{16} will be produced at the same excitation energies as will be produced by the bombardment of N^{14} with deuteron of the above energies. In order to see whether the correspondence between the two reactions with regard to the compound nucleus 0^{16} is accidental, the $N^{14}(d, p)N^{15}$ ground state reaction was studied at lower deuteron energies corresponding to the alpha-particle energies where the critical energy dependence of the angular distribution for the $C^{12}(\alpha, p)^{15}$ ground state reaction is reported[2)].

The deuteron beam was accelerated with the cyclotron of the Institute for Nuclear Study at University of Tokyo. The experimental arrangements of the slit system, scattering chamber and particle detectors were the same as those used in the previous experiment. As the target, melamine ($C_3H_6N_6$) of 1.63 mg/cm² in thickness evaporated onto the silver foil was used, instead of nitrogen gas filled in the gas cell which had been used in the previous experiment. Two sets of scintillation counter, composed of $C_sI(Tl)$ crystal of 2 mm in thickness, were mounted at 180° to each other on the turn table in the scattering chamber, and the measurements were done simultaneously at two opposite directions to the deuteron beam. The values of the differential cross sections at 90° in the laboratory system obtained with the two counters at each deuteron energy agreed reasonably each other showing that the error due to the geometrical arrangement was sufficiently small. A monitor counter of similar construction was set at 55° to the beam direction.

The angular distributions for the $N^{14}(d, p)N^{15}$ ground state reaction in the center-of-mass system at different deuteron energies are shown in Fig. 1. In this figure, the angular distributions at the deuteron energies of 16.7, 16.2, 15.2 and 13.8 MeV are the results obtained in our experiments and those at the deuteron energies of 11.4 and 7.9 MeV are the results obtained by M. Takeda[3] and W. M. Gibson and E. E. Thomas[4], respectively, and those at 3.2 and 2.5 MeV are the results by one of the authors, N. Kawai[5]. In Fig. 1, the angular distributions for the $C^{12}(\alpha, p)N^{15}$ ground state reaction, obtained by I. Nonaka *et al.*[2] and M. Takeda[6], are also shown by dotted curves. The angular distributions for the two reactions shown together refer to the bombarding deuteron and alpha-particle energies which correspond to nearly the same excitation energy of the compound nucleus 0^{16}.

Fig. 1. The angular distributions for the $N^{14}(d, p)N^{15}$ ground state reaction at different energies, including the experimental results obtained by other authors. Dotted curves are the angular distributions for the $C^{12}(\alpha, p)N^{15}$ ground state reaction obtained by Nonaka *et al.*[2)] and Takeda[6)]. The solid and dotted curves shown together correspond to nearly the same excitation energy of the compound nucleus 0^{16}.

Contrary to the expectation described in the previous paper[1)], the angular distributions for these two reactions become quite different as the bombarding energies get lower, particularly in the extremely forward and backward directions. It is evident that the $N^{14}(d, p)N^{15}$ ground state reaction proceed mainly via the stripping process in the energy range of deuteron above 8 MeV. Since the compound nucleus process is expected generally to have somewhat larger contribution to the (α, p) reaction than to the (d, p) reaction, the compound nucleus process might have some contribution to the critical energy dependence of the angular distribution for the $C^{12}(\alpha, p)N^{15}$ ground state reaction. It seems reasonable, however, that this energy dependence of the angular distribution is due to an interference effect of some direct processes in view of the high alpha-particle energy and high excitation energy of the compound nucleus involved. In order to understand the remarkable energy dependence of the angular distribution for the $C^{12}(\alpha, p)N^{15}$ ground state reaction, it will be significant to see whether some correspondence between this reaction and the deuteron induced reactions on N^{14} other than the (d, p) reaction with regard to the compound nucleus 0^{16} exists, in the wide range of deuteron energy, as we did about the $N^{14}(\alpha, p)N^{15}$ reaction in the present work.

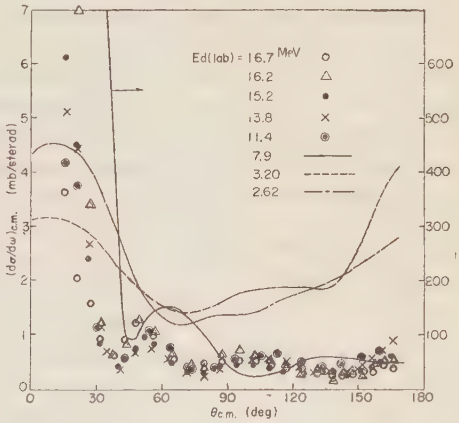

Fig. 2. The angular distributions for the $N^{15}(d, p)N^{15}$ ground state reaction at different deuteron energies.

In Fig. 2, the angular distributions for the $N^{14}(d, p)N^{15}$ ground state reaction, shown in Fig. 1, are replotted together in order to facilitate the comparison. The angular distribution at the deuteron energy of 2.6 MeV shown in this figure is also the result obtained by Kawai. The scale on the ordinate at the right side, which refers to the differential cross section at the deuteron energy of 7.9 MeV obtained by Gibson and Thomas[4)], gives a value larger by two orders of magnitude than the scale on the ordinate at the left side, which refers to the differential cross sections at the other deuteron energies, does. The differential cross section at 7.9 MeV may be erroneous in its estimation.

Fig. 3 shows the same angular distributions plotted against, instead of the angle θ, the momentum transfer k defined by

$$k=k_d^2+k_p^2-2k_dk_p\cos\theta\ ,$$

where k_d and k_p are the amplitudes of the wave number vectors of the incoming deuteron and the outgoing proton respectively. The plane wave approximation of the stripping theory predicts the angular distributions which are represented by the square of the spherical Bessel function, $\{j_1(kr)\}^2$, multiplied by a factor which decreases monotonically with the increasing angle and does not depend critically on the bombarding deuteron energy. Therefore, it is expected that the maxima and minima in the angular distributions for a certain reaction at different deuteron energies occur at the same values of k, if the reaction concerned can be well explained by the plane wave approximation of the stripping theory using the interaction radius, r, approximately independent of the bombarding energy. It is noted that the positions of the maxima and minima of the angular distributions shown in Fig. 3 are more convergent to each other than those shown in Fig. 2 are.

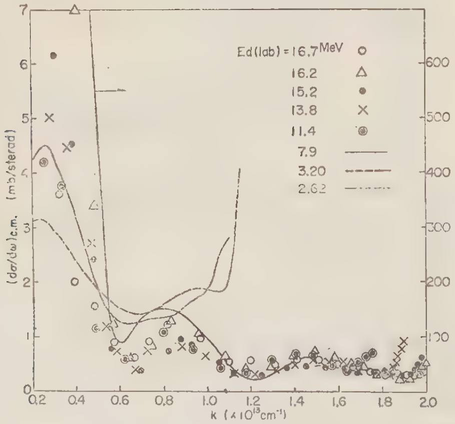

Fig. 3. The angular distributions for the $N^{15}(d, p)N^{15}$ ground state reaction, plotted against the momentum transfer k instead of the reaction angle.

This behavior of the angular distribution is consistent with the results found in the reactions $C^{12}(d, p)C^{13}$ and $0^{16}(d, p)0^{17}$ by E. W. Hamburger[7].

The values of the interaction radius, which were determined by fitting the simple deuteron stripping theory to the experimental angular distributions at different deuteron energies, are plotted against the deuteron energy and are shown in Fig. 4. The interaction radius is approximately independent of deuteron energy and tends to get larger as deuteron energy decreases.

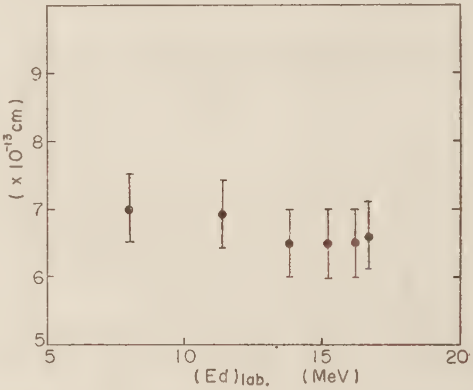

Fig. 4. The values of the interaction radius for the $N^{14}(d, p)N^{15}$ ground state reaction at different deuteron energies, estimated from the experimental angular distributions using the simple deuteron stripping theory.

The authors are very grateful to the cyclotron crew of the Institute for Nuclear Study of University of Tokyo for operation of the cyclotron. They are also much indebted to Prof. E. W. Hamburger and Dr. M. Takeda for sending their results prior to publication.

(α, p) Reactions near $Z=26$

By Itaru NONAKA, Hisashi YAMAGUCHI, Takashi MIKUMO,
Iwao UMEDA*, Tatsuro TABATA** and Saburo HITAKA***

Institute for Nuclear Study, University of Tokyo,
Tanashi-machi, Kitatama-gun, Tokyo, Japan

(Received May 11 1961)

Spectra of protons from the (α, p) reactions on Ti, Cr, Fe, Ni, Cu and Zn were measured at the energy of alpha particles near 28 MeV. For Ti and Fe the shapes of the spectra and the distributions of the observed levels of residual nuclei resemble each other. This is also true for Cr and Ni, and for Cu and Zn.

Angular distributions of the first, the second and the third proton groups for Ni, and of the first and the second proton groups for Zn were all known to show the direct process type forward peaking. The integrated total cross sections of these proton groups are 0.5_4(first), 0.4_9(second) and 0.7_2(third) mb for Ni and 0.2_4(first) and 0.2_4(second) mb for Zn respectively.

§ 1. Introduction

A variety of experiments have been performed by many investigators to implement the understanding of the mechanisms of medium energy nuclear reactions. On the (α, p) reactions most of the experiments are studies of angular distributions of protons from the reactions. However, sufficient experimental informations concerning emission spectra will be important for the understanding of reaction mechanisms.

Concerning the (α, p) reactions, emission spectra have been measured by R. M. Eisberg and others[1] at alpha particle energy of 40 MeV on heavy elements, by W. Swenson and N. Cindro[2] at 30.5 MeV on medium weight elements, and by N. O. Lassen and V. A. Sidrov[3] at 19.3 to 11.9 MeV on medium weight elements. Main purpose of these investigations, however, seems to be in studies of level density distributions in the residual nuclei.

In the (α, p) reactions of medium energy it is certain from the studies of angular distributions of protons that there are considerable contributions from the direct process type reaction mechanisms. We tried to measure the emission spectra of protons from the (α, p) reactions on medium weight nuclei in the forward directions where the direct process type reaction will predominate. It is considered that by the above method we can obtain some informations on the levels of residual nuclei which are strongly excited by the (α, p) reactions.

§ 2. Experimental Procedures

The experimental arrangements and procedures are the same as those in our previous experiments[4),5)]. The external alpha particle beam of 28.4 MeV from the I.N.S. variable energy cyclotron was brought into the 100 cm scattering chamber and the emitted protons were detected by a thin NaI(Tl) scintillation counter located in the scattering chamber. The energy scales of the detected protons were determined by making use of the known energy values of the recoil protons which were originated from the moisture contamination on the surfaces of target foils.

The targets used were foils of natural elements of Ti, Cr, Fe, Ni, Cu and Zn which were 1.21, 3.5, 2.06, 2.31, 3.45 and 4.58 mg/cm² thick respectively. They were set to make an angle of 45° to the beam direction. The energy values of alpha particles in the centres of the targets were between 28.0 and 28.3 MeV according as the thickness of each target foil.

The spectra were measured at angles of 11° and 30° for Ti, Cr, Fe and Cu. For Ni and Zn, measurements were performed at several angles and the angular distributions of the first, the second and the third proton groups were obtained.

§ 3. Results and Discussions

In Fig. 1, the proton spectra at 30° (lab.) expressed as $(d^2\sigma/d\omega.\,dQ)_{\text{cm}}$ v.s. Q-value are shown. Reaction particles other than protons are considered to be not contained in the spectra because the aluminium absorber of 269 mg/cm² in thickness inserted in front of the scintillation counter can stop the elastically scattered alpha particles and also the deuterons from the (d, α) reactions which have high negative Q-values. The (α, np) and $(\alpha, 2p)$ reactions have also high negative Q-values and have little contributions in the observed proton spectra.

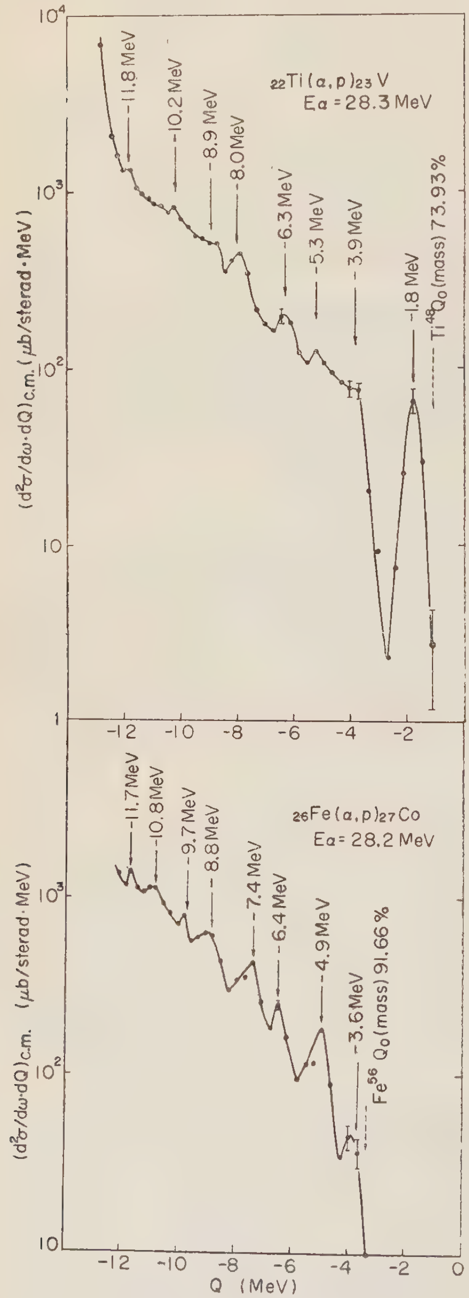

Fig. 1 (a). Spectra of protons at 30°(lab.) from $_{22}$Ti$(\alpha, p)_{23}$V and $_{26}$Fe$(\alpha, p)_{27}$Co.

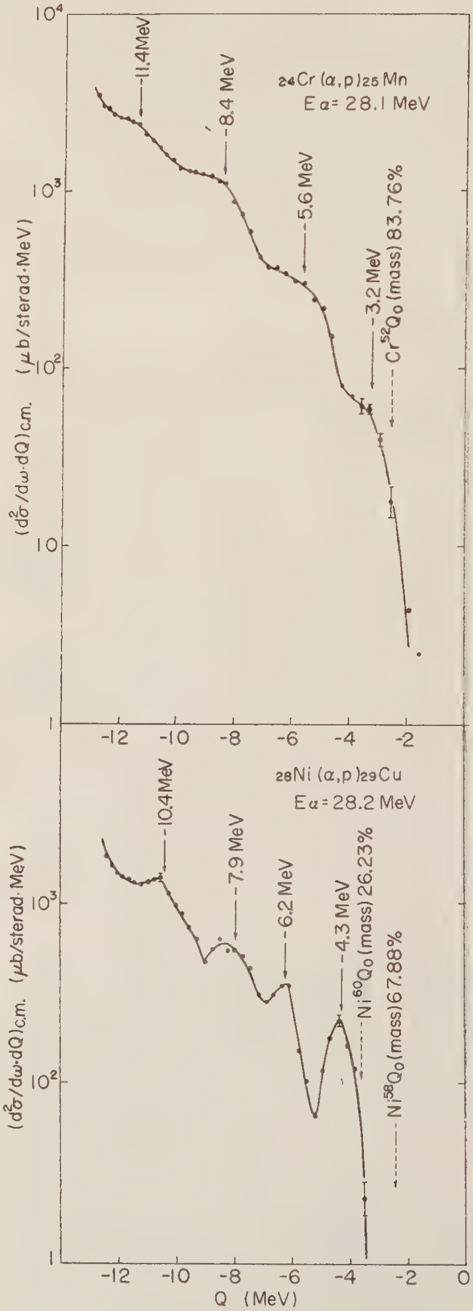

Fig. 1 (b). Spectra of protons at 30°(lab.) from $_{24}$Cr$(\alpha, p)_{25}$Mn and $_{28}$Ni$(\alpha, p)_{29}$Cu.

For $_{22}$Ti and $_{26}$Fe the shapes of spectra resemble each other. This is also true for, $_{24}$Cr and $_{28}$Ni, and for $_{29}$Cu and $_{30}$Zn. Positions of the excited levels of residual nuclei measured from the lowest ones which are excited by the (α, p) reactions are shown in Fig. 2. The distributions of the observed levels have good correspondence between the above mentioned pairs of reactions, $_{22}$Ti$(\alpha,p)_{23}$V and $_{26}$Fe$(\alpha, p)_{27}$Co, $_{24}$Cr$(\alpha, p)_{25}$Mn and $_{28}$Ni$(\alpha, p)_{29}$Cu, $_{29}$Cu$(\alpha, p)_{30}$Zn and $_{30}$Zn$(\alpha, p)_{31}$Ga.

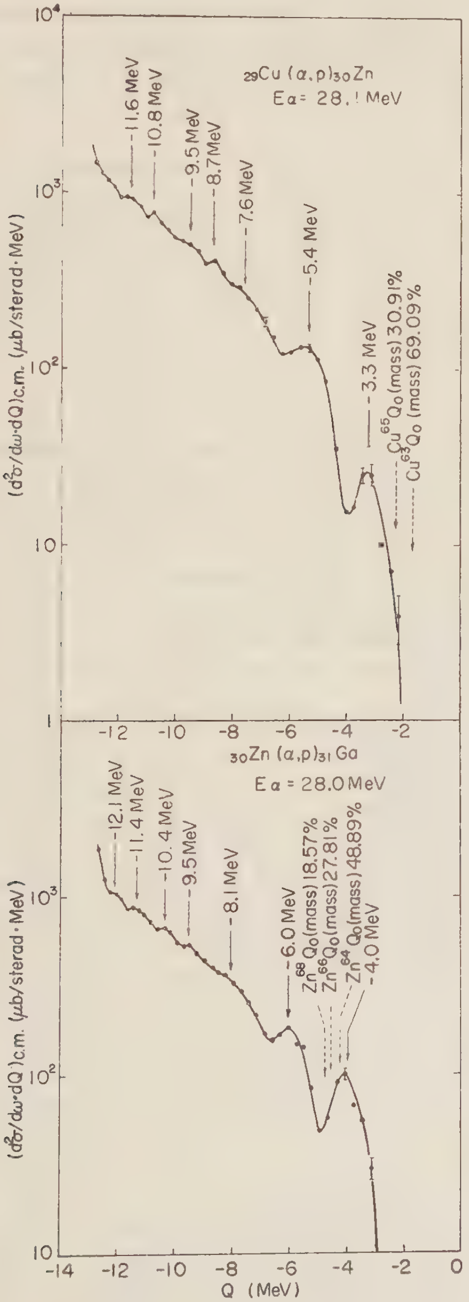

Fig. 1(c). Spectra of protons at 30°(lab.) from $_{29}$Cu$(\alpha, p)_{30}$Zn and $_{30}$Zn$(\alpha, p)_{31}$Ga.

The targets were of natural elements. but in the cases of Ti, Cr and Fe the reactions might be considered to be produced by the single isotopes $_{22}$Ti^{48}, $_{24}$Cr^{52} and $_{26}$Fe^{56} respectively, because other isotopes have abundances smaller than 10 per cent. In the cases of Ni, Cu and Zn, however, the reactions might not be considered to be produced by single isotopes.

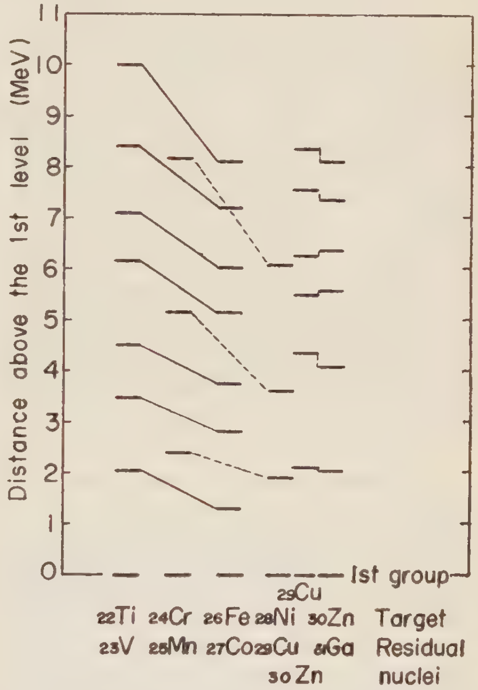

Fig. 2. Positions of levels excited by the (α, p) reactions measured from the first proton groups.

In some cases, Q-value of the lowest observed level does not coincide with that of the ground state of the residual nucleus calculated from known mass values[6] which is indicated as Q_0 in Fig. 1. Especially, in the cases of Ni and Cu targets these discrepancies are considered to be greater than the experimental errors (~0.3 MeV), so we must conclude that the ground states are difficult to be produced by the (α, p) reactions in these cases. N. O. Lassen and V. A. Sidrov[3] also found that the ground state of $_{30}$Zn^{66} was not produced by the $_{20}$Cu$^{63}(\alpha, p)_{30}$Zn^{66} reaction in the region of alpha particle energies between 11.9 and 19.3 MeV.

If we consider the (α, p) reaction to proceed through stripping of the incident alpha particle into a proton and a triton as J. L. Yntema[11] does in the case of the (α, t) reaction, then the states of residual nucleus which are strongly excited by the (α, p) reaction will be those which are nearly expressed by a system of the target nucleus plus a triton. The level structures shown in Fig. 2 are considered to show the distributions of such states in the residual nuclei. The reason why the distributions of these levels should have the characters shown in Fig. 2 is not known in the present states of theoretical consideration.

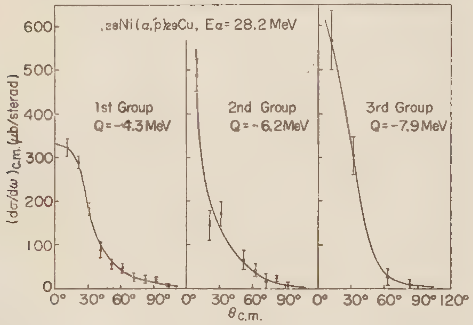

Fig. 3 (a). Angular distributions of the proton groups from Ni target.

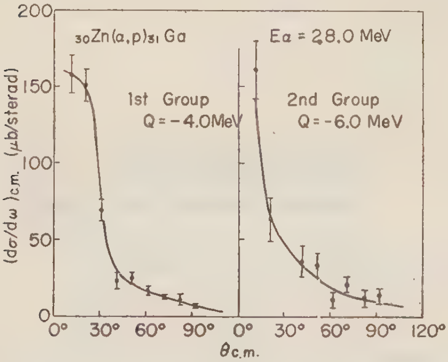

Fig. 3 (b). Angular distributions of the proton groups from Zn target.

The angular distributions of the first, the second and the third proton groups for Ni, and of the first and the second proton groups for Zn were all known to show the direct process type forward peaking which has negligibly small differential cross sections at angles greater than 90° as shown in Fig. 3.

Total cross sections of these proton groups were obtained by integrating the angular distributions and the results are shown in Table I.

Table I. Integrated total cross section.

Target	E_α (MeV)	Total cross section (mb)		
		First group	Second group	Third group
$_{28}$Ni	28.2	0.5_4	0.4_9	0.7_2
$_{30}$Zn	28.0	0.2_4	0.2_4	

The authors express their cordial thanks to the cyclotron technical staffs of the Institute for Nuclear Study.

Resonant Scattering of Photons in Mg and Si

By Masumi SUGAWARA

Department of Physics, Faculty of Science,
Tohoku University, Sendai, Japan

(Received May 21, 1961)

An NaI(Tl) scintillation spectrometer was used to study the resonant scattering of photons generated by the bremsstrahlung x-rays. The resonant levels were found at 10.2 and 9.3 MeV in Mg and at 11.3 MeV in Si. Their level widths were obtained by the self absoption method. They are 3.8 eV and 0.9 eV in Mg, and 8.3 eV in Si, respectively. The spins and parities of these levels were assigned to be 1^+ by considering the isotopic spin multiplets.

§1. Introduction

The resonant scattering of photons has been studied in the energy region below the particle thresholds using bremsstrahlung or gamma rays from nuclear reactions. Very few reports are available concerning the reaction of this kind using bremsstrahlung x-rays, because the cross sections averaged over the energy are rather small as compared with the electronic cross sections and the continuous spectrum of bremsstrahlung makes very troublesome background. Although the measurement is difficult, it is interesting to investigate the properties of the nuclei when irradiated by the photons. Such a kind of experiment may give information on the energies, widths, spins and parities of the levels. On the other hand, the experiment at the energies around the particle thresholds may give the relation between the phenomena of gamma-ray scattering by the discrete levels and by the continuous region.

Broad peaks in the elastic scattering cross section around the particle threshold energies were found and have been explained as those corresponding to the lower part of the giant resonance.[1)2)] These broad resonances in light nuclei are composed of several isolated levels and have a magnetic dipole character, but in heavier nuclei it is not clear whether they are divided into isolated levels, nor is it known what type of the electromagnetic interaction they have.

The experiments of this kind have been done for some light nuclei using the bremsstrahlung x-rays.[3)–7)] They are 3.56 MeV level in Li^6, 4.46 MeV and 5.03 MeV in B^{11}, 15.1 MeV in C^{12}, 10.15 MeV in Mg and 11.4 MeV in Si. γ-rays from $F^{19}(p, \alpha\gamma)O^{16}$ were also used to take a survey of the averaged character of resonant elastic scattering on several tens of elements at the energies of about 6 or 7 MeV.[8)]

The purpose of the present report is to clarify some of the problems mentioned above. Recently Tobin reported the resonant scattering by Mg and Si.[7)] The present results do not agree very well with his results and we shall discuss the discrepancies between his results and ours and also the problems which he did not mention.

§2. Experimental arrangement

The experiment was performed using the bremsstrahlung x-rays from the platinum target in a 25 MeV betatron whose repetition rate is 50 cycles per second. Produced x-rays were defined by iron and lead collimators and electrons in the beam were swept away by a sweep magnet set in a tunnel in the shielding wall which consisted of heavy concrete and water saturated with boric acid. Blocks made of lead, iron or paraffin were used to avoid the neutron and x-ray background. Then the x-ray beam brought into the next room hit the scatterer which was located in front of the detector. The distance between the platinum target and the scatterer was about 4 meters. The x-ray beam had a diameter of 4.0 cm at the scatterer and was hardened by a graphite absorber of 5.65 g/cm² in thickness which was directly attached to the front of the collimator.

The beam intensities were monitored by the thin walled transmission ionization chamber with electrodes composed of seven aluminum foils 30 μ in thickness and 10 cm in diameter. The current fed by the ionization chamber was measured by a vibrating reed electrometer and was recorded.

A scattered photon detector was an 8″×8″ NaI(Tl) crystal viewed by three photomultipliers (Du Mont 6363). The crystal, the photomultipliers and a cathode follower were all located in the lead shield with walls 15 cm thick in the side of the betatron room and 10 cm thick in other sides, surrounded with blocks made of paraffin and a mixture of boric acid and paraffin.

The detector was placed at 120 degrees from the incident beam direction and subtended the solid angle of 0.108 ster. through a hole 15 cm long tapered toward the center of the scatterer in a lead collimater which was located in front of the detector. The hole was filled with alluminum plug 5 cm thick and covered with a 4 cm thick paraffin plate in order to filter out soft x-rays and electrons. The front surface of the NaI detector was 40 cm distant from the scatterer.

The width of the primary x-rays was broadened to about 20 μ sec. to diminish the pile up effect. The pulses from the cathode follower were amplified by a somewhat fast dipole amplifier and were analysed by a 30 channel pluse height analyser. The amplifier was biased to discriminate small pulses caused by low energy photons and other processes. The pulse height analyser was operated for about 40 μ sec. in each betatron cycle simultaneously with betatron pulses to reduce the cosmic ray background.

Stability of the electronic detecting circuits was monitored at every three hours by 1.28 MeV monochromatic γ-rays of Na^{22}. The scatterer and the absorber of Mg were metal plates. The thickness was 1.74 cm and 1.54 cm respectively, and the diameter was 9.0 cm in both cases. In the case of Si, metal powder contained in thin walled cans made of aluminum, 10 cm in diameter and 2 cm thick as a scatterer and 8.0 cm in diameter and 2 cm thick as an absorber, were used.

Each scatterer was situated so that the direction normal to the surface of the scatterer might divide equally the angle between the direction of the incident beam and that of the axis of the NaI(Tl) crystal. Each absorber was placed in the incident beam at 50 cm forward the scatterer. The position of the absober will be called "the absorber position" in the following sections. The experimental arrangement is shown in Fig. 1. The place marked by a broken line is "the absorber position".

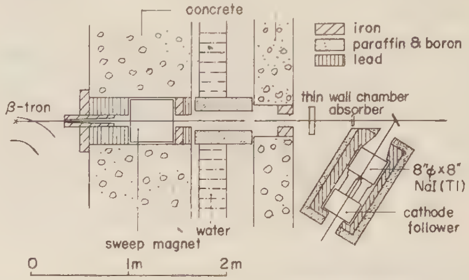

Fig. 1. The arrangement of the apparatus. The place marked by the broken line is "the absorber position" used in the self absorption measurements.

§ 3. Experimental procedure

The thickness of Mg and Si scatterers used was 3.03 g/cm^2 and 2.20 g/cm^2 respectively, as shown in Table I.

The spectra of photons scattered from the targets were measured when these are bombarded with the bremsstrahlung x-rays. The betatron energy was set to be 16.0 MeV, since the bremsstrahlung of this maximum energy has photons enough to excite nuclei to about 10 MeV without giving much background x-rays to the detector. The measured spectra are shown in Figs. 2 and 3 by the solid lines.

Table I. Thickness of the scatterer and the absorber.

Element	Thickness of scatterer used	Thickness of absorber used
Mg	3.03 g/cm^2	2.84 g/cm^2
Si	2.20 g/cm^2	2.26 g/cm^2

In the spectrum of Mg, a large broad peak was found at about 10 MeV and two small peaks at about 8 and 6 MeV. The peak at 10 MeV was divided into two photon groups which corresponded to 10.2 MeV and 9.3 MeV levels, and the existence of this splitting was verified by the excitation yield curve as shown later. It was not determined exactly whether the peak at 8 MeV was due to another resonant level or occured from other processes.

The last one around 6 MeV was identified to be the photons of neutron capture process in lead, because it was found even in the measurement in which the gating pulses were delayed to exclude the photons induced by the scattering process.

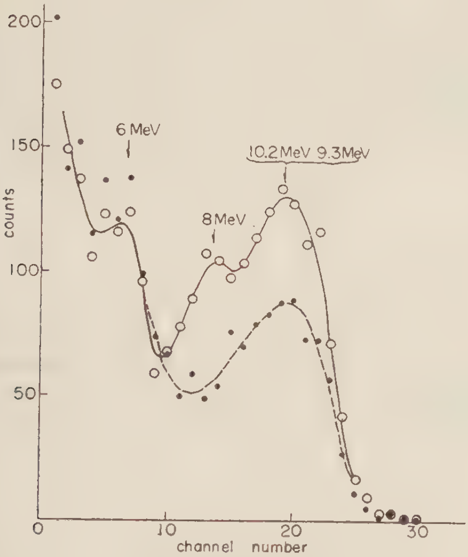

Fig. 2. The spectra of the scattered photons from the Mg scatterer. The solid line is the spectra measured without the Mg absorber and the broken line with the absorber. They are all normalized to the unit charge of the ionization chamber.

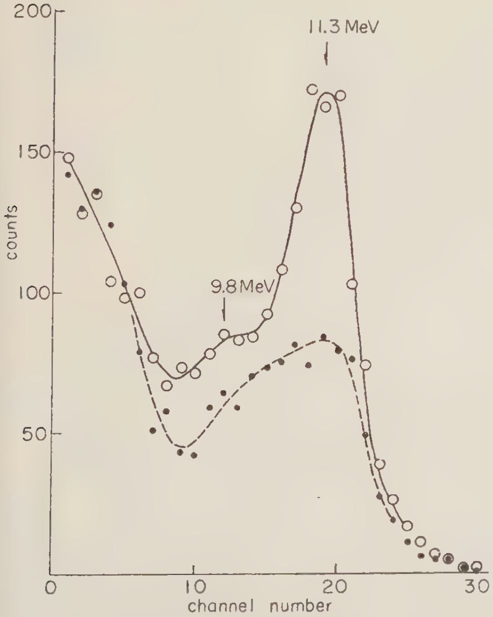

Fig. 3. The same as Fig. 2 with Si scatterer and absorber.

In the spectrum of Si, a large peak was found at about 11 MeV and a small one at about 10 MeV.

Setting the absorber between the scatterer and the monitor, the scattered photon spectra were measured by the same procedure and at the same maximum energy of the bremsstrahlung as that without the absorber. The thickness of the absorbers was 2.84 g/cm^2 in Mg and 2.26 g/cm^2 in Si. The spectra were shown by broken lines in Figs. 2 and 3. It was clear that the photons corresponding to the main peaks were considerably reduced by the absorber in both elements, since the photons to be scattered were seriously absorbed into the same level of the absorber.

Excitation curves were studied to determine more definitely the energies of the levels. Fig. 4 shows the excitation curve of Mg measured by changing the maximum energy of the bremsstrahlung at intervals of 0.33 MeV and 0.50 MeV. At each energy the counts from 6th to 27th channel were summed to get the yields and normalized to the unit charge fed by the ionization chamber. These channels can involve photons of 7 MeV to 14 MeV.

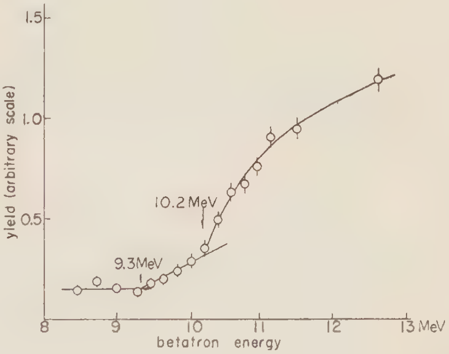

Fig. 4. The yield curve for Mg. The count at each bombarding energy of the incident bremsstrahlung was normalized to the unit charge from the monitor. The vertical lines show the statistical errors.

The caliblation of the maximum energy of the bremsstrahlung x-rays was made by measuring the resonant scattering of photons by 15.1 MeV level in C^{12} and the threshold energy of Cu$^{63}(\gamma, n)$ reaction, 10.8 MeV. Activities of Cu^{62} were detected by a G–M counter. There were two clear breaks at 9.3 MeV and 10.2 MeV. Comparing with the scattered photon spectra shown in Fig. 2, it was found that both breaks correspond to the broad peak at about 10 MeV. The break corresponding to 8 MeV peak was not obtained in the yield curve measurement, because of relatively high background at these lower energies. However, the spectrum shows clearly that there is a photon group of about 8 MeV. The yield curve was used to estimate the ratio of the 9.3 MeV photon group to that of 10.2 MeV group to be 0.35±0.08, both groups being normalized to a unit number of incident photons. This value was used to get the ratio of the two level widths, as shown in the next sections.

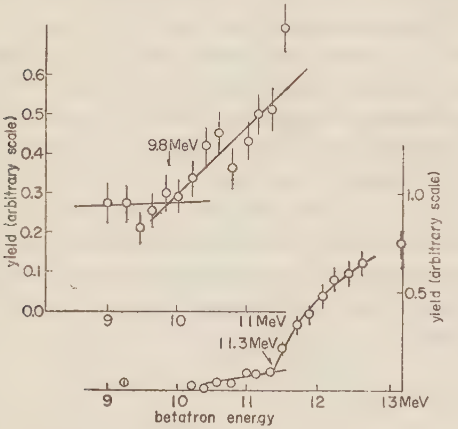

Fig. 5. The excitation curve of Si. The upper curve was obtained by the counts of 1st to 14th channel and the lower curve by the counts of 16th to 24th.

Fig. 5 shows the excitation curves of Si. The lower curve was obtained by the sum of counts from 16th to 24th channel normalized to the unit charge of the monitor and it had a clear break at 11.3 MeV. In the upper curve, the summed counts from 1st to 14th channel were plotted to get another break at 9.8 MeV. Two channel groups can contain photons of 6.0 MeV to 10.0 MeV and 10.5 MeV to 13,0 MeV, respectively. The energies corresponding to these breaks were in agreement with those corresponding to the peaks in the spectra shown in Fig. 3.

To obtain the level widths by the self absorption measurement, the ratio of the photon yields without the absorber to the yields with the absorber in the absorber position must be estimated from the spectra shown in Fig. 2 and Fig. 3.

In the case of Mg the ratio $A(\varDelta)/A(0)$ was given by

$$\left(\frac{A(\varDelta)}{A(0)}\right)_{(10.2+9.3)}=0.67\ ,$$

where $A(\varDelta)$ and $A(0)$ were yields with and without the absorber and the suffix implies the levels involved, i.e. 10.2 MeV and 9.3 MeV levels. The yield could not be separated into each level.

The ratio for the case of Si was estimated as

$$\left(\frac{A(\varDelta)}{A(0)}\right)_{(11.3)}=0.60$$

for 11.3 MeV level.

§ 4. Calculation

When the scatterer was set in front of the detecter and the absorber in the absorber position, the yield of photons by a single resonant level is given by

$$A(\varDelta)=g\int_0^\infty \varPhi(E)\frac{\sigma_s}{\sigma_n+2\sigma_e}e^{-(\sigma_n+\sigma_e)\varDelta N}\\ \times[1-e^{-(\sigma_n+2\sigma_e)NT/\cos\beta}]dE\ , \qquad (1)$$

where $\varDelta$; absorber thickness in cm, T; scatterer thickness in cm, N; number of the atoms per unit volume of the target and the absorber, β; the angle between the incident beam and the normal to the front face of the scatterer, $\varPhi(E)$; bremsstrahlung spectrum, σ_s; elastic scattering cross section of photon, σ_n; nuclear absorption cross section, σ_e; electronic absorption cross section, and g; other factors which do not depend on energy, for example, geometrical factor.

Assuming that $\varPhi(E)$ and σ_e are constant in the energy interval where σ_s and σ_n are not zero but have the finite values, we get a more convenient form as

$$A(\varDelta)=g\varPhi(E)e^{-\sigma_e\varDelta N}\int\frac{\sigma_s}{\sigma_n+2\sigma_e}e^{-\sigma_n\varDelta N}\\ \times[1-e^{-(\sigma_n+2\sigma_e)NT/\cos\beta}]dE\ . \qquad (2)$$

Though the level widths are broadened to several tens of eV by the Doppler effect caused by the lattice oscillation in the target metal, this effect is not so serious as to invalidate the approximation of taking $\varPhi(E)e^{-\sigma_e\varDelta N}$ out of the integrand in (1). If the measurement with and without the absorber is performed by the bremsstrahlung of the same maximum energy, the yield ratio of the former case to the latter is given by

$$\frac{A(\varDelta)}{A(0)}$$
$$=e^{-\sigma_e \varDelta N}\frac{\int \frac{\sigma_s}{\sigma_n+2\sigma_e} e^{-\sigma_n \varDelta N}[1-e^{-(\sigma_n+2\sigma_e)NT/\cos\beta}]dE}{\int \frac{\sigma_s}{\sigma_n+2\sigma_e}[1-e^{-(\sigma_n+2\sigma_e)NT/\cos\beta}]dE} \tag{3}$$

since $\varPhi(E)$, σ_e and g have the same values in both cases. Provided that σ_s has the same shape as σ_n, but differs only in magnitude, the ratio is rewritten as

$$\frac{A(\varDelta)}{A(0)} e^{+\sigma_e \varDelta N}=\frac{I(\varDelta)}{I(0)}, \tag{4}$$

where

$$I(\varDelta)\equiv\int \frac{\sigma_n}{\sigma_n+2\sigma_e} e^{-\sigma_n \varDelta N}[1-e^{-(\sigma_n+2\sigma_e)NT/\cos\beta}]dE$$

and $I(0)$ is the value without the absorber. An absorption cross section is expressed using the Doppler width, δ, and the total level width at half maximum, $\varGamma$, as

$$\sigma_n=\sigma_n{}^0 \frac{1}{2\sqrt{\pi t}} \int_{-\infty}^{\infty} \frac{e^{-(x-y)^2/4t}}{1+y^2} dy, \tag{5}$$

where $\sigma_n{}^0$ is the peak value of the total absorption cross section, $t=(\delta/\varGamma)^2$, and $x=2(E-E_0)/\varGamma$.[9] δ is given by $\delta=E_0(2kT/Mc^2)^{1/2}$ where E_0 is the resonant energy, M the mass of the target nucleus, k the Boltzman constant, c the velocity of light and T the effective temperature in the sample.

When the values, $A(\varDelta)$ and $A(0)$, are measured separately at each resonant level and $\sigma_n{}^0$ is known, the level width, $\varGamma$, can be determined by comparing the experimental value of $\{A(\varDelta)/A(0)\}\exp(\sigma_e \varDelta N)$ with $I(\varDelta)/I(0)$ given by the numerical calculation in (4). It is not easy to obtain the level widths when $A(0)$ and $A(\varDelta)$ are not separated into each level in experiments, as it appeared in the case of Mg. When two levels of widths, $\varGamma_1$ and $\varGamma_2$, contribute, the yields are given by $A(\varDelta)=A_1(\varDelta)+A_2(\varDelta)$ and $A(0)=A_1(0)+A_2(0)$. If $\sigma_e(E_{01})$ nearly equals to $\sigma_e(E_{02})$,

$$\frac{A(\varDelta)}{A(0)} e^{\sigma_e \varDelta N}=\frac{I_1(\varDelta)+I_2(\varDelta)\varPhi(E_{02})/\varPhi(E_{01})}{I_1(0)+I_2(0)\varPhi(E_{02})/\varPhi(E_{01})}, \tag{6}$$

where $\varPhi(E_{01})$ and $\varPhi(E_{02})$ are the photon fluxes in the unit energy interval at the resonant levels. The level widths $\varGamma_1$ and $\varGamma_2$ can be obtained by calculating the right hand side of (6) with adequate pairs of $\varGamma_1$ and $\varGamma_2$ which are allowed by the ratios estimated from the excitation curves, and by comparing with the experimental values in the left hand side.

In calculation it was assumed that all of the absorption processes of x-rays are dipole, i.e. $\sigma_n{}^0=6\pi\lambda\!\!\!^{-2}$ and that the resonant levels decay only to the ground state and the isotopes which contribute to these resonances are Mg^{24} and Si^{28}. The discussion on these assumptions will be given later.

In the case of Mg there are three levels as mentioned in the last section, i.e. at 10.2 MeV, 9.3 MeV and at about 8 MeV. Since $A(0)$'s corresponding to 10.2 MeV and 9.3 MeV were not separated because of the poor resolution of the detector, the yield ratio of two photon groups, $A_{9.3}(0)/A_{10.2}(0)$ was determined using the excitation curve in Fig. 4. From this ratio the relation between $\varGamma_{9.3}$ and $\varGamma_{10.2}$ were calculated by

$$\frac{A_{9.3}(0)}{A_{10.2}(0)} \cdot \frac{\varPhi(10.2)}{\varPhi(9.3)}=\frac{I_{9.3}(0)}{I_{10.2}(0)}, \tag{7}$$

where suffixes 9.3 and 10.2 in $A(0)$ denote the energies of the levels. The resultant relation between $t_{9.3}^{1/2}=\delta/\varGamma_{9.3}$ and $t_{10.2}^{1/2}=\delta/\varGamma_{10.2}$ is shown in Fig. 6, in which the solid line is the ratio and the broken lines are the limits of the statistical errors.

Finally $\varGamma_{9.3}$ and $\varGamma_{10.2}$ were given by substituting $I(0)$ and $I(\varDelta)$ calculated for the allowed pairs of $\varGamma_{9.3}$ and $\varGamma_{10.2}$ into the right hand side of (6) and by comparing with the

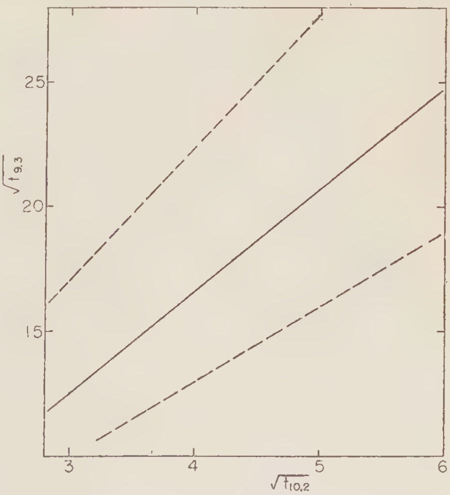

Fig. 6. Relation between $t_{10.2}^{1/2}=\frac{\delta}{\varGamma_{10.2}}$ and $t_{9.3}^{1/2}=\frac{\delta}{\varGamma_{9.3}}$. The broken lines are the limits of the statistical errors.

experimental values (in the left hand side). This procedure is shown in Fig. 7. In the figure the curve is the calculated value of $\frac{I_{10.2}(\Delta)+I_{9.3}(\Delta)\Phi(9.3)/\Phi(10.2)}{I_{10.2}(0)+I_{9.3}(0)\Phi(9.3)/\Phi(10.2)}$ by making use of the $\Gamma_{9.3}$ and $\Gamma_{10.2}$ given by Fig. 6 and the horizontal bar crossing the curve shows the experimental value of

$$\left(\frac{A(\Delta)}{A(0)}\right)_{(10.2+9.3)} e^{\sigma_e \Delta N}=0.71\,.$$

The level widths, $\Gamma_{10.2}$ and $\Gamma_{9.3}$, were determined to be $3.8^{+1.2}_{-0.6}$ eV and 0.9 eV respectively. The width for 8 MeV level was approximately estimated to be 0.9 eV from the spectra in Fig. 2 by

$$\Gamma_8=\Gamma_{10.2}\cdot\frac{A_8(0)}{A_{10.2}(0)}\cdot\frac{6\pi\bar{\lambda}^2_{10.2}}{6\pi\bar{\lambda}^2_8} \qquad (8)$$

where $\bar{\lambda}_{10.2}$ and $\bar{\lambda}_8$ are the wavelength of 10.2 MeV and 8 MeV photons. The errors were estimated only for the statistical fluctuations.

In the case of Si, the width for 11.3 MeV state was easily calculated by (4), to be 8.3 ± 2.5 eV, since the spectra in Fig. 3 were separated into two photon groups which belong to 11.3 MeV and 9.8 MeV levels. The width of 9.8 MeV level was found by using the ratio of this level to 11.3 MeV photon

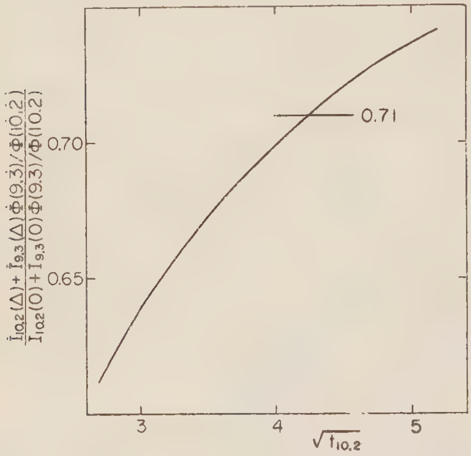

Fig. 7. The curve is $\frac{I_{10.2}(\Delta)+I_{9.3}(\Delta)\Phi(9.3)/\Phi(10.2)}{I_{10.2}(0)+I_{9.3}(0)\Phi(9.3)/\Phi(10.2)}$ calculated by using the values of $t^{1/2}_{10.2}=\delta/\Gamma_{10.2}$ and $t^{1/2}_{9.3}=\delta/\Gamma_{9.3}$ given in Fig. 6. The horizontal bar is the experimental value, $\left\{\frac{A(\Delta)}{A(0)}\right\}_{(10.2+9.3)} e^{\sigma_e \Delta N}=0.71$.

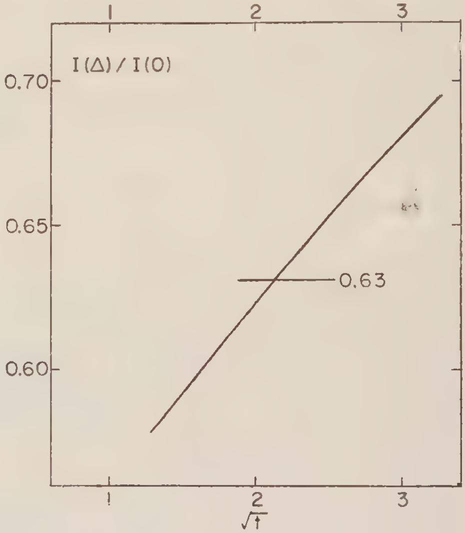

Fig. 8. The curve is $I(\Delta)/I(0)$ vs. $\sqrt{t}$. The horizontal bar shows the experimental value, $\left\{\frac{A(\Delta)}{A(0)}\right\}_{(11.3)} e^{\sigma_e \Delta N}=0.63$.

Table II. The energies of levels found in the present experiment, the Doppler widths and the peak absorption cross sections used to calculate the level widths, and the resultant level widths. The level widths shown in blacket in the last column are Tobin's data[7].

Element	Level energy (MeV)	Doppler width (eV)	Peak absorption cross section (b)	$t^{1/2}$	Level width (eV)
Mg	10.2	16.0	71.7	$4.26^{+1.3}_{-0.7}$	$3.8^{+1.2}_{-0.6}$ $(4.80^{+1.6}_{-1.4})$
	9.3	14.5	86.2	18.	0.9
	8.		117.		0.5
Si	11.3	17.5	58.4	2.12 ± 0.65	8.3 ± 2.5 $(2.89^{+1.0}_{-0.8})$
	9.8		77.7		0.9

group in the sameway as in Mg. These results are listed in the 6th column in Table II.

§ 5. Discussion

The isotope abundance and the particle threshold energies were considered in order to determine which isotope made the dominant contribution to the resonant scattering in the present experiment. A single level of higher energy than the particle threshold hardly scatters photons, since the particle emission predominates over photon scattering. Thus, the isotopes which have the particle threshold energies lower than the photon energies of interest need not be considered. Isotopes of little abundance are also excluded in this experiment.

In the calculation of the level widths the type of the photon absorption was assumed to be dipole, and the excited states were assigned to decay only to the ground states by electromagnetic transition. In the measurements the cascade gamma rays have chances to occur through the first excited state of Mg^{24} or Si^{28}, since these states are of 2^+ in both elements. If the cascade takes place, the energy of such photons should be about 8 MeV for Mg^{24} and 10 MeV for Si^{28}. In the case of Si, the gamma-rays of about 9.8 MeV were detected in the scattered photon spectra, but they were identified as the photons decaying from a 9.8 MeV resonant level to the ground state by analysing the spectra and the excitation curves. The circumstances are somewhat complicated in the case of the 8 MeV gamma-rays of Mg^{24}. We can not exclude the possibility of cascade decay since the excitation curve was not measured at the energies around 8 MeV. However, the existence of the 8 MeV level was assigned considering the fact that most of the states of various elements excited by photon absorption hardly decay in cascade.

Another assumption was that the excited states do not emit alpha particles. If these levels were assigned to $T=1$ as shown later, this assumption is acceptable since $T=1$ states do not decompose into two $T=0$ particles. The forbiddenness of the alpha particle emission was found in the excited state of 15.1 MeV in C^{12}. The same circumstances seem to occur in Mg and Si.

Table III. The isotope abundance and the particle threshold energies.

Element	Abundance (%)	Particle threshold (γ, p)	Particle threshold (γ, n)
Mg^{24}	78.60	11.69 MeV	16.56 MeV
Mg^{25}	10.11	12.06	7.33
Mg^{26}	11.29	14.03	11.11
Si^{28}	92.18	11.59	17.20
Si^{29}	4.71	12.34	8.47
Si^{30}	3.12	13.79	10.61

The angular momenta of the photons which excited the nuclei to these weak levels were not determined in the present experiment, and so there is no clear evidence for the dipole transition. Therefore, the levels of 8 MeV in Mg^{24} and 9.8 MeV in Si^{28} may be of 1^+, 1^- or 2^+. Tobin recently reported that breaks in his excitation curves corresponding to the present ones at 9.3 MeV in Mg and 9.8 MeV in Si were made by neutron emission from $Mg^{25}(\gamma, n)Mg^{24}$ and $Si^{29}(\gamma, n)Si^{28}$ reactions respectively, but the present experiment found that his arguments were not true, by measuring the capture photon spectra caused by the neutrons in the targets and the enviroments of the detector.

The level width of the present experiment agrees with Tobin's in Mg^{24}. In Si^{28} there is a large discrepancy between his value and the present one, i.e. the latter is about three times as large as the former.

The parities of the highly excited states, 11.3 MeV in Si^{28} and 10.2 and 9.3 MeV states in Mg^{24}, were not determined experimentally. However, there are important evidences that these levels are 1^+ and the transitions between these levels and the ground state are caused by magnetic dipole. If the isotopic spin multiplet theory is applicable to these levels and the 9.3 MeV level in Si^{28} is the lowest $T=1$ level, a 1^+ level corresponding to the 1.37 MeV 1^+ level in Al^{28} 10) must appear at the excitation energy of about 11 MeV in Si^{28}. In the same reason two 1^+ levels may occur around 10 MeV in Mg^{24} corresponding to 0.47 and 1.34 MeV 1^+ levels in Na^{24}. The interval of the two levels is 0.9 MeV in both Mg^{24} and Na^{24}. The 8 MeV level of Mg^{24} can not be explained along the same line at present.

The level schemes which help to understand these discussions are shown in Fig. 9 and

Fig. 10. According to a discussion about the magnetic dipole transition in a self conjugate nucleus,[11] these identifications of the transitions have more solid foundation, since the isotopic spin selection rule reduces the M1 transition strengths between levels with the same *T*.

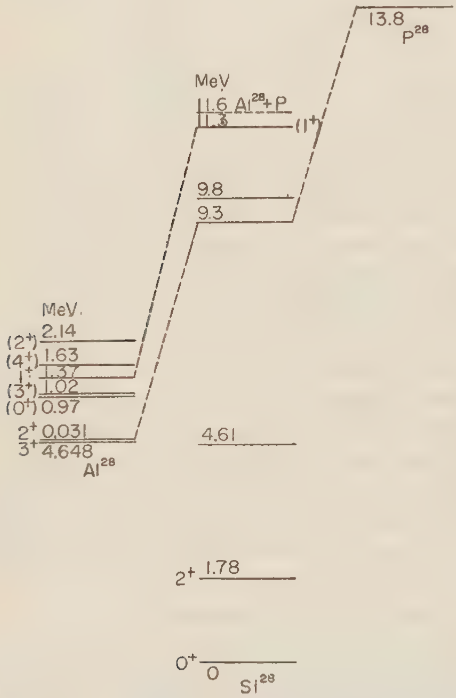

Fig. 9. Correspondence between the levels in Si^{28} and Al^{28}.

It seems interesting that the strong resonant absorptions just below particle thresholds are made by magnetic dipole in most of elements studied by measurements similar to the present one. The 15.1 MeV state of C^{12}, 3.56 MeV state of Li^6 and 4.46 MeV state of B^{11} are also excited by M1. Regarding the isotopic spins, all transitions were induced between $T=1$ excited states and $T=0$ ground states in even-even nuclei.

The excitation energies of the lowest $T=1$, $J^{\pi}=1^+$ levels seem to decrease with mass number systematically in light elements composed of alpha particles, such as Be^8, C^{12}, O^{16}, Ne^{20}, Mg^{24}, Si^{28} and S^{32}. Such a level has not been found for O^{16} so far. It is difficult to observe the level of O^{16} by the photon scattering, since the excitation energy is higher than the particle threshold. In the case of Ne^{20} the level whose energy is about 11 MeV and is lower than the particle threshold has not been found, but it will be measured by this scattering method if the target is available.

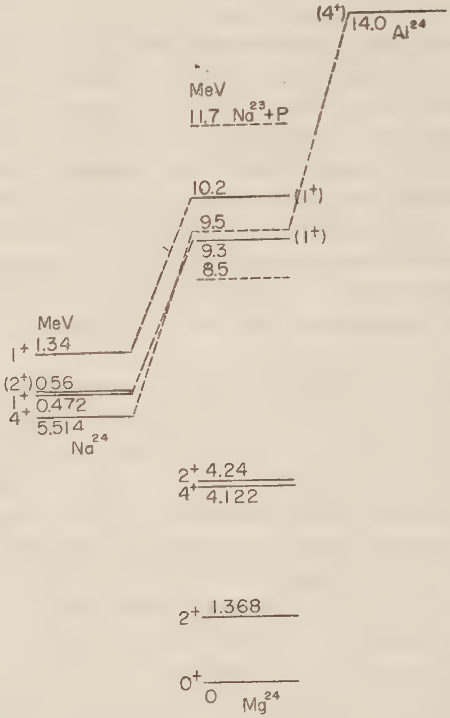

Fig. 10. Correspondence between the levels in Mg^{24} and Na^{24}.

The elastic scattering cross sections of photons were measured at the energies 5 to 14 MeV in many elements.[2] The cross sections have a broad peak around 8 to 10 MeV with a few exceptions. Those peaks are probably composed of several sharp resonance levels in lighter elements, and also in heavier elements they will have the same structure, although the actual measurement could not resolve the fine structure. It may be possible to suggest that these broad resonance peaks just below the particle threshold consist of an assembly of levels induced by magnetic dipole processes. It was also noted by Weisskopf that the electric dipole absorption is depressed by correlation of nucleons at the lower energies and M1 becomes important.

The author would like to express his sincere gratitude to Professor M. KIMURA for helpful discussions and continual interests throughout this work. Thanks are also due to Dr. T.

Tohei for his encouragement in the earlier stage and to Mr. S. Mori for discussions in detail and operation of the machine.

Effect of Impurity-Core on Carrier Mobility in Heavily Doped Germanium

By P. CSAVINSZKY

Research Division, General Dynamics/Electronics, Rochester, New York

(Received May 25, 1961)

The effect of the impurity core on the mobility of charge carriers in heavily doped Ge is investigated by analyzing the role the core plays in the process of ionized impurity scattering. It is concluded, in agreement with experiments, that at the same doping level the electron mobility in an Sb-doped Ge crystal should be larger than in an As-doped Ge crystal. The dependence of the mobility ratio on the electron concentration is also investigated and found to be due to changes in the screening of the impurity ions.

§ 1. Introduction

Recent measurements[1] on the electron mobility in heavily doped n-type Ge show an interesting effect. It has been found that at a given electron concentration and compensation the electron mobility in the degenerate semiconductor depends on the specific nature of the dopant. The findings[1] can be summarized in two points.

1. At $T=293$°K and at electron concentrations of $n=$several times 10^{18}/cc the $\mu(\mathrm{Sb})/\mu(\mathrm{As})$ mobility ratio, as inferred from the published figure[1] is between about 1.2 and 1.4.

2. In the above concentration range the $\mu(\mathrm{Sb})/\mu(\mathrm{As})$ ratio is a monotonic function of electron concentration and increases a few percent with increasing n. An extrapolation of the measured mobility values towards lower electron concentrations shows that the mobility ratio asymptotically decreases to unity at $n \approx 10^{18}$/cc.

§ 2. Theory

For these findings the following explanation is proposed.

1. The mobility difference at a given electron concentration is due to the difference in the total cross section of ionized impurity scattering which, in the present case, is assumed to be the dominant scattering process. The difference in the total scattering cross section is attributed to the difference in the potential of the Sb^+ and As^+ impurity cores.

2. The concentration dependence of the mobility ratio is due to the fact that as the electron concentration in a degenerate Ge crystal increases the screening of the impurity ions by the free electrons becomes more

effective. This means a decrease in the "range" of the ion potential, which, inturn, means that the short range core potential, becomes more important.

In what follows we shall show that the above assumptions can lead to an explanation of findings 1 and 2.

1. *Mobility Difference at a given Electron Concentration.*

In a degenerate Ge sample the electron mobility is given by

$$\mu = \frac{e}{m^*}\tau_F \,, \qquad (1)$$

where e is the electronic charge, m^* is the effective mass of the electron, assumed to be isotropic for the present purposes, and τ_F is the relaxation time taken simply at the Fermi surface as indicated by the suffix F. In the the case of ionized impurity scattering the relaxation time can be expressed[2] as

$$\tau_F = \frac{1}{N_i v_F Q_F} \,, \qquad (2)$$

where N_i is the number of scattering ions/cc, v_F is the velocity of an electron at the Fermi surface and Q_F is the total scattering cross section of an electron of velocity v_F. It follows from Eqs. (1) and (2) that

$$\frac{\mu(\mathrm{Sb})}{\mu(\mathrm{As})} = \frac{Q_F(\mathrm{As}^+)}{Q_F(\mathrm{Sb}^+)} \,. \qquad (3)$$

Let us assume now that the potential of an Sb^+ ion in the Ge crystal differs from that of an As^+ ion only in the core region[3] while far from the nuclei both potentials approach the same screened Coulomb type potential[4]. This is shown schematically in Fig. 1, where the potential energy of an electron is plotted as a function of the distance from the nucleus of an Sb^+ and an As^+ ion. It is assumed that the core potentials are such that the potential energies of the electron satisfy the relation

$$\eta(r) = V_{\mathrm{As}^+}(r) - V_{\mathrm{Sb}^+}(r) \leq 0 \,.$$

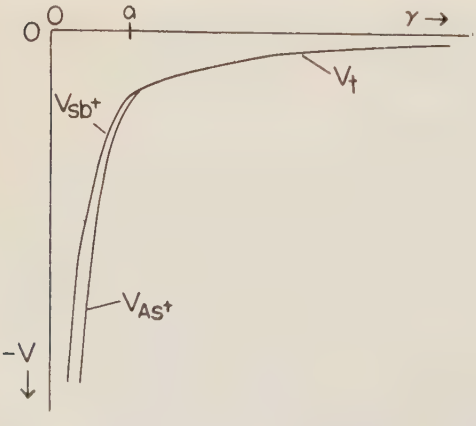

Fig. 1. Schematic representation of the potential energy of an electron as a function of the distance from the nucleus of an Sb^+ and an As^+ ion in a Ge crystal. In the $0<r<a$ core region the ion potentials are different and in the $r>a$ region both approach the same screened Coulomb potential, V_t.

The basis for this assumption is the fact that in Ge semiconductor the ionization energy of an As donor is roughly 30% larger than that of an Sb donor[5]. In this case if $V_{\mathrm{Sb}^+}(r)$ is associated with the ground level E_{Sb}, described by a wave function ψ, then, using first order perturbation theory, $V_{\mathrm{As}^+}(r)$ leads to an energy level $E_{\mathrm{As}} = E_{\mathrm{Sb}} + \varepsilon$, where

$$\varepsilon = \int |\psi|^2 \eta \, dv \,.$$

Since ε is known to be a negative quantity it follows that η is also negative.

Using the Born approximation[6] the scattering amplitude for scattering of an electron by an Sb^+ ion is given by

$$f_{\mathrm{Sb}^+}(\vartheta) = -\frac{8\pi^2 m^*}{h^2}\int_0^\infty \frac{\sin Kr}{Kr} V_{\mathrm{Sb}^+}(r) r^2 dr \,, \qquad (4)$$

where

$$K = 2k_F \sin(\tfrac{1}{2}\vartheta) \,. \qquad (5)$$

In Eq. (5) k_F stands for the wave number of an electron at the Fermi surface and can be determined from

$$E_F = \frac{h^2}{8m^*}\left(\frac{3n}{\pi}\right)^{2/3} = \frac{h^2 k_F^2}{8\pi^2 m^*} \,.$$

To determine the sign of $f_{\mathrm{Sb}^+}(\vartheta)$ in Eq. (4) use is made of the fact that at large distances from the impurity nucleus the potential is a screened Coulomb potential with screening length[4] R. The screening factor[4] depends on R as $\exp(-r/R)$ and, for this reason, in the integrand of Eq. (4), $V_{\mathrm{Sb}^+}(r)$ becomes very small if $r>R$. In this case the upper limit of integration in Eq. (4) can be replaced by R with a good approximation. If Kr is smaller than π, then $(\sin Kr)/Kr$ is positive from $r=0$ to $r=R$. For an n-type Ge crystal with an electron concentration of several times 10^{18}/cc it can be shown that $Kr = 2k_F r \cdot \sin(\tfrac{1}{2}\vartheta) < \pi$ for all values of ϑ. It is seen, now, that $f_{\mathrm{Sb}^+}(\vartheta)$ is positive since $V_{\mathrm{Sb}^+}(r)$ is everywhere negative.

Knowing the scattering amplitude the total scattering cross section is calculated[6] from

$$Q_F(\mathrm{Sb}^+)=2\pi\int_0^\pi [f_{\mathrm{Sb}^+}(\vartheta)]^2 \sin\vartheta d\vartheta\ . \qquad (6)$$

For an As^+ ion, using the $V_{\mathrm{As}^+}(r)=V_{\mathrm{Sb}^+}(r)+\eta(r)$ relation one obtains

$$f_{\mathrm{As}^+}(\vartheta)=f_{\mathrm{Sb}^+}(\vartheta)+\varphi(\vartheta)\ , \qquad (7)$$

where

$$\varphi(\vartheta)=-\frac{8\pi^2m^*}{h^2}\int_0^\infty \frac{\sin Kr}{Kr}\eta(r)r^2dr\ . \qquad (8)$$

One may again replace the upper limit of integration by R in Eq. (8) and show by the same arguments as those used in connection with Eq. (4) that $\varphi(\vartheta)$ is a positive quantity since $\eta(r)$ is everywhere negative.

The total scattering cross section for scattering of an electron by an As^+ ion can now be written as

$$Q_F(\mathrm{As}^+)=Q_F(\mathrm{Sb}^+)+q_1+q_2\ , \qquad (9)$$

where
